This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history,

laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

DEDICATION

To my family, Jonathan, Max, Sarah, Marcia, Brandy, Ken, and Ginger. Thank you for always encouraging and supporting me.—Marcy Verduin

To the people who most inspire me, my family: Susan, Rich and Greg, Jordan, Wyatt, Richard, Heather, Lisa, and Phillip.—Bob Boland

To all persons who work to improve the lives of persons with mental illness.—Drs. Verduin and Boland

About the Editors

ROBERT J. BOLAND, M.D.

Dr. Boland is the chief of staff and senior vice president at The Menninger Clinic in Houston, Texas. He is also a vice-chair of the Menninger Department of Psychiatry and Behavioral Sciences at Baylor College of Medicine (BCM) and the Brown Foundation Endowed Chair in Psychiatry at BCM.

Before coming to Houston, he served as vice-chair of education and director of the psychiatry residency program at Brigham and Women's Hospital in Boston, Massachusetts, and as an associate professor of psychiatry at Harvard Medical School. He is board-certified in psychiatry with expertise in medical education, consultation-liaison, and geriatric psychiatry. He is an alumnus of Georgetown University, where he earned his undergraduate and medical degrees.

Before joining Brigham and Women's Hospital, Dr. Boland had an 18-year tenure at the Alpert School of Medicine at Brown University, Providence, Rhode Island. For more than 30 years, he has been an active member of the American Psychiatric Association. Dr. Boland is the former president of the American Association of Directors of Psychiatric Residency Training, the Academy of Consultation-Liaison Psychiatry, and the Association for Academic Psychiatry. He is currently a Director of the American Board of Psychiatry and Neurology and a member of the Board of Regents for the American College of Psychiatrists.

Dr. Boland has authored or co-authored over 100 publications and is a frequent speaker at grand rounds and national meetings. In addition, he is the co-editor of the Kaplan and Sadock series of textbooks, which are the most popular texts in psychiatry. Dr. Boland is also the co-host of the Menninger Clinic's Mind Dive Podcast.

MARCIA L. VERDUIN, M.D.

Dr. Verduin is the Associate Dean for Students and a Professor of Psychiatry at the University of Central Florida College of Medicine in Orlando, Florida. She graduated from the University of Florida College of Medicine and completed her residency training and addiction psychiatry fellowship at the Medical University of South Carolina. She is a Fellow of the American College of Psychiatrists and a Distinguished Fellow of both the American Psychiatric Association and the Association for Academic Psychiatry. In 2007, Dr. Verduin became the first psychiatry faculty member at UCF's new medical school, where she played an integral role in developing the overarching undergraduate medical education curriculum and securing LCME accreditation.

In addition to her roles at the University of Central Florida College of Medicine, Dr. Verduin is a Past President for the Association for Academic Psychiatry, Past Chair of the Association of American Medical College's (AAMC) Southern Group on Student Affairs, prior Associate Editor of the Psychiatry Residency In-Training Examination, and has served as a member of the Board of Regents for the American College of Psychiatrists and an examiner for the American Board of Psychiatry and Neurology. She is currently the First Vice President of the American College of Psychiatrists and the Chair for the AAMC's Group on Student Affairs.

Dr. Verduin has a special interest in combatting the burden of stigma associated with mental health disorders, particularly in faith-based communities. She has been invited to speak around the world, including in Australia, New Zealand, Fiji, the Philippines, Southeast Asia, and Nigeria. Her contributions to advancing mental health care in those areas of the world have been covered in various U.S. and international media.

Contents

About the Editors
Contributors
Preface
Foreword

VOLUME I

1 Neural Sciences

- **1.1 The Neuroscience of Psychiatry**
  John H. Krystal, M.D.
- **1.2 Functional Neuroanatomy**
  Darlene S. Melchitzky, M.S., and David A. Lewis, M.D.
- **1.3 Functional Genomics of Human Brain Development**
  Kartik Pattabiraman, M.D., Ph.D., Sirisha Pochareddy, Ph.D., John C. Silbereis, Ph.D., John N. Constantino, M.D., and Nenad Sestan, M.D., Ph.D.
- **1.4 Neural Development and Neurogenesis**
  Emanuel DiCicco-Bloom, M.D., and Courtney R. McDermott, B.A.
- **1.5 Cellular and Synaptic Basis of Neural Signaling**
  Charles F. Zorumski, M.D., and Steven Mennerick, Ph.D.

1.6 Amino Acid Neurotransmitters
Joseph T. Coyle, M.D.
1.7 Biogenic Amine Neurotransmitters
John D. Elsworth, Ph.D.
1.8 Neuropeptides: Biology, Regulation and Role in Neuropsychiatric Disorders
Michael J. Owen, B.Sc. (Hons.), M.B., Ch.B., Ph.D., F.R.C.P.sych., Shaun P. Brothers, Ph.D., M.B.A., Larry J. Young, Ph.D., and Charles B. Nemeroff, M.D., Ph.D.
1.9 Novel Neurotransmitters
Thomas W. Sedlak, M.D., Ph.D., Bindu D. Paul, Ph.D., and Adam I. Kaplin, M.D., Ph.D.
1.10 Neurotrophic Factors
Jihye Kim, M.D., Francis S. Lee, M.D., Ph.D., and Moses V. Chao, Ph.D.
1.11 Intraneuronal Signaling
John A. Gray, M.D., Ph.D.
1.12 Psychoneuroendocrinology
Victor I. Reus, M.D.
1.13 Immune–Brain Interactions in Psychiatry
Ebrahim Haroon, M.D., Andrew H. Miller, M.D., and Charles L. Raison, M.D.
1.14 Chronobiology, Circadian Rhythm, and Psychiatry
Chester Wu, M.D., and Joshua J. Rodgers, M.D.
1.15 Basic Science of Sleep
Ruth M. Benca, M.D., Ph.D., Chiara Cirelli, M.D., Ph.D., and Giulio Tononi, M.D., Ph.D.
1.16 Pain Systems: Interface with Affective and Motivational Mechanisms
John Lotfi, M.D., J.D., and Jon-Kar Zubieta, M.D., Ph.D.
1.17 Basic Science of Appetite
Nori Geary, Ph.D., and Timothy H. Moran, Ph.D.

1.18 Genome, Transcriptome, and Proteome: The Molecular Genetics, Biochemistry, and Multi-Omics Underlying the Neurobiology of Mental Disorders

Evan E. Afshin, M.D., and Christopher E. Mason, Ph.D.

1.19 Gene Mapping Investigations of Psychiatric Disorders

Scott C. Fears, M.D., Ph.D.

1.20 Epigenetics in Psychiatry: The Promise for New Biomarkers and Treatments

Arie Kaffman, M.D., Ph.D.

1.21 Pharmacogenetics

Julio Licinio, M.D., Ph.D., M.B.A., M.S., and Ma-Li Wong, M.D., Ph.D.

1.22 Animal Models in Psychiatry

Janna K. Moen, B.A., Ph.D., and Paul J. Kenny, Ph.D.

1.23 Basic Systems Neuroscience

André A. Fenton, Ph.D., and Dino Dvorak, Ph.D.

1.24 Computational Modeling Approaches to Psychiatry

John D. Murray, Ph.D., and Alan Anticevic, Ph.D.

1.25 Nuclear Magnetic Resonance Imaging and Spectroscopy: Basic Principles and Recent Findings in Neuropsychiatric Disorders

Graeme F. Mason, Ph.D., John H. Krystal, M.D., and Gerard Sanacora, M.D., Ph.D.

1.26 Electroencephalography in Psychiatry

Jason K. Johannesen, Ph.D., and Patrick D. Skosnik, Ph.D.

1.27 Radiotracer Imaging with Positron Emission Tomography and Single Photon Emission Computed Tomography: Fundamental Principles, Methodology and Role in Neuropsychiatric Research

Mark Slifstein, Ph.D., John H. Krystal, M.D., and Anissa Abi-Dargham, M.D.

1.28 Functional Brain Connectivity and Psychopathology

Deanna M. Barch, Ph.D.
- 1.29 Neuropsychiatry of Self
  David R. Vago, Ph.D., Debra A. Gusnard, M.D., and David A. Silbersweig, M.D.
- 1.30 Learning Theory and Psychosis, Anxiety, and Addiction
  Philip R. Corlett, Ph.D.
- 1.31 Neuroscience of Substance Use Disorders
  Khaled Moussawi, M.D., Ph.D.
2 Neuropsychiatry and Behavioral Neurology
- 2.1 The Neuropsychiatric Approach to the Patient
  Fred Ovsiew, M.D.
- 2.2 Neuropsychiatric Aspects of Cerebrovascular Disorders
  Stanley Lyndon, M.D., and Juan Carlos Urizar, M.D.
- 2.3 The Neuropsychiatry of Brain Tumors
  Alasdair G. Rooney, MB.ChB., M.D., Ph.D.
- 2.4 Neuropsychiatric Aspects of Epilepsy and Psychogenic Nonepileptic Seizures
  Mario F. Mendez, M.D., Ph.D., Leila Parand, M.D., and Gaston Baslet, M.D.
- 2.5 Neuropsychiatric Consequences of Traumatic Brain Injury
  Melissa B. Jones, M.D., Amy R. Corcoran, M.D., Joanne A. Byars, M.D., and Ricardo E. Jorge, M.D.
- 2.6 Neuropsychiatric Aspects of Movement Disorders
  Laura Marsh, M.D., and Russell L. Margolis, M.D.
- 2.7 Neuropsychiatric Aspects of Multiple Sclerosis and Other Demyelinating Disorders
  Joshua J. Rodgers, M.D.
- 2.8 Neuropsychiatric Aspects of HIV Infection and AIDS
  Glenn Jordan Treisman, M.D., Ph.D., Andrew F. Angelino, M.D., Jeffrey Hsu, M.D., Anna Moukouri Kouoh, C.R.N.P.,

and Nicholas P. Schweizer, Ed.D., L.C.A.D.C., L.C.P.C.

2.9 Neuropsychiatric Aspects of Other Infectious Diseases (Non-HIV)

Jessica Harder, M.D., Rishab Gupta, M.B.B.S., M.D., Ruth McCann, M.D., and Irene Gonsalvez, M.D.

2.10 Neuropsychiatric Aspects of Prion Disease

Brian Giunta, M.D., Ph.D., Alireza Minagar, M.D., M.B.A., Paul Shapshak, Ph.D., Nadejda Alekseeva, M.D., and Francisco Fernandez, M.D.

2.11 Neuropsychiatric Aspects of Headache

Kathleen Ries Merikangas, Ph.D., Tarannum Lateef, M.D., M.P.H., and James R. Merikangas, M.D.

2.12 Neuropsychiatric Aspects of Neuromuscular Diseases

Timothy P. Wuerz, D.O., M.Sc., Rajeet Shrestha, M.D., and Alan J. Lerner, M.D.

2.13 Psychiatric Aspects of Child Neurology

Jeffrey E. Max, M.D., M.B.B.Ch., Sarah Mattson, Ph.D., Yvonne E. Vaucher, M.D., M.P.H.J., Sharon Nichols, Ph.D., and Mark P. Nespeca, M.D.

2.14 Neuropsychiatry of Neurometabolic and Neuroendocrine Disorders

Mark Walterfang, M.B.B.S. (Hons), Ph.D., F.R.A.N.Z.C.P., Ramon Mocellin, M.B.B.S., M.Sc., F.R.A.N.Z.C.P., Olivier Bonnot, M.D., Ph.D., and Dennis Velakoulis, M.B.B.S., M.P.M., Dip.Crim., D.Med.Sci., F.R.A.N.Z.C.P.

2.15 Catatonia

Joshua J. Rodgers, M.D., and Thanh Thuy Truong, M.D.

3 Contributions of the Psychological Sciences

3.1 Contributions of the Psychological Sciences: Sensation, Perception, and Cognition

Aldrich Chan, Psy.D., Louis J. Cozolino, Ph.D., and Daniel J. Siegel, M.D.

- 3.2 Piaget and Cognitive Development: History, Theory, Extensions, and Modifications
  Harrell Woodson, Ph.D.
- 3.3 Learning Theory
  Mark E. Bouton, Ph.D.
- 3.4 Biology of Memory
  Shruti Dave, Ph.D., and Joel L. Voss, Ph.D.
- 3.5 Normality and Mental Health
  George E. Vaillant, M.D.
- 3.6 Neuroscience of Psychoanalytic Object Relations Theory
  Dragan M. Svrakic, M.D., Ph.D., Charles F. Zorumski, M.D., and Otto F. Kernberg, M.D.

4 Contribution of the Social Sciences
- 4.1 Neurocentrism: Implications for Addiction and the Courtroom
  Sally L. Satel, M.D., and Stephen J. Morse, J.D., Ph.D.
- 4.2 Transcultural Psychiatry
  Kenneth Fung, M.D., F.R.C.P.C., M.Sc., and Robert Kohn, M.D.
- 4.3 Evolutionary Foundations for Psychiatric Research and Practice
  Randolph M. Nesse, M.D.

5 Quantitative and Experimental Methods in Psychiatry
- 5.1 Quantitative and Experimental Methods in Psychiatry: Epidemiology
  Diana E. Clarke, Ph.D., M.Sc., Lamyaa Yousif, M.D., Ph.D., M.Sc., Nusrat Rahman, Ph.D., Adrienne Grzenda, M.D., Ph.D., M.S., and William E. Narrow, M.D., M.P.H.
- 5.2 Statistics and Experimental Design
  Eugene Laska, Ph.D., Carole E. Siegel, Ph.D., and Isaac Galatzer-Levy, Ph.D.

6 Theories of Personality and Psychopathology

6.1 Psychoanalytic Theories and Treatment: Perspective from North America and Great Britain

Sylvia Gonzalez Cruz, M.D., Shweta Sharma, Psy.D., Cynthia Mulder, L.C.S.W.S., and Deeba Ashraf, M.D.

6.2 Erik H. Erikson

Dorian S. Newton, Ph.D., and Sudhir Kakar, Ph.D.

6.3 Other Psychodynamic Schools

Kristine L. Mccaslin, Psy.D., and Adam M. Brenner, M.D.

6.4 Approaches Derived from Philosophy and Psychology

Paul T. Costa, Jr., Ph.D., and Ralph L. Piedmont, Ph.D.

7 Diagnosis and Psychiatry: Examination of the Psychiatric Patient

7.1 Psychiatric Interview, History, and Mental Status Examination of the Adult Patient

Rory P. Houghtalen, M.D., and John S. McIntyre, M.D.

7.2 The Psychiatric Report and Outline for a Psychiatric Examination

Benjamin J. Sadock, M.D.

7.3 Practice Guidelines in Psychiatry

Laura J. Fochtmann, M.D., M.B.I., and John S. McIntyre, M.D.

7.4 Neuropsychological Assessment of Adults

Joseph R. Sadek, Ph.D., A.B.P.P.-C.N., Owen Gaasedelen, Ph.D., Rex M. Swanda, Ph.D., A.B.P.P.-C.N., and Kathleen Y. Haaland, Ph.D., A.B.P.P.-C.N.

7.5 Personality Assessment of Adults

Russell L. Adams, Ph.D., A.B.P.P-NP., C.L., and David L. Adams, Psy.D., B.C.B.A.-D.

7.6 Medical Assessment and Laboratory Testing in Psychiatry

Jennifer L. Kruse, M.D., and John O. Brooks, III, Ph.D., M.D.

7.7 Principles and Applications of Quantitative Electroencephalography in Psychiatry

Leslie S. Prichep, Ph.D.

7.8 Psychiatric Rating Scales

Samuel Justin Sinclair, Ph.D., Mark A. Blais, Psy.D., and Deborah Blacker, M.D., Sc.D.

7.9 Electronic Media in Psychiatry

Zebulon Taintor, M.D.

7.10 Cultural Competency in the Organization and Delivery of Psychiatric Care

Carole E. Siegel, Ph.D., Helena B. Hansen, M.D., Ph.D., and Jonathan Michel Metzl, M.D., Ph.D.

7.11 Medical Error

Nora C. Oberfield, M.D.

8 Clinical Manifestations of Psychiatric Disorders

Anu A. Matorin, M.D., Andres A. Avellaneda Ojeda, M.D., Asim A. Shah, M.D., and Pedro Ruiz, M.D.

9 Classification in Psychiatry

9.1 Present and Future of Classification Systems for Mental Disorders

Javier I. Escobar, M.D., M.Sc., and Humberto Marin, M.D.

9.2 The Classification of Mental Disorders in the International Classification of Diseases (ICD-11)

Javier I. Escobar, M.D., M.Sc., and Carlos López-Jaramillo, M.D., Ph.D.

10 Neurocognitive Disorders

10.1 Cognitive Disorders: Introduction

Iqbal Ahmed, M.D., F.R.C.Psych.

10.2 Delirium

Mandayam Sujata, M.D., Marie Anne Gebara, M.D., Tanya Fabian, Pharm.D., Ph.D., and LalithKumar Solai, M.D.

10.3 Major Neurocognitive Disorders (Dementia)

Julie Graziane, M.D., and Iqbal Ahmed, M.D., F.R.C.Psych.

10.4 Mild Cognitive Impairment and Amnestic Disorders
Daniel Varon, M.D., and Carmen Andreescu, M.D.
10.5 Cognitive Disorders Due to Another Medical Condition or Substance
Robert J. Boland, M.D., and Iqbal Ahmed, M.D., F.R.C.Psych.
11 Substance-Related Disorders
11.1 Substance Use Disorders: Introduction
Joji Suzuki, M.D.
11.2 Alcohol-Related Disorders
Marc A. Schuckit, M.D.
11.3 Stimulant-Related Disorders
Rocco A. Iannucci, M.D., and Roger D. Weiss, M.D.
11.4 Caffeine-Related Disorders
Laura M. Juliano, Ph.D., and Mary Margaret Sweeney, Ph.D.
11.5 Cannabis-Related Disorders
Janni Leung, Ph.D., Wayne D. Hall, Ph.D., and Louisa Degenhardt, Ph.D.
11.6 Hallucinogen-Related Disorders
Brian S. Barnett, M.D., and Joji Suzuki, M.D.
11.7 Inhalant-Related Disorders
Cameron J. Davidson, Ph.D., D.W. Svenson, M.A., and Scott E. Bowen, Ph.D.
11.8 Tobacco-Related Disorders
Smita Das, M.D., Ph.D., M.P.H., Brian Isakson, Ph.D., and Douglas M. Ziedonis, M.D., M.P.H.
11.9 Opioid Use and Related Disorders: From Neuroscience to Treatment
Sean X. Luo, M.D., Ph.D., and Adam Bisaga, M.D.
11.10 Sedative-, Hypnotic-, or Anxiolytic-Related Disorders
John J. Mariani, M.D.

11.11 Anabolic-Androgenic Steroid-Related Disorders
Harrison G. Pope, Jr., M.D., and Gen Kanayama, M.D., Ph.D.
12 Schizophrenia and Other Psychotic Disorders
12.1 Introduction and Overview
Carol A. Tamminga, M.D.
12.2 Phenomenology of Schizophrenia
Stephen F. Lewis, B.S., M.D., Rodrigo Escalona, M.D., and Samuel J. Keith, M.D.
12.3 Global Burden of Schizophrenia
Daniel Mamah, M.D., M.P.E.
12.4 Genetics of Schizophrenia
Kimberley M. Kendall, B.Sc. (Hons.), M.B.B.Ch., Ph.D., M.R.C.Psych., Elliott Rees, B.Sc. (Hons.), Ph.D., and Michael J. Owen, B.Sc. (Hons.), M.B., Ch.B., Ph.D., F.R.C.P.sych.
12.5 The Clinical Epidemiology of Psychosis Spectrum Disorder
Jim van Os, M.D., Ph.D., and Ulrich Reininghaus, Ph.D.
12.6 Cellular and Molecular Neuropathology of Schizophrenia
Ali S. Imami, M.B.B.S., M.S., Nicholas D. Henkel, Ph.D., Justin F. Creeden, Ph.D., and Robert E. McCullumsmith, M.D., Ph.D.
12.7 Structural Brain Imaging in Schizophrenia
Amanda E. Lyall, Ph.D., Marek Kubicki, M.D., Ph.D., and Martha E. Shenton, Ph.D.
12.8 Functional Brain Imaging in Schizophrenia
Raquel E. Gur, M.D., Ph.D., and Ruben C. Gur, Ph.D.
12.9 Molecular Brain Imaging in Schizophrenia
Dean F. Wong, M.D., Ph.D., Ganesh B. Chand, Ph.D., Gerhard Gründer, M.D., Jimmy E. Jakobsson, Ph.D., and Albert Gjedde, M.D., D.Sc.

12.10 Neurocognition in Schizophrenia
Philip D. Harvey, Ph.D.
12.11 Phenotypes of Psychosis
Brett Clementz, Ph.D.
12.12 Schizophrenia: Pharmacologic Treatment
John M. Kane, M.D., and Christoph U. Correll, M.D.
12.13 Psychiatric Rehabilitation
Robert E. Drake, M.D., Ph.D., Gary R. Bond, Ph.D., and Dror Ben-Zeev, Ph.D.
12.14 Medical Health in Schizophrenia
Robert J. Boland, M.D.
12.15 Recovery in Schizophrenia
Dina Hooshyar, M.D., M.P.H., Chacku Mathai, A.A.S., Drew Musa, C.P.S., and Mark Ragins, M.D.
12.16 Psychosis as a Defining Dimension in Schizophrenia
Elena I. Ivleva, M.D., Ph.D., and Carol A. Tamminga, M.D.
12.17 Other Psychotic Disorders
Ramin Mojtabai, M.D., Ph.D., M.P.H., Laura J. Fochtmann, M.D., M.B.I., and Evelyn J. Bromet, Ph.D.
13 Mood Disorders
13.1 Mood Disorders: Historical Introduction and Conceptual Overview
Robert J. Boland, M.D.
13.2 Mood Disorders: Epidemiology
Kathleen Ries Merikangas, Ph.D., and Zoltán Rihmer, M.D., Ph.D., D.Sc.
13.3 Mood Disorders: Clinical Features
Robert J. Boland, M.D.
13.4 Mood Disorders: Intrapsychic and Interpersonal Aspects
John C. Markowitz, M.D., and Barbara L. Milrod, M.D.
13.5 Mood Disorders: Suicidal Behavior

Maurizio Pompili, M.D., Ph.D., and Zoltán Rihmer, M.D., Ph.D., D.Sc.
13.6 Mood Disorders: Pharmacologic Treatment of Depression and Bipolar Disorders
Lakshmi N. Yatham, M.B.B.S., F.R.C.P.C.S., M.R.C.Psych(UK), M.B.A.(Exec), Sidney H. Kennedy, M.D., F.R.C.P.C., F.R.C.Psych., Ayal Schaffer, M.D., F.R.C.P.C., and Wegdan Rashad, M.D.
13.7 Mood Disorders: Psychotherapy
John R. McQuaid, Ph.D., and Michael E. Thase, M.D.
13.8 Mood Disorders: Neurobiology
Michael E. Thase, M.D., Vladimir Maletic, M.D., M.S., and Charles L. Raison, M.D.
14 Anxiety Disorders
14.1 Anxiety Disorders: Introduction and Overview
Kathleen Ries Merikangas, Ph.D.
14.2 Clinical Features of the Anxiety Disorders
Ryan J. Kimmel, M.D., Joseph M. Cerimele, M.D., M.P.H., and Peter Roy-Byrne, M.D.
14.3 Epidemiology of Anxiety Disorders
Kathleen Ries Merikangas, Ph.D., and Michelle M. Theodory, B.A.
14.4 Anxiety Disorders: Neurobiology and Neuroscience
Sara Costi, M.D., Adriana Feder, M.D., Brian Iacoviello, Ph.D., James W. Murrough, M.D., Ph.D., and Dennis S. Charney, M.D.
14.5 Neuroimaging and the Neuroanatomical Circuits Implicated in Anxiety Disorders
Elizabeth R. Kitt, M.S., M.Phil., Emily M. Cohodes, M.S., M.Phil., and Dylan G. Gee, Ph.D.
14.6 Anxiety Disorders: Cognitive-Behavioral Therapy
Jonathan D. Huppert, Ph.D., and Edna B. Foa, Ph.D.
14.7 Somatic Therapies for Anxiety Disorders

Lakshmi N. Ravindran, M.D., F.R.C.P.C., and Murray B. Stein, M.D., M.P.H.

15 Obsessive-Compulsive and Related Disorders

Dan J. Stein, M.D., Ph.D., and Christine Lochner, Ph.D.

16 Pathological and Problem Gambling: Gambling Disorder

Harvey Roy Greenberg, M.D.

17 Post-Traumatic Stress Disorder

Arieh Y. Shalev, M.D., and Charles R. Marmar, M.D.

18 Somatic Symptom and Related Disorders

Javier I. Escobar, M.D., M.Sc., and Joel E. Dimsdale, M.D.

19 Factitious Disorder

Davin K. Quinn, M.D., Dora Wang, M.D., M.A., Seth Powsner, M.D., and Stuart J. Eisendrath, M.D.

20 Dissociative Disorders

Richard J. Loewenstein, M.D., Roberto Lewis-Fernández, M.D., M.T.S., and Paul Frewen, Ph.D., C.Psych.

21 Normal Sexuality and Sexual Disorders

21.1 Normal Human Sexuality and Sexual Dysfunctions

Virginia A. Sadock, M.D.

21.2 Homosexuality, Gay and Lesbian Identities, and Homosexual Behavior

Jack Drescher, M.D., and William M. Byne, M.D., Ph.D.

21.3 Paraphilic Disorders

Reneé M. Sorrentino, M.D.

21.4 Gender Identity, Gender Diversity, Gender Dysphoria/Incongruence

Jack Drescher, M.D., and William M. Byne, M.D., Ph.D.

21.5 Sexual Addiction

Marcy Verduin, M.D.

22 Feeding and Eating Disorders

Christine C. Call, Ph.D., Evelyn Attia, M.D., and B. Timothy Walsh, M.D.

23 Sleep Disorders

Amir Sharafkhaneh, M.D., Ph.D., Habibolah Khazaie, M.D., and Max Hirshkowitz, Ph.D.

24 Impulse-Control Disorders

24.1 Intermittent Explosive Disorder

Taylor A. Ochalek, Ph.D., and F. Gerard Moeller, M.D.

24.2 Pyromania

Taylor A. Ochalek, Ph.D., and F. Gerard Moeller, M.D.

24.3 Kleptomania

Taylor A. Ochalek, Ph.D., and F. Gerard Moeller, M.D.

25 Adjustment Disorders

Jeffrey W. Katzman, M.D., and Cynthia Geppert, M.D., Ph.D., D.P.S., M.A., M.P.H., M.S.B., M.S.J., F.A.C.L.P., D.F.A.P.A., F.A.S.A.M., H.E.C-C.

26 Personality Disorders

C. Robert Cloninger, M.D., Ph.D., and Nigel Lester, M.D.

VOLUME II

27 Consultation-Liaison Psychiatry and Psychosomatic Medicine

27.1 History and Current Trends

Carol L. Alter, M.D., and Steven A. Epstein, M.D.

27.2 Cardiovascular Disorders

Judith Restrepo, M.D., Margo C. Funk, M.D., M.A., F.A.C.L.P., and Scott Beach, M.D.

27.3 Gastrointestinal Disorders

Ashwini Nadkarni, M.D.

27.4 Psychosomatic Medicine: Obesity

Megan E. Lavery, Psy.D., and Ninoska D. Peterson, Ph.D.

27.5 Respiratory Disorders

Thomas Ritz, Ph.D., Hannah O. Nordberg, M.A., Ph.D., Chelsey A. Werchan, Ph.D., and E. Sherwood Brown, M.D., Ph.D., M.B.A.

27.6 Diabetes: Psychosocial Issues and Psychiatric Disorders

Paul Ciechanowski, M.D., M.P.H., and Robert J. Boland, M.D.

27.7 Endocrine and Metabolic Disorders

Katherine E. Williams, M.D., Kathleen Watson, Ph.D., and Natalie Rasgon, M.D., Ph.D.

27.8 Psycho-Oncology

Daniel McFarland, D.O., M.S., Yesne Alici, M.D., and William S. Breitbart, M.D., F.A.C.L.P., D.F.A.P.A., F.A.P.O.S.

27.9 End-of-Life and Palliative Care

Xiomara Rocha-Cadman, M.D., and Mindy Greenstein, Ph.D.

27.10 Stress and Psychiatry

Traci J. Speed, M.D., Ph.D., Paul S. Nestadt, M.D., and Elizabeth J. Prince, D.O.

27.11 Psychiatric Morbidity Following Critical Illness

Christian Romanchek, M.D., Dimitry S. Davydow, M.D., M.P.H., F.A.C.L.P., and O. Joseph Bienvenu, M.D., Ph.D.

27.12 Psychocutaneous Disorder

Ravenna Khanna, M.D., and Jason P. Caplan, M.D.

27.13 Organ Transplantation

Andrea Frances DiMartini, M.D., Mary Schwab Seligman, M.D., M.A.R., Ph.D., Catherine Chang Crone, M.D., and Gerald Scott Winder, M.D., M.Sc.

27.14 Psychiatric Care of the Burned Patient

Martha C. Gamboa, M.D., Ejine Okoroafor, M.D., F.A.P.A., Reena Baharani, M.D., Yvette Smolin, M.D., M.Ed., and Michael Blumenfield, M.D.

27.15 Management of Chronic Pain

J. Gregory Hobelmann, M.D., M.P.H., and Michael R. Clark, M.D., M.P.H., M.B.A.

28 Additional Conditions That May Be a Focus of Clinical Attention

28.1 Malingering

Frank John Ninivaggi, M.D.

28.2 Adult Antisocial Behavior, Criminality, and Violence

Dorothy Otnow Lewis, M.D., F.A.C.P., Harrell Woodson, Ph.D., and Robert J. Boland, M.D.

28.3 Borderline Intellectual Functioning and Academic or Educational Problem

Frank John Ninivaggi, M.D.

28.4 Relational Problems

William Bernet, M.D.

29 Cultural Concepts of Distress and Assessment

29.1 Cultural Concepts of Distress

Roberto Lewis-Fernández, M.D., M.T.S., Laurence J. Kirmayer, M.D., and Brandon A. Kohrt, M.D., Ph.D.

29.2 Cultural Assessments in Psychiatry

Neil Krishan Aggarwal, M.D., M.B.A., M.A., and Roberto Lewis-Fernández, M.D., M.T.S.

30 Special Areas of Interest

30.1 Psychiatry and Reproductive Medicine

Helen Bradshaw, M.D., Marika Toscano, M.D., and Lauren M. Osborne, M.D.

30.2 Genetic Counseling for Psychiatric Conditions

Jehannine Austin, Ph.D., M.S., F.C.A.H.S., C.G.C., and Holly L. Peay, Ph.D., M.S.

30.3 Physical Violence on Adults

Shannon F. Stromberg, M.D., Kyle Owen, D.O., and Nancy Martin, M.D.

30.4 Complementary, Alternative, and Integrative Approaches in Mental Health Care

James H. Lake, M.D.

30.5 Micronutrient Monitoring and Supplementation in Psychiatric Illness

Jessica L. Principe, M.D., M.S., and Norman K. Pollock, Ph.D.

30.6 Disaster Psychiatry: Disasters, Terrorism, and War

David M. Benedek, M.D., Joshua C. Morganstein, M.D., James C. West, M.D., and Robert J. Ursano, M.D.

30.7 Psychiatry and Spirituality

Shweta Kapoor, M.D., Ph.D.

30.8 Physician and Medical Student Mental Health

Neeta Jain, M.D., and Cynthia M. Stonnington, M.D.

30.9 Computers in Psychiatry

John Luo, M.D.

31 Psychiatric Emergencies

31.1 Suicide: Overview of Epidemiology, Risk and Protective Factors, Treatment, and Prevention

Danuta Wasserman, M.D., Ph.D., and Vladimir Carli, M.D., Ph.D.

31.2 Suicide Treatment

Katrina A. Rufino, Ph.D.

31.3 Other Psychiatric Emergencies

Robert T. Cobb, M.D., and Katherine Camfield, M.D., M.P.H.

32 Psychotherapies

32.1 Psychotherapy Integration

Adam M. Brenner, M.D., and Amy S. Brenner, M.S.W., L.C.S.W.

32.2 Supportive Psychotherapy

John Battaglia, M.D.

32.3 Psychoanalysis and Psychoanalytic Psychotherapy

Adam Critchfield, M.D., Christina Kitt Garza, M.D., and Philip R. Muskin, M.D., M.A., D.L.F.A.P.A., L.F.A.C.L.P.

32.4 Psychoanalytic Treatment of Anxiety, Obsessive-Compulsive and Trauma-Related Disorders

Eric M. Plakun, M.D.

32.5 Intensive Short-Term Psychodynamic Psychotherapies

Manuel Trujillo, M.D.

32.6 Individual Psychodynamic Psychotherapy and Cognitive-Behavioral Therapy for Psychosis

Michael D. Garrett, M.D.

32.7 Treatment of Borderline Personality Disorder

Lois Choi-Kain, M.D., M.Ed., Evan Iliakis, B.A., M.D./Ph.D., Grace Murray, B.A., and Ana Rodriguez-Villa, M.D., M.B.A.

32.8 Behavior Therapy

Jenessa S. Price, Ph.D.

32.9 Cognitive Behavior Therapy

Judith S. Beck, Ph.D., and Robert Hindman, Ph.D.

32.10 Interpersonal Psychotherapy

Robert W. Guynn, M.D.

32.11 Dialectical Behavior Therapy

M. Zachary Rosenthal, Ph.D., Jacqueline Trumbull, B.A., Ph.D., and Rachel Guetta, B.A.

32.12 Solution-Focused Brief Therapy

Anne Bodmer Lutz, B.S.N., M.D.

32.13 Single-Session Therapy

Michael F. Hoyt, Ph.D.

32.14 Mentalization-Based Treatment

Anthony W. Bateman, M.A., F.R.C.Psych., and Peter Fonagy, O.B.E., F.Med.Sci., F.B.A., F.Ac.S.S.

32.15 Narrative Psychiatry

Bradley Lewis, M.D., Ph.D.

32.16 Positive Psychology

Nansook Park, Ph.D.

32.17 Acceptance and Commitment Therapy
Courtney Barry, Psy.D., M.S., Zabrina Ebert, D.O., and Joanna Petrides, M.B.S., Psy.D.
32.18 Hallucinogen-Assisted Psychotherapy
Erika Steinbrenner, M.D.
32.19 Hypnosis
Allan David Axelrad, M.D., Daniel P. Brown, Ph.D., and Harold J. Wain, Ph.D.
32.20 Family and Couples Therapy
Henry I. Spitz, M.D., D.F.A.P.A., D.F.A.G.P.A., and Susan Spitz, A.C.S.W., C.G.P.
32.21 Group Psychotherapy
Henry I. Spitz, M.D., D.F.A.P.A., D.F.A.G.P.A.
32.22 Psychodrama, Sociodrama, Sociometry, and Sociatry
Edward J. Schreiber, T.E.P., and Scott Giacomucci, D.S.W., L.C.S.W., B.C.D., C.G.P., F.A.A.E.T.S., T.E.P.
32.23 Other Methods of Psychotherapy
Adam M. Brenner, M.D., and Aaron Van Wright, M.D.
32.24 Evaluating Psychotherapy: Research Methods, Findings, and Future Directions
Lindsay E. Holly, Ph.D., Megan L. Petrik, Ph.D., and Stephen M. Saunders, Ph.D.
33 Biologic Therapies
  33.1 Preface
    33.1a General Principles of Psychopharmacology
    Olusola Ajilore, M.D., Ph.D., and Mark M. Rasenick, Ph.D.
    33.1b Drug Development and Approval Process in the United States
    Amir Kalali, M.D.
    33.1c Classification of Psychotropics: Neuroscience-Based Nomenclature (NbN)

Joseph Zohar, M.D., Sasson Zemach, M.D., and Daniel Minkin Levy, M.D.

33.2 Dopamine Blockers (“Antipsychotics”)

33.2a Dopamine Antagonists

Martin T. Strassnig, M.D., and Philip D. Harvey, Ph.D.

33.2b Dopamine-Serotonin Antagonists

Stephen R. Marder, M.D., and Walter Dunn, M.D., Ph.D.

33.2c Dopamine Blockers and Neuromotor Adverse Effects

Philip G. Janicak, M.D., and Kumail Hussain, M.D.

33.3 Dopamine Partial agonists

33.3a Dopamine Partial Agonists

Stephen R. Marder, M.D., and Walter Dunn, M.D., Ph.D.

33.4 Dopamine Enhancers

33.4a Dopamine Receptor Agonists

Carlos A. Zarate, Jr., M.D., and Lawrence T. Park, A.M., M.D.

33.4b Amphetamines, Methylphenidate, Atomoxetine, and Modafinil

Manpreet Kaur Singh, M.D., M.S.

33.5 Monoamine Enhancers (“Antidepressants”)

33.5a Reuptake Inhibitors

33.5a.1 Serotonin Reuptake Inhibitors (SRIs)

Simon Lafrenière, M.D., M.Sc., and Pierre Blier, M.D., Ph.D.

33.5a.2 Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)

Pierre Blier, M.D., Ph.D., and Michael E. Thase, M.D.

33.5a.3 Tricyclics and Tetracyclics

J. Craig Nelson, M.D.
33.5a.4 **Dopamine-Noradrenaline Reuptake Inhibitors (Bupropion)**
Charles DeBattista, D.M.H., M.D., and Alan F. Schatzberg, M.D.
33.5b **5HT$_{1A}$ Receptor Partial Agonists (Buspirone)**
Pierre Blier, M.D., Ph.D., and Cary Kogan, Ph.D., M.S.C.P.
33.5c **Vilazodone and Vortioxetine**
Pierre Blier, M.D., Ph.D., and Charles Desfossés, M.D.
33.5d **Monoamine Oxidase Inhibitors**
Ethan F. Karsen, M.D., and Paul E. Holtzheimer, M.D., M.S.
33.6 **Monoamine Modulators**
33.6a **Trazodone**
John T. Vernon, M.D., and Susan G. Kornstein, M.D.
33.6b **Nefazodone**
Amir A. Khan, M.D., and Susan G. Kornstein, M.D.
33.6c **Mirtazapine**
Mousa Sobhy Azer Botros, M.D., Radu V. Saveanu, M.D., and Michael E. Thase, M.D.
33.7 **Serotonin Antagonists/Inverse Agonists**
33.7a **Pimavanserin**
Joan M. Striebel, M.D., Jennifer A. O’Day, M.D., Nekisa Haghighat, M.D., M.P.H., and Stephen M. Stahl, M.D., Ph.D., D.Sc. (Hon.)
33.8 **Noradrenaline Modulators**
33.8a **α_2-Adrenergic Receptor Agonists: Clonidine, Clonidine Extended Release, Guanfacine, and Guanfacine Extended Release**
Eric Hollander, M.D., and Migena Dervishi, M.D.

  - 33.8b **β-Adrenergic Receptor Antagonists**
    Migena Dervishi, M.D., and Eric Hollander, M.D.
- 33.9 **GABA Enhancers**
  - 33.9a **Barbiturates and Similarly Acting Substances**
    Steven L. Dubovsky, M.D., and Dori Marshall, M.D.
  - 33.9b **Benzodiazepine Receptor Agonists and Antagonists**
    Steven L. Dubovsky, M.D., and Dori Marshall, M.D.
- 33.10 **Cation Function Modulators and Lithium (“Mood Stabilizers”)**
  - 33.10a **Calcium Channel Inhibitors**
    Steven L. Dubovsky, M.D., and Dori Marshall, M.D.
  - 33.10b **Gabapentin, Topiramate, Tiagabine, Levetiracetam, Zonisamide, and Pregabalin**
    Hiroyuki Uchida, M.D., Ph.D.
  - 33.10c **Carbamazepine**
    Robert M. Post, M.D., and Mark A. Frye, M.D.
  - 33.10d **Lamotrigine**
    Robert M. Post, M.D.
  - 33.10e **Valproate**
    Robert M. Post, M.D., and Mark A. Frye, M.D.
  - 33.10f **Lithium**
    Robert H. Belmaker, M.D.
- 33.11 **Acetylcholine Blockers and Enhancers**
  - 33.11a **Anticholinergics and Amantadine**
    Samoon Ahmad, M.D.
  - 33.11b **Cholinesterase Inhibitors and Memantine**
    Samir A. Sabbag, M.D., Zelde Espinel, M.D., M.P.H., Luminita Luca, M.D., Ph.D., and Elizabeth A. Crocco, M.D.
- 33.12 **Histamine Modulators**
  - 33.12a **Histamine Blockers and Enhancers**

Sasson Zemach, M.D., and Abraham Weizman, M.D.
33.13 Pharmacological Treatments of Substance Abuse
  33.13a Opioid Receptor Modulators
    33.13a.1 Opioid Maintenance Treatments: Methadone and Buprenorphine
      Jonathan R. Buchholz, M.D., Kelly Barth, D.O., and Andrew J. Saxon, M.D.
    33.13a.2 Opioid Receptor Antagonists: Naltrexone and Nalmefene
      Oluwole O. Jegede, M.D., M.P.H., Stephanie S. O'Malley, Ph.D., Tiffany Arnold, B.S., M.D., Katherine S. Pier, M.D., and Srinivas B. Muvvala, M.D., M.P.H.
  33.13b Disulfiram and Acamprosate
    Katherine S. Pier, M.D.
33.14 Fast-Acting Pharmacologic Treatments
  33.14a Esketamine and Ketamine
    Carlos A. Zarate, Jr., M.D., and Lawrence T. Park, A.M., M.D.
  33.14b MDMA, Psilocybin, Ayahuasca, and Ibogaine
    David Nutt, F.R.C.P., F.R.C.Psych., F.B.Ph.S., F.Med.Sci., D.Laws., and David Erritzoe, M.D., Ph.D., M.R.C.Psych.
33.15 Hormone Receptor Enhancers
  33.15a Melatonin Receptor Agonists
    Tawny L. Smith, Pharm.D., B.c.p.p., and d. jeffrey Newport, m.d., m.s., M.Div.
  33.15b Thyroid Hormones
    Rena Cooper-Kazaz, M.D., and Bernard Lerer, M.D.
33.16 Combination Pharmacotherapy

Charles DeBattista, D.M.H., M.D., and Alan F. Schatzberg, M.D.

33.17 Sex and Psychopharmacology

- **33.17a Sex Differences in Psychopharmacology**
  Anna E. Bauer, Ph.D., M.P.H., and Samantha Meltzer-Brody, M.D., M.P.H.
- **33.17b Reproductive Hormonal Therapy: Theory and Practice**
  David R. Rubinow, M.D., and Peter J. Schmidt, M.D.
- **33.17c Pharmacologic Treatment of Sexual Dysfunction**
  Caridad Ponce Martinez, M.D., Saria El Haddad, M.D., and Anita H. Clayton, M.D.

33.18 Psychopharmacology Across the Life Cycle

- **33.18a Pediatric Psychopharmacology**
  Jeffrey R. Strawn, M.D., and Laura B. Ramsey, Ph.D.
- **33.18b Biologic Therapies: Geriatric Psychopharmacology**
  Ari B. Cuperfain, M.D., M.Sc., and Bruce G. Pollock, M.D., Ph.D., F.R.C.P.C.

33.19 Biologic Therapies Around the Globe

- **33.19a Essential List of Medicines**
  Sasson Zemach, M.D., Daniel Minkin Levy, M.D., and Joseph Zohar, M.D.
- **33.19b Biologic Therapies in Africa**
  Oye Gureje, Ph.D., D.Sc., F.R.C.Psych., F.W.A.C.P., and Olatunde Ayinde, M.B.B.S., M.S., F.W.A.C.P.
- **33.19c Biologic Therapies in India**
  E. Mohandas, M.B.B.S., M.D., Sandeep Grover, M.B.B.S., M.D., and Ajit Avasthi, M.B.B.S., M.D.

        33.19d **Biologic Therapies in Latin America**
            Rodolfo Furlan Damiano, M.D., Ph.D., and André Russowsky Brunoni, M.D., Ph.D.
    33.20 **Brain Stimulation**
        33.20a **Electroconvulsive Therapy**
            Joan Prudic, M.D.
        33.20b **Brain Stimulation Methods**
            Stefan B. Rowny, M.D., M.F.A., and Lawrence Amsel, M.D., M.P.H.
        33.20c **Neurosurgical Treatments**
            Benjamin D. Greenberg, M.D., Ph.D., and Nicole C.R. McLaughlin, Ph.D.
34 **Child Psychiatry**
    34.1 **Introduction and Overview**
        Caroly Sue Pataki, M.D.
    34.2 **Child Development**
        Gabrielle Shapiro, M.D., D.F.A.A.C.A.P., D.F.A.P.A., Robert J. Jaffe, M.D., Alexander Kolevzon, M.D., and Tresha A. Gibbs, M.D.
    34.3 **Adolescent Development**
        Ardis C. Martin, M.D., and Caroly Sue Pataki, M.D.
35 **Child Psychiatric Examination**
    35.1 **Psychiatric Examination of the Infant, Child, and Adolescent**
        Robert A. King, M.D., Prudence W. Fisher, Ph.D., Michael H. Bloch, M.D., M.S., Mary Schwab Seligman, M.D., M.A.R., Ph.D., Walter S. Gilliam, Ph.D., and Michael Vitulano, Ph.D.
    35.2 **Psychiatric Assessment of Preschool Children**
        Helen Link Egger, M.D., and Caroly Sue Pataki, M.D.
    35.3 **Neuropsychological and Psychoeducational Assessment of Children**

Evangelina Barnard, Psy.D., and Patricia D. Walshaw, Ph.D.
35.4 Psychiatric Emergencies in Children and Adolescents
Alexandra Junewicz, M.D., and Ruth S. Gerson, M.D.
36 Genetics in Child Psychiatry
Gil D. Hoftman, M.D., Ph.D., James T. McCracken, M.D., and Erika L. Nurmi, M.D., Ph.D.
37 Neuroimaging in Psychiatric Disorders of Childhood
Frank P. Macmaster, Ph.D., Kayla D. Stone, Ph.D., Sneha Chenji, Ph.D., and David R. Rosenberg, M.D.
38 Temperament: Risk and Protective Factors for Child Psychiatric Disorders
David C. Rettew, M.D.
39 Intellectual Disability
Evan Taniguchi, M.D., Soo-Jeong Kim, M.D., and Karen E. Toth, Ph.D.
40 Specific Learning Disorder
Oren Boxer, Ph.D.
41 Developmental Coordination Disorder
Vijay Vishwanath, M.D., Ph.D., and Wendy G. Mitchell, M.D.
42 Communication
42.1 Language Disorder
Tuana Kant, M.Sc., Emiko Koyama, Ph.D., Mahliqa Ashraf, H.B.Sc., and James L. Kennedy, M.D., F.R.C.P.C., F.R.S.C.
42.2 Social (Pragmatic) Communication Disorder
Mirelle Kass, B.A., Young Shin Kim, M.D., M.S., M.P.H., Ph.D., and Bennett L. Leventhal, M.D.
42.3 Speech Sound Disorder
Emiko Koyama, Ph.D., Mahliqa Ashraf, H.B.Sc., Tuana Kant, M.Sc., and James L. Kennedy, M.D., F.R.C.P.C., F.R.S.C.
42.4 Stuttering

Emiko Koyama, Ph.D., Mahliqa Ashraf, H.B.Sc., James L. Kennedy, M.D., F.R.C.P.C., F.R.S.C., and Tuana Kant, M.Sc.

42.5 Unspecified Communication Disorder

Tim Bressmann, Ph.D.

43 Autism Spectrum Disorders

Fred R. Volkmar, M.D., Giacomo Vivanti, Ph.D., Ryan K. C. Yuen, Ph.D., and Kevin Pelphrey, Ph.D.

44 Attention-Deficit Disorders

44.1 Attention-Deficit/Hyperactivity Disorder

Lily T. Hechtman, M.D., F.R.C.P., A.B.P.N., Margaret D. Weiss, M.D., Ph.D., and Philippe Hwang, M.B., B.Ch., B.A.O., M.Sc.

44.2 Adult Manifestations of Attention-Deficit/Hyperactivity Disorder

James J. McGough, M.D., M.S.

45 Disruptive Behavior Disorders in Children and Adolescents

Erin P. Vaughan, M.A., Eva R. Kimonis, Ph.D., M.S., and Paul J. Frick, Ph.D.

46 Feeding and Eating Disorders of Infancy and Early Childhood

Irene Chatoor, M.D., and Loredana Lucarelli, Psy.D.

47 Tic Disorders

Rahil R. Jummani, M.D., Elizabeth A. Deckler, M.D., and Barbara J. Coffey, M.D., M.S.

48 Elimination Disorders

Edwin Jens Mikkelsen, M.D.

49 Other Disorders of Infancy, Childhood, and Adolescence

49.1 Reactive Attachment Disorder and Disinhibited Social Engagement Disorder

Karin M. Best, Ph.D., Mary Margaret Gleason, M.D., and Charles H. Zeanah, M.D.

49.2 Stereotypic Movement Disorders in Children

Robert Lloyd Doyle, M.A., D.D.S., M.D.

50 Mood Disorders in Children and Adolescents

- 50.1 Depressive Disorders and Suicide
  Karen Dineen Wagner, M.D., Ph.D., Tami Benton, M.D., and Catharyn A. Turner, II, M.D., M.Ed.
- 50.2 Early-Onset Bipolar Disorder
  Gabrielle A. Carlson, M.D., Manpreet Kaur Singh, M.D., M.S., Danella Hafeman, M.D., Ph.D., and Caroly Sue Pataki, M.D.

51 Anxiety Disorders in Children

- 51.1 Obsessive-Compulsive Disorder in Childhood
  Adam B. Lewin, Ph.D., A.B.P.P., and John Piacentini, Ph.D., A.B.P.P.
- 51.2 Posttraumatic Stress Disorder in Children and Adolescents
  Judith A. Cohen, M.D.
- 51.3 Separation Anxiety, Generalized Anxiety, and Social Anxiety
  Benjamin N. Schneider, M.D., Ruben G. Martinez, Ph.D., and Tara S. Peris, Ph.D.
- 51.4 Selective Mutism
  R. Lindsey Bergman, Ph.D., and Araceli Gonzalez, Ph.D.

52 Early-Onset Psychotic Disorders

Kaitlin Boyle, M.D., Linmarie Sikich, M.D., M.A., and Tara Chandrasekhar, M.D.

53 Child Psychiatry: Psychiatric Treatment

- 53.1 Psychodynamic Psychotherapy (Child Psychiatry)
  David L. Kaye, M.D., and Michael Shapiro, M.D.
- 53.2 Cognitive-Behavioral Psychotherapy for Children and Adolescents
  Anne Marie Albano, Ph.D., and Sandra S. Pimentel, Ph.D.
- 53.3 Group Psychotherapy
  Margo L. Thienemann, M.D.

53.4 Family Therapy
John Sargent, M.D., and Neha Sharma, D.O.
53.5 Pediatric Psychopharmacology
Jeffrey R. Strawn, M.D., and Laura B. Ramsey, Ph.D.
53.6 Inpatient Psychiatric, Partial Hospitalization, and Residential Treatment for Children and Adolescents
Cynthia Wilson, M.D., and Andrés Martin, M.D., Ph.D.
53.7 Community-Based Treatment
Andrés J. Pumariega, M.D.
53.8 The Treatment of Adolescents
Khadijah Booth Watkins, M.D., M.P.H., Steven C. Schlozman, M.D., and Eugene V. Beresin, M.D., M.A.
54 Child Psychiatry: Special Areas of Interest
54.1 Adoption and Foster Care
Dale Aaron Peeples, M.D., and Sandra B. Sexson, M.D.
54.2 Child Maltreatment
Heather Williams, M.D., and Bradley Freeman, M.D.
54.3 Children's Reaction to Illness and Hospitalization
Susan Beckwitt Turkel, M.D., Julienne Jacobson, M.D., and Maryland Pao, M.D.
54.4 Psychiatric Sequel of HIV and AIDS
Mark DeAntonio, M.D.
54.5 Adolescent Substance Use Disorders
Sean R. LeNoue, M.D., and Paula D. Riggs, B.A., M.A., M.D.
54.6 Forensic Child and Adolescent Psychiatry
Peter Ash, M.D., and Elissa P. Benedek, M.D.
54.7 Ethical Issues in Child and Adolescent Psychiatry
Adrian N. Sondheimer, M.D., and Takahiro Soda, M.D., Ph.D.
54.8 School Consultation and Collaborating With the Educational System

Sheryl Kataoka, M.D., M.S.H.S., Ilaina Blum, M.A., M.F.T., Edward Castelo, M.D., and Roya Ijadi-Maghsoodi, M.D., M.S. H.P.M.

54.9 Prevention of Psychiatric Disorders in Children and Adolescents

William R. Beardslee, M.D.

54.10 Child Mental Health Services Research

Bonnie T. Zima, M.D., M.P.H., and Regina Bussing, M.D., M.S.H.S.

54.11 Impact of Terrorism and School Shootings on Children

Nayla M. Khoury, M.D., M.P.H., and Wanda P. Fremont, M.D.

54.12 Impact on Parents of Raising a Child with Psychiatric Illness and/or Developmental Disability

Alice R. Mao, M.D., Matthew N. Brams, M.D., Kathryn Forneris, D.O., M.P.H., and Pieter Joost Van Wattum, M.D., M.A.

54.13 Pediatric Sleep Disorders

Jess P. Shatkin, M.D., M.P.H., and Anna Ivanenko, M.D., Ph.D.

54.14 Internet Gaming Disorder in Youth

Michael Feldmeier, M.D., Michael Ogata, M.D., Caroly Sue Pataki, M.D., and Roxy Szeftel, M.D.

54.15 Social Media and Youth

Christina Guest, M.D., Yeun J. Lim, M.D., Michael Feldmeier, M.D., Roxy Szeftel, M.D., and Caroly Sue Pataki, M.D.

54.16 Gay, Bisexual, Transgender, Queer/Questioning, Intersex, and Asexual (LGBTQIA) Youth

Natalia Ramos, M.D., M.P.H., Serena Chang, M.D., B.A., and Mikiko Thelwell, M.D., M.P.H.

54.17 **Racism and Discrimination’s Impact on the Health and Well-Being of Developing Children and Adolescents**
Wanjikũ F.M. Njoroge, M.D., Ewurama Sackey, M.D., Nana Asabere, M.D., and Eraka Bath, M.D.
54.18 **Forensic Evaluations of Child and Adolescent Migrants**
Olivia Shadid, M.D., and Shawn Singh Sidhu, M.D.
55 **Geriatric Psychiatry**
55.1 **Introduction to Geriatric Psychiatry**
Dilip V. Jeste, M.D., Dylan J. Jester, Ph.D., M.P.H., and Ellen E. Lee, M.D.
55.2 **Assessment**
55.2a **Psychiatric Assessment of the Older Patient**
Davangere P. Devanand, M.D., and Andrea Delgado-Peraza, M.D.
55.2b **Complementary and Integrative Geriatric Psychiatry**
Sarah A. Nguyen, M.D., Hanadi Ajam Oughli, M.D., Harris A. Eyre, M.B.B.S., Ph.D., and Helen Lavretsky, M.D., M.S.
55.2c **The Aging Brain**
Robert J. Boland, M.D., and Iqbal Ahmed, M.D., F.R.C.Psych.
55.2d **Psychological Changes With Normal Aging**
Tina L. Mayes, Ph.D., Maya A. Reiter, M.S., Ph.D., and Jennifer J. Dunkin, Ph.D.
55.2e **Neuropsychological Evaluation**
Gauri Savla, Ph.D., and Barton W. Palmer, Ph.D.
55.2f **Genetics of Late-Life Neurodegenerative Disorders**
Seethalakshmi Ramanathan, M.D., M.P.A., and Stephen J. Glatt, Ph.D.
55.3 **Psychiatric Disorders of Late Life**

55.3a Assessment of Functioning
David J. Moore, Ph.D., Maulika Kohli, M.S., and Pariya L. Fazeli, Ph.D.
55.3b Psychiatric Problems in the Medically Ill Geriatric Patient
Anna Borisovskaya, M.D., Beth Ann Labardi, M.D., Matthew Alan Schreiber, M.D., Ph.D., and Marcella Pascualy, M.D.
55.3c Sleep Disorders in Older Adults
Jana R. Cooke, M.D., and Sonia Ancoli-Israel, Ph.D.
55.3d Anxiety Disorders in Older Adults
Helmet T. Karim, Ph.D., and Carmen Andreescu, M.D.
55.3e Geriatric Mood Disorders
Talya Shahal, M.D., Jennie Davidow, M.D., Jennifer R. Gatchel, M.D., Ph.D., and Brent P. Forester, M.D., M.Sc.
55.3f Alzheimer Disease and Other Neurocognitive Disorders
Gary W. Small, M.D., and Stephen T. Chen, M.D.
55.3g Delirium
Jayson Varughese, M.D., M.S., and Susan W. Lehmann, M.D.
55.3h Schizophrenia and Other Psychotic Disorders
Carl I. Cohen, M.D., and Paul D. Meesters, M.D.
55.3i Personality Disorders
Marc E. Agronin, M.D.
55.3j Alcohol and Substance Abuse in Older Adults
Steve Koh, M.D., M.P.H., M.B.A., Hilary Gould, Ph.D., Omar Ghosn, M.D., and Michael Hann, M.D., M.B.A., M.S., C.P.E., F.A.C.H.E., F.A.P.A.
55.4 Treatment of Psychiatric Disorders

55.4a Geriatric Psychopharmacology: General Principles
Bruce G. Pollock, M.D., Ph.D., F.R.C.P.C.
55.4b Antidepressants and Mood Stabilizers
Carl Salzman, M.D.
55.4c Antianxiety Drugs
Alastair J. Flint, M.B., and Kathleen S. Bingham, M.D., Ph.D.
55.4d Antipsychotic Drugs
Kelly C. Lee, Pharm.D., M.A.S., B.C.P.P., and Vivian Hook, Ph.D.
55.4e Antidementia Drugs
Iqbal Ahmed, M.D., F.R.C.Psych.
55.4f Electroconvulsive Therapy and Neurostimulation Treatments
Mustafa M. Husain, M.D., Tarek K. Rajji, M.D., F.R.C.P.C., and Robert Garrett, M.D.
55.4g Psychosocial Factors in Psychotherapy of the Older Adult s
Joel I. Sadavoy, M.D., F.R.C.P.(C)
55.4h Individual Psychotherapy
Joel I. Sadavoy, M.D., F.R.C.P.(C), and Lawrence W. Lazarus, M.D.
55.4i Cognitive-Behavioral Therapy
John R. McQuaid, Ph.D., Eric Granholm, Ph.D., and Patricia A. Areán, Ph.D.
55.4j Family Intervention and Therapy With Older Adults
Lauren N. DeCaporale-Ryan, Ph.D., Ann Elizabeth Cornell, Psy.D., C.E.A.P., Jessica Goodman, Ph.D., and Carol Ann Podgorski, Ph.D., M.P.H., M.S.
55.4k Group Therapy

Kenneth M. Schwartz, M.D., F.R.C.P.C., Ingrid Söchting, Ph.D., R.Psych., C.G.P., Shayne Vitemb, M.A., L.M.F.T., C.G.P., and Alvin Keng, M.D., F.R.C.P.C.

55.4l Counseling and Support Needs of Dementia Caregivers

Liat Ayalon, Ph.D., and Patricia A. Areán, Ph.D.

55.5 Financial Issues in the Delivery of Geriatric Psychiatric Care

Steve Koh, M.D., M.P.H., M.B.A., Helen H. Kyomen, M.D., M.S., Michael Hann, M.D., M.B.A., M.S., C.P.E., F.A.C.H.E., F.A.P.A., and Hilary Gould, Ph.D.

55.6 Special Areas of Interest

55.6a Psychiatric Aspects of Long-Term Care

Abhilash K. Desai, M.D., and George T. Grossberg, M.D.

55.6b Forensic Aspects

David Naimark, M.D., Keith A. Davidson, J.D., Ariana Nesbit, M.D., M.B.E., and Ansar M. Haroun, M.D. (Retired)

55.6c Ethical Issues

Nathan Fairman, M.D., M.P.H.

55.6d Gender Issues

Helen H. Kyomen, M.D., M.S.

55.6e The Legal and Ethical Analysis of Older Adult Abuse

Paul Richard Greenwood, L.L.B. (Hons.), Ansar M. Haroun, M.D. (Retired), David Naimark, M.D., and Ariana Nesbit, M.D., M.B.E.

55.6f Geriatric Psychiatry: Sexuality and Aging

Abesh Kumar Bhattacharjee, M.D., Ph.D., Niraj K. Asthana, M.D., and Daniel D. Sewell, M.D.

55.6g HIV and Aging

Laura M. Campbell, M.S., María Marquine, Ph.D., and Raeanne C. Moore, Ph.D.

55.6h Technology for Seniors

Avery Quynh, B.S., Vanessa Scott, B.S., Colin A. Depp, Ph.D., and Ipsit V. Vahia, M.D.

55.6i Positive Psychiatry of Aging

Barton W. Palmer, Ph.D., and Dilip V. Jeste, M.D.

56 Public Psychiatry

56.1 Public and Community Psychiatry

Nidal Moukaddam, M.D., Ph.D., and Asim A. Shah, M.D.

56.2 Reforming Health Care

Nidal Moukaddam, M.D., Ph.D., and Asim A. Shah, M.D.

56.3 The Role of the Hospital in the Care of Persons with Mental Illness

Erica Taylor, M.D., M.P.H.

56.4 Mental Health Services Research

Lisa B. Dixon, M.D., M.P.H., and Milton Wainberg, M.D.

56.5 The Psychiatric Hospitalist

Angel Cienfuegos, M.D.

56.6 Psychiatric Rehabilitation

Lujain Alhajji, M.D., Vanessa Padilla, M.D., and Radu V. Saveanu, M.D.

56.7 A Sociocultural Framework for Mental Health and Substance Abuse Service Inequities

Margarita Alegría, Ph.D., Bernice A. Pescosolido, Ph.D., Kiara Alvarez, Ph.D., and Glorisa Canino, Ph.D.

56.8 Criminalization of Persons With Serious Mental Illness

Linda E. Weinberger, Ph.D., and H. Richard Lamb, M.D.

57 Psychiatric Education

57.1 Graduate Psychiatric Education

George Alan Keepers, M.D.

57.2 Examining Professional Patients

M. Sagman Kayatekin, M.D., George Bombel, Ph.D., and Kim-Lan Tran Czelusta, M.D.

58 Ethics and Forensic Psychiatry

58.1 Clinical-Legal Issues in Psychiatry

Clarence Watson, J.D., M.D., Spencer Eth, M.D., and Gregory B. Leong, M.D.

58.2 Ethics in Psychiatry

Laura Weiss Roberts, M.D., M.A.

58.3 Correctional Psychiatry

Arya Shah, M.D., and Jhilam Biswas, M.D.

59 History of Psychiatry

Edward Shorter, Ph.D., F.R.S.C.

60 World Aspects of Psychiatry

Sam Gnanapragasam, B.Sc., M.B.B.S., M.R.C.Psych., Max Pemberton, M.B.B.S., B.Sc., M.R.C.Psych., Pedro Ruiz, M.D., Antonio Ventriglio, M.D., Ph.D., and Dinesh Bhugra, C.B.E., M.A., M.Sc., M.B.B.S., F.R.C.P., F.R.C.P.E., F.R.C.Psych., F.F.P.H., M.Phil., Ph.D., F.R.C.Psych. (Hon), F.H.K.C.Psych. (Hon), F.A.C.P. (Hon), F.A.M.S. (Singapore), F.I.M.S.A. (Hon)

27.14 Psychiatric Care of the Burned Patient

Deanna M. Barch, Ph.D. Professor of Psychological and Brain Sciences, Psychiatry, and Radiology; Vice Dean of Research, Arts & Sciences; Gregory B. Couch Professor of Psychiatry; Editor-in-Chief, Biological Psychiatry: Global Open Science, Washington University in St. Louis, School of Medicine, St. Louis, Missouri
1.28 Functional Brain Connectivity and Psychopathology

Evangelina Barnard, Psy.D. Postdoctoral Fellow in Pediatric Neuropsychology, Division of Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
35.3 Neuropsychological and Psychoeducational Assessment of Children

Brian S. Barnett, M.D. Assistant Professor of Psychiatry, Department of Psychiatry and Psychology, Cleveland Clinic Lerner College of Medicine, Cleveland, Ohio
11.6 Hallucinogen-Related Disorders

Courtney Barry, Psy.D., M.S. Assistant Professor, Department of Psychiatry and Behavioral Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin
32.17 Acceptance and Commitment Therapy

Kelly Barth, D.O. Professor, Department of Psychiatry and Behavioral Sciences, Internal Medicine, Medical University of South Carolina, College of Medicine, Charleston, South Carolina
33.13a.1 Opioid Maintenance Treatments: Methadone and Buprenorphine

Gaston Baslet, M.D. Chief, Division of Neuropsychiatry, Department of Psychiatry, Brigham and Women’s Hospital/ Harvard University, Harvard Medical School, Boston, Massachusetts
2.4 Neuropsychiatric Aspects of Epilepsy and Psychogenic Nonepileptic Seizures

Anthony W. Bateman, M.A., F.R.C.Psych. Consultant Psychiatrist and Visiting Professor, Department of Clinical, Educational and Health Psychology, Anna Freud Centre and University College London, London, United Kingdom
32.14 Mentalization-Based Treatment

Eraka Bath, M.D. Clinical Professor of Psychiatry, Department of Psychiatry, Division of Population Behavioral Health, University of California, David Geffen School of Medicine, Los Angeles, California
54.17 Racism and Discrimination's Impact on the Health and Well-Being of Developing Children and Adolescents

John Battaglia, M.D. Clinical Adjunct Professor of Psychiatry, Department of Psychiatry, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin
32.2 Supportive Psychotherapy

Anna E. Bauer, Ph.D., M.P.H. Assistant Professor, Center for Women's Mood Disorders, Department of Psychiatry, University of North Carolina School of Medicine, Chapel Hill, North Carolina
33.17a Sex Differences in Psychopharmacology

Scott Beach, M.D. Associate Professor of Psychiatry, Division of Psychiatry and Medicine, Massachusetts General Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
27.2 Cardiovascular Disorders

William R. Beardslee, M.D. Director, Baer Prevention Initiatives and Distinguished Gardner/Monks, Professor of Child Psychiatry, Department of Psychiatry, Boston Children's Hospital, Boston, Massachusetts
54.9 Prevention of Psychiatric Disorders in Children and Adolescents

Judith S. Beck, Ph.D. Clinical Professor of Psychology in Psychiatry, Department of Psychiatry, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine, Philadelphia, Pennsylvania
32.9 Cognitive Behavior Therapy

Robert H. Belmaker, M.D. Professor Emeritus of Psychiatry, Division of Psychiatry, Faculty of Medicine, Ben-Gurion University, Be'er-Sheva, Israel

33.10f Lithium

Dror Ben-Zeev, Ph.D. Professor of Psychiatry and Behavioral Sciences, Psychiatry and Behavioral Sciences, University of Washington, School of Medicine, Seattle, Washington
12.13 Psychiatric Rehabilitation

Ruth M. Benca, M.D., Ph.D. Professor and Chair, Department of Psychiatry and Behavioral Medicine, Wake Forest University, School of Medicine, Atrium Health Wake Forest Baptist, Winston-Salem, North Carolina
1.15 Basic Science of Sleep

Elissa P. Benedek, M.D. Adjunct Clinical Professor, Department of Psychiatry, University of Michigan Medical School; Psychiatric Resident Teaching, Forensic Fellow Teaching, Medical Student Teaching, Ann Arbor, Michigan; Clinical Professor, Department of Psychiatry, Michigan State University, College of Human Medicine, East Lansing, Michigan; Clinical Professor, Department of Psychiatry and Behavior Neurosciences, Wayne State University School of Medicine, Detroit, Michigan
54.6 Forensic Child and Adolescent Psychiatry

David M. Benedek, M.D. Professor and Chair, Department of Psychiatry, School of Medicine, Uniformed Services University of the Health Sciences, F. Edward Hébert School of Medicine, Bethesda, Maryland
30.6 Disaster Psychiatry: Disasters, Terrorism, and War

Tami Benton, M.D. Chair, Department of Child and Adolescent Psychiatry and Behavioral Sciences, Department of Psychiatry, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine, The Children’s Hospital of Philadelphia, Philadelphia, Pennsylvania
50.1 Depressive Disorders and Suicide

Eugene V. Beresin, M.D., M.A. Executive Director, The Clay Center for Young Healthy Minds; Director, Division of Professional and Public Education, Department of Psychiatry, Massachusetts General Hospital; Professor of Psychiatry, Harvard University, Harvard Medical School, Department of Psychiatry, Massachusetts General Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
53.8 The Treatment of Adolescents

R. Lindsey Bergman, Ph.D. Division of Child and Adolescent Psychiatry, University of California, David Geffen School of Medicine, Los Angeles, California
51.4 Selective Mutism

William Bernet, M.D. Professor Emeritus, Department of Psychiatry and Behavioral Sciences, Vanderbilt University School of Medicine, Nashville, Tennessee
28.4 Relational Problems

Karin M. Best, Ph.D. Assistant Adjunct Professor, Department of Psychiatry and Biobehavioral Sciences, Division of Child and Adolescent Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior, David Geffen School of Medicine, University of California, David Geffen School of Medicine, Los Angeles, California
49.1 Reactive Attachment Disorder and Disinhibited Social Engagement Disorder

Abesh Kumar Bhattacharjee, M.D., Ph.D. Associate Professor, Department of Psychiatry, University of California, School of Medicine/VA San Diego Healthcare system, San Diego, California
55.6f Geriatric Psychiatry: Sexuality and Aging

Dinesh Bhugra, C.B.E., M.A., M.Sc., M.B.B.S., F.R.C.P., F.R.C.P.E., F.R.C.Psych., F.F.P.H., M.Phil., Ph.D., F.R.C.Psych. (Hon), F.H.K.C.Psych. (Hon), F.A.C.P. (Hon), F.A.M.S. (Singapore),

F.I.M.S.A. (Hon) Emeritus Professor of Mental Health and Cultural Diversity, Health Service & Population Research, Institute of Psychiatry, Psychology and Neuroscience at King's College London, London, United Kingdom
60 World Aspects of Psychiatry

O. Joseph Bienvenu, M.D., Ph.D. Judy Yin Shih, PhD Professor in Anxiety Disorders, Psychiatry and Behavioral Sciences, Johns Hopkins Hospital/Johns Hopkins University School of Medicine, Baltimore, Maryland
27.11 Psychiatric Morbidity Following Critical Illness

Kathleen S. Bingham, M.D., Ph.D. Assistant Professor of Psychiatry, Department of Psychiatry, University Health Network/University of Toronto, Toronto, Ontario, Canada
55.4c Antianxiety Drugs

Adam Bisaga, M.D. Professor of Psychiatry at CUMC, Department of Psychiatry, New York State Psychiatric Institute/Columbia University Vagelos College of Physicians and Surgeons, New York, New York
11.9 Opioid Use and Related Disorders: From Neuroscience to Treatment

Jhilam Biswas, M.D. Director of the Psychiatry, Law and Society Program, Department of Psychiatry, Brigham and Women's Hospital, Newton Highlands, Massachusetts
58.3 Correctional Psychiatry

Deborah Blacker, M.D., Sc.D. Professor of Psychiatry, Harvard University, Harvard Medical School; Professor and Deputy Chair, Harvard T.H. Chan School of Public Health, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts
7.8 Psychiatric Rating Scales

Mark A. Blais, Psy.D. Associate Professor of Psychology (Psychiatry), Massachusetts General Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
7.8 Psychiatric Rating Scales

Pierre Blier, M.D., Ph.D. Professor, Department of Psychiatry, University of Ottawa, Ottawa, Ontario, Canada
33.5a.2 Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)
33.5a.1 Serotonin Reuptake Inhibitors (SRIs), 33.5b $5HT_{1A}$ *Receptor Partial Agonists (Buspirone), 33.5c Vilazodone and Vortioxetine*

Michael H. Bloch, M.D., M.S. Associate Professor, Child Study Center, Department of Psychiatry, Yale University, School of Medicine, New Haven, Connecticut
35.1 Psychiatric Examination of the Infant, Child, and Adolescent

Ilaina Blum, M.A., M.F.T. Education Consultant, Division of Child/Adolescent Psychiatry, UCLA Resnick Neuropsychiatric Hospital (RNPH), University of California, David Geffen School of Medicine, Los Angeles, California
54.8 School Consultation and Collaborating With the Educational System

Michael Blumenfield, M.D. Sidney E. Frank Distinguished Professor Emeritus of Psychiatry and Behavioral Sciences, Department of Psychiatry, New York Medical College, Valhalla, New York
27.14 Psychiatric Care of the Burned Patient

Robert J. Boland, M.D. Senior Vice President and Chief of Staff, The Menninger Clinic; Professor and Vice Chair, Menninger Department of Psychiatry and Behavioral Sciences, The Brown Foundation Endowed Chair in Psychiatry, Baylor University, College of Medicine, Houston, Texas

10.5 Cognitive Disorders Due to Another Medical Condition or Substance, 12.14 Medical Health in Schizophrenia, 13.1 Mood Disorders: Historical Introduction and Conceptual Overview, 13.3 Mood Disorders: Clinical Features, 27.6 Diabetes: Psychosocial Issues and Psychiatric Disorders, 28.2 Adult Antisocial Behavior, Criminality, and Violence, 55.2c The Aging Brain

George Bombel, Ph.D. Assistant Professor/Senior Clinical Psychologist, Department of Psychiatry and the Behavioral Sciences, Baylor University, College of Medicine/The Menninger Clinic, Houston, Texas
57.2 Examining Professional Patients

Gary R. Bond, Ph.D. Senior Research Associate, Westat, Lebanon, New Hampshire
12.13 Psychiatric Rehabilitation

Olivier Bonnot, M.D., Ph.D. Full Professor of Child and Adolescent Psychiatry, Child and Adolescent Department, Barthelemy Durand Hospital/Paris-Saclay School of Medicine, Kremlin-Bicetre, France
2.14 Neuropsychiatry of Neurometabolic and Neuroendocrine Disorders

Anna Borisovskaya, M.D. Clinical Associate Professor of Psychiatry, Department of Psychiatry and Behavioral Sciences, University of Washington, School of Medicine, Seattle Neuropsychiatric Treatment Center, Seattle, Washington
55.3b Psychiatric Problems in the Medically Ill Geriatric Patient

Mousa Sobhy Azer Botros, M.D. Assistant Professor of Clinical Psychiatry, Psychiatry and Behavioral Sciences, University of Miami Leonard M. Miller School of Medicine, Miami, Florida
33.6c Mirtazapine

Mark E. Bouton, Ph.D. University Distinguished Professor and Robert B. Lawson Green & Gold Professor of Psychology,

Department of Psychological Science, University of Vermont, Robert Larner MD College of Medicine, Burlington, Vermont
3.3 Learning Theory

Scott E. Bowen, Ph.D. Professor and Department Chair, Psychology/Behavioral, Cognitive Neuroscience, Wayne State University, School of Medicine/College of Liberal Arts & Sciences, Detroit, Michigan
11.7 Inhalant-Related Disorders

Oren Boxer, Ph.D. Clinical Neuropsychologist, Department of Psychiatry, Insight Collective, South Pasadena, California; University of California, David Geffen School of Medicine, Los Angeles, California
40 Specific Learning Disorder

Kaitlin Boyle, M.D. Child and Adolescent Psychiatry Fellow, Department of Psychiatry and Behavioral Sciences, Duke University Health System, Durham, North Carolina
52 Early-Onset Psychotic Disorders

Helen Bradshaw, M.D. Resident Physician, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland
30.1 Psychiatry and Reproductive Medicine

Matthew N. Brams, M.D. Clinical Professor of Psychiatry, Department of Psychiatry, Baylor University, College of Medicine, Houston, Texas
54.12 Impact on Parents of Raising a Child with Psychiatric Illness and/or Developmental Disability

William S. Breitbart, M.D., F.A.C.L.P., D.F.A.P.A., F.A.P.O.S. Chairman, Department of Psychiatry and Behavioral Sciences, Memorial Sloan Kettering Cancer Center, New York, New York
27.8 Psycho-Oncology

Adam M. Brenner, M.D. Distinguished Teaching Professor and Vice Chair for Education, Department of Psychiatry Department, University of Texas Southwestern Medical School, Dallas, Texas
6.3 Other Psychodynamic Schools, 32.1 Psychotherapy Integration, 32.23 Other Methods of Psychotherapy

Amy S. Brenner, M.S.W., L.C.S.W. Volunteer Clinical Faculty, Department of Psychiatry, University of Texas Southwestern Medical School, Dallas, Texas
32.1 Psychotherapy Integration

Tim Bressmann, Ph.D. Associate Professor, Speech-Language Pathology, Temerty Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada
42.5 Unspecified Communication Disorder

Evelyn J. Bromet, Ph.D. Distinguished Professor Emerita, Department of Psychiatry, Stony Brook University, Renaissance School of Medicine, Stony Brook, New York
12.17 Other Psychotic Disorders

John O. Brooks, III, Ph.D., M.D. Professor-in-Residence, Department of Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
7.6 Medical Assessment and Laboratory Testing in Psychiatry

Shaun P. Brothers, Ph.D., M.B.A. Associate Professor, Department of Psychiarty and Behavioral Sciences, University of Miami, Leonard M. Miller School of Medicine, Miami, Florida
1.8 Neuropeptides: Biology, Regulation and Role in Neuropsychiatric Disorders

E. Sherwood Brown, M.D., Ph.D., M.B.A. Professor and Vice Chair of Clinical Research, Department of Psychiatry, University of Texas Southwestern, Medical School, Dallas, Texas
27.5 Respiratory Disorders

André Russowsky Brunoni, M.D., Ph.D. Associate Professor, Psychiatry, Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil
33.19d Biologic Therapies in Latin America

Jonathan R. Buchholz, M.D. Assistant Professor, Department of Psychiatry and Behavioral Sciences, VA Puget Sound Health Care System and University of Washington, School of Medicine, Seattle, Washington
33.13a.1 Opioid Maintenance Treatments: Methadone and Buprenorphine

Regina Bussing, M.D., M.S.H.S. Professor, Department of Psychiatry, University of Florida, College of Medicine, Gainesville, Florida
54.10 Child Mental Health Services Research

Joanne A. Byars, M.D. Assistant Professor of Psychiatry, Department of Psychiatry and Behavioral Health, Geisinger/Geisinger Commonwealth School of Medicine, Danville, Pennsylvania
2.5 Neuropsychiatric Consequences of Traumatic Brain Injury

William M. Byne, M.D., Ph.D. Professor of Clinical Psychiatry, Department of Psychiatry, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
21.2 Homosexuality, Gay and Lesbian Identities, and Homosexual Behavior, 21.4 Gender Identity, Gender Diversity, Gender Dysphoria/Incongruence

Christine C. Call, Ph.D. Postdoctoral Fellow, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
22 Feeding and Eating Disorders

Katherine Camfield, M.D., M.P.H. Attending Physician, Psychiatric Emergency Services, Department of Behavioral Health, Denver Health Medical Center, Denver, Colorado
31.3 Other Psychiatric Emergencies

Laura M. Campbell, M.S. Predoctoral Fellow, Department of Psychiatry, San Diego State University/University of California, School of Medicine, Joint Doctoral Program in Clinical Psychology, San Diego, California
55.6g HIV and Aging

Glorisa Canino, Ph.D. Professor, Director Behavioral Sciences Research Institute, Department of Academic Affairs, University of Puerto Rico, School of Medicine, San Juan, Puerto Rico
56.7 A Sociocultural Framework for Mental Health and Substance Abuse Service Inequities

Jason P. Caplan, M.D. Professor of Psychiatry, Department of Psychiatry, St. Joseph's Hospital and Medical Center, Phoenix, Arizona/Creighton University School of Medicine, Omaha, Nebraska
27.12 Psychocutaneous Disorder

Vladimir Carli, M.D., Ph.D. Associate Professor of Psychiatry, National Centre for Suicide Research and Prevention of Mental Ill-Health (NASP), Karolinska Institute, Stockholm, Sweden
31.1 Suicide: Overview of Epidemiology, Risk and Protective Factors, Treatment, and Prevention

Gabrielle A. Carlson, M.D. Professor of Psychiatry and Pediatrics, Department of Psychiatry and Behavioral Health, Stony Brook University, Renaissance School of Medicine, Stony Brook, New York
50.2 Early-Onset Bipolar Disorder

Edward Castelo, M.D. Fellow Physician, Department of Child and Adolescent Psychiatry, Jane and Terry Semel Institute for

Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
54.8 School Consultation and Collaborating With the Educational System

Joseph M. Cerimele, M.D., M.P.H. Associate Professor, Department of Psychiatry and Behavioral Sciences, UW Medicine/University of Washington School of Medicine, Seattle, Washington
14.2 Clinical Features of the Anxiety Disorders

Aldrich Chan, Psy.D. Adjunct Professor Course Lead, Neuropsychologist, Graduate School of Education and Psychology, Pepperdine University, Los Angeles, California
3.1 Contributions of the Psychological Sciences: Sensation, Perception, and Cognition

Ganesh B. Chand, Ph.D. Assistant Professor of Radiology, Department of Radiology, Washington University in St. Louis, School of Medicine, St. Louis, Missouri
12.9 Molecular Brain Imaging in Schizophrenia

Tara Chandrasekhar, M.D. Assistant Professor of Psychiatry and Behavioral Sciences, Division of Child & Family Mental Health & Community Psychiatry, Duke Health/Duke University School of Medicine, Durham, North Carolina
52 Early-Onset Psychotic Disorders

Serena Chang, M.D., B.A. Director of Psychiatry, Department of Behavioral Health, Callen-Lorde Community Health Center, New York, New York
54.16 Gay, Bisexual, Transgender, Queer/Questioning, Intersex, and Asexual (LGBTQIA) Youth

Moses V. Chao, Ph.D. Professor, Departments of Cell Biology, Neuroscience and Physiology, and Psychiatry, New York University Grossman School of Medicine, New York, New York

1.10 Neurotrophic Factors

Dennis S. Charney, M.D. Dean, Office of the Dean, Icahn School of Medicine at Mount Sinai/Mount Sinai Health System, New York, New York
14.4 Anxiety Disorders: Neurobiology and Neuroscience

Irene Chatoor, M.D. Professor of Psychiatry and Pediatrics, Department of Psychiatry and Behavioral Sciences, Children's National Medical Center and George Washington University, School of Medicine and Health Sciences, Washington, DC
46 Feeding and Eating Disorders of Infancy and Early Childhood

Stephen T. Chen, M.D. Health Sciences Clinical Professor, Department of Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
55.3f Alzheimer Disease and Other Neurocognitive Disorders

Sneha Chenji, Ph.D. Postdoctoral Research Associate, Psychiatry, Cumming School of Medicine, University of Calgary, Calgary, Alberta, Canada
37 Neuroimaging in Psychiatric Disorders of Childhood

Lois Choi-Kaisn, M.D., M.Ed. Director, Gunderson Personality Disorders Institute, Division of Women's Mental Health, McLean Hospital, Belmont, Massachusetts
32.7 Treatment of Borderline Personality Disorder

Paul Ciechanowski, M.D., M.P.H. Clinical Associate Professor, Department of Psychiatry and Behavioral Sciences, University of Washington, School of Medicine, Seattle, Washington
27.6 Diabetes: Psychosocial Issues and Psychiatric Disorders

Angel Cienfuegos, M.D. Associate Clinical Professor, Department of Psychiatry and Biobehavioral Sciences, Los Angeles County

Department of Mental Health, University of California, David Geffen School of Medicine, Los Angeles, California
56.5 The Psychiatric Hospitalist

Chiara Cirelli, M.D., Ph.D. Professor, Department of Psychiatry, University of Wisconsin, School of Medicine and Public Health, Madison, Wisconsin
1.15 Basic Science of Sleep

Michael R. Clark, M.D., M.P.H., M.B.A. Associate Professor, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland
27.15 Management of Chronic Pain

Diana E. Clarke, Ph.D., M.Sc. Director of Research and Senior Epidemiologist/Research Statistician, Division of Research, American Psychiatric Association, Washington, DC
5.1 Quantitative and Experimental Methods in Psychiatry: Epidemiology

Anita H. Clayton, M.D. Wilford W. Spradlin Professor and Chair, Department of Psychiatry and Neurobehavioral Sciences, University of Virginia School of Medicine, Charlottesville, Virginia
33.17c Pharmacologic Treatment of Sexual Dysfunction

Brett Clementz, Ph.D. Distinguished Research Professor, Departments of Psychology and Neuroscience, University of Georgia, Athens, Georgia
12.11 Phenotypes of Psychosis

C. Robert Cloninger, M.D., Ph.D. Professor Emeritus of Psychiatry, Department of Psychiatry, Washington University in St. Louis, School of Medicine, St. Louis, Missouri
26 Personality Disorders

Robert T. Cobb, M.D. Associate Professor of Clinical Psychiatry, Department of Psychiatry and Behavioral Science, University of Southern California, Keck School of Medicine, Los Angeles, California
31.3 Other Psychiatric Emergencies

Barbara J. Coffey, M.D., M.S. Professor and Chairman, Department of Psychiatry and Behavioral Sciences, University of Miami Leonard M. Miller School of Medicine, Miami, Florida
47 Tic Disorders

Carl I. Cohen, M.D. State University of New York, Distinguished Service Professor, Division of Geriatric Psychiatry and Center of Excellence for Alzheimer's Disease, State University of New York, Downstate Health Sciences University, College of Medicine, Brooklyn, New York
55.3h Schizophrenia and Other Psychotic Disorders

Judith A. Cohen, M.D. Professor of Psychiatry, Psychiatry and Behavioral Health Institute, Allegheny Health Network, Drexel University College of Medicine, Pittsburgh, Pennsylvania
51.2 Posttraumatic Stress Disorder in Children and Adolescents

Emily M. Cohodes, M.S., M.Phil. Ph.D. Candidate in Clinical Psychology, Department of Psychology, Yale University, School of Medicine, New Haven, Connecticut
14.5 Neuroimaging and the Neuroanatomical Circuits Implicated in Anxiety Disorders

John N. Constantino, M.D. Liz and Frank Blake Chair for Children's Behavioral and Mental Health; Chief, Center for Behavioral and Mental Health, Children's Healthcare of Atlanta; Vice Chair, Department of Pediatrics; Professor of Psychiatry and Behavioral Sciences, Emory University School of Medicine; Adjunct Clinic Professor of Psychiatry and Behavioral Sciences, Morehouse College, School of Medicine, Atlanta, Georgia

1.3 Functional Genomics of Human Brain Development

Jana R. Cooke, M.D. Clinical Assistant Professor, Pulmonary Disease/Adult and Pediatric Sleep Medicine, Department of Medicine, Washington State University, Elson S. Floyd School of Medicine, Spokane, Washington; The Everett Clinic, Part of Optum Care, Everett, Washington
55.3c Sleep Disorders in Older Adults

Rena Cooper-Kazaz, M.D. Senior Lecturer (Clinical), Department of Psychiatry, Clalit Health Services, Tel Aviv Brull Community Mental Health Center (Ramat Chen), Affiliated With Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel
33.15b Thyroid Hormones

Amy R. Corcoran, M.D. Assistant Professor of Psychiatry and Neurology, Department of Psychiatry and Behavioral Sciences, The Ken & Ruth Davee Department of Neurology, Northwestern University, Feinberg School of Medicine, Chicago, Illinois
2.5 Neuropsychiatric Consequences of Traumatic Brain Injury

Philip R. Corlett, Ph.D. Associate Professor, Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut
1.30 Learning Theory and Psychosis, Anxiety, and Addiction

Ann Elizabeth Cornell, Psy.D., C.E.A.P. Associate Professor of Psychiatry, Division of Collaborative Care and Wellness, University of Rochester, School of Medicine and Dentistry/Medical Center, Rochester, New York
55.4j Family Intervention and Therapy With Older Adults

Christoph U. Correll, M.D. Professor of Psychiatry and Molecular Medicine, Department of Psychiatry and Molecular Medicine; Professor of Child and Adolescent Psychiatry, Department of Child and Adolescent Psychiatry; Hofstra University/Northwell Health,

Donald and Barbara Zucker School of Medicine, Hempstead, New York; Charité—Universitätsmedizin Berlin, Berlin, Germany
12.12 Schizophrenia: Pharmacologic Treatment

Paul T. Costa, Jr., Ph.D. Adjunct Professor, Department of Geriatrics, Duke University School of Medicine, Durham, North Carolina
6.4 Approaches Derived from Philosophy and Psychology

Sara Costi, M.D. Clinical Instructor, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, New York; Wellcome Trust Doctoral Fellow, Department of Psychiatry, University of Oxford; Honorary Consultant, Oxford Health NHS Foundation Trust, Oxford, United Kingdom
14.4 Anxiety Disorders: Neurobiology and Neuroscience

Joseph T. Coyle, M.D. Eben S. Draper Professor of Psychiatry and Neuroscience (Emeritus), Department of Psychiatry, McLean Hospital, Belmont, Massachusetts/Harvard University, Harvard Medical School, Boston, Massachusetts
1.6 Amino Acid Neurotransmitters

Louis J. Cozolino, Ph.D. Professor of Psychology, Graduate School of Education and Psychology, Pepperdine University, Los Angeles, California
3.1 Contributions of the Psychological Sciences: Sensation, Perception, and Cognition

Justin F. Creeden, Ph.D. Graduate Research Assistant, Department of Neurosciences, University of Toledo, College of Medicine and Life Sciences, Toledo, Ohio
12.6 Cellular and Molecular Neuropathology of Schizophrenia

Adam Critchfield, M.D. Assistant Clinical Professor of Psychiatry, Department of Psychiatry, Columbia University, Vagelos College of

Physicians and Surgeons/Irving Medical Center, New York, New York
32.3 Psychoanalysis and Psychoanalytic Psychotherapy

Elizabeth A. Crocco, M.D. Medical Director, UM Memory Disorders Clinic, Center for Cognitive Neuroscience and Aging; Professor and Chief, Division of Geriatric Psychiatry, Department of Psychiatry and Behavioral Sciences, University of Miami Leonard M. Miller School of Medicine; Geriatric Psychiatry Training Director, Jackson Memorial Hospital, Miami, Florida
33.11b Cholinesterase Inhibitors and Memantine

Catherine Chang Crone, M.D. Director of Education, Department of Behavioral Health, Inova Health System, Falls Church, Virginia
27.13 Organ Transplantation

Ari B. Cuperfain, M.D., M.Sc. Psychiatry Resident, Department of Psychiatry, Temerty Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada
33.18b Biologic Therapies: Geriatric Psychopharmacology

Kim-Lan Tran Czelusta, M.D. Associate Professor of Psychiatry, Menninger Department of Psychiatry and Behavioral Sciences, Baylor University, College of Medicine, Houston, Texas
57.2 Examining Professional Patients

Rodolfo Furlan Damiano, M.D., Ph.D. Collaborator Professor, Department of Psychiatry, Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil
33.19d Biologic Therapies in Latin America

Smita Das, M.D., Ph.D., M.P.H. Clinical Associate Professor, Psychiatry and Behavioral Sciences, Stanford University, School of Medicine, Palo Alto, California
11.8 Tobacco-Related Disorders

Shruti Dave, Ph.D. Postdoctoral Fellow, Department of Medical Social Sciences, Northwestern University, Feinberg School of Medicine, Chicago, Illinois
3.4 Biology of Memory

Jennie Davidow, M.D. Instructor in Psychiatry and Staff Psychiatrist, Department of Psychiatry, Beth Israel Deaconess Medical Center/Harvard University, Harvard Medical School, Boston, Massachusetts
55.3e Geriatric Mood Disorders

Cameron J. Davidson, Ph.D. Postdoctoral Fellow, Psychology/Behavioral, Cognitive Neuroscience, Wayne State University, School of Medicine/College of Liberal Arts and Sciences, Detroit, Michigan
11.7 Inhalant-Related Disorders

Keith A. Davidson, J.D. Managing Partner, Albertson & Davidson, LLP, San Diego, California
55.6b Forensic Aspects

Dimitry S. Davydow, M.D., M.P.H., F.A.C.L.P. Psychiatrist and Chief Medical Officer, Comprehensive Life Resources, Tacoma, Washington
27.11 Psychiatric Morbidity Following Critical Illness

Mark DeAntonio, M.D. Professor of Clinical Psychiatry, Department of Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, California
54.4 Psychiatric Sequel of HIV and AIDS

Charles DeBattista, D.M.H., M.D. Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry, Stanford University, School of Medicine, Palo Alto, California

33.5a.4 Dopamine-Noradrenaline Reuptake Inhibitors (Bupropion), 33.16 Combination Pharmacotherapy

Lauren N. DeCaporale-Ryan, Ph.D. Associate Professor and Clinical Psychologist, Department of Psychiatry, Medicine, and Surgery, University of Rochester, School of Medicine and Dentistry/Medical Center, Rochester, New York
55.4j Family Intervention and Therapy With Older Adults

Elizabeth A. Deckler, M.D. Resident Physician, Psychiatry and Behavioral Sciences, University of Miami, Leonard M. Miller School of Medicine/Jackson Memorial Hospital, Miami, Florida
47 Tic Disorders

Louisa Degenhardt, Ph.D. Scientia Professor and Deputy Director, National Drug and Alcohol Research Centre, University of New South Wales, Sydney, New South Wales, Australia
11.5 Cannabis-Related Disorders

Andrea Delgado-Peraza, M.D. Attending Physician, Geriatric Psychiatrist, Department of Psychiatry, VA Caribbean Healthcare System, San Juan/Ponce Health Sciences University, School of Medicine, Ponce, Puerto Rico
55.2a Psychiatric Assessment of the Older Patient

Colin A. Depp, Ph.D. Professor, Department of Psychiatry, University of California, School of Medicine, San Diego, California
55.6h Technology for Seniors

Migena Dervishi, M.D. Research Fellow, Department of Psychiatry and Behavioral Sciences, Albert Einstein College of Medicine, New York, New York
33.8a α_2-Adrenergic Receptor Agonists: Clonidine, Clonidine Extended Release, Guanfacine, and Guanfacine Extended Release, 33.8b β-Adrenergic Receptor Antagonists

Abhilash K. Desai, M.D. Adjunct Associate Professor, Psychiatry and Behavioral Sciences, University of Washington, School of Medicine, Seattle, Washington
55.6a Psychiatric Aspects of Long-Term Care

Charles Desfossés, M.D. Clinical Professor of Psychiatry, Department of Psychiatry and Neuroscience, Institut universitaire en santé mentale de Québec/Université Laval, Québec City, Québec, Canada
33.5c Vilazodone and Vortioxetine

Davangere P. Devanand, M.D. Professor of Psychiatry and Neurology, Area Brain Aging and Mental Health, Department of Psychiatry, New York State Psychiatric Institute and Columbia University, Vagelos College of Physicians and Surgeons/Irving Medical Center, New York, New York
55.2a Psychiatric Assessment of the Older Patient

Emanuel DiCicco-Bloom, M.D. Professor of Neuroscience and Cell Biology/Pediatrics, Department of Neuroscience and Cell Biology/Pediatrics, Division of Child Neurology and Neurodevelopmental Disabilities, Rutgers University, Robert Wood Johnson Medical School, Piscataway, New Jersey
1.4 Neural Development and Neurogenesis

Andrea Frances DiMartini, M.D. Professor of Psychiatry and Surgery, Department of Psychiatry, University of Pittsburgh Medical Center/University of Pittsburgh, School of Medicine, Pittsburgh, Pennsylvania
27.13 Organ Transplantation

Joel E. Dimsdale, M.D. Distinguished Professor Emeritus, Department of Psychiatry, University of California, School of Medicine, San Diego, California
18 Somatic Symptom and Related Disorders

Lisa B. Dixon, M.D., M.P.H. Edna L. Edison Professor of Psychiatry, Department of Psychiatry, Division of Behavioral Health Services and Policy Research, New York State Psychiatric Institute/Columbia University Vagelos College of Physicians and Surgeons, New York, New York

56.4 Mental Health Services Research

Robert Lloyd Doyle, M.A., D.D.S., M.D. Assistant Medical Director, Department of Child and Adolescent Inpatient Unit, McLean Hospital, Brighton, Massachusetts

49.2 Stereotypic Movement Disorders in Children

Robert E. Drake, M.D., Ph.D. Professor of Clinical Psychiatry, Columbia University, Vagelos College of Physicians and Surgeons, New York, New York

12.13 Psychiatric Rehabilitation

Jack Drescher, M.D. Clinical Professor, Department of Psychiatry, Columbia University, Vagelos College of Physicians and Surgeons, New York, New York

21.2 Homosexuality, Gay and Lesbian Identities, and Homosexual Behavior, 21.4 Gender Identity, Gender Diversity, Gender Dysphoria/Incongruence

Steven L. Dubovsky, M.D. Professor and Chair, Department of Psychiatry, University at Buffalo, Jacobs School of Medicine and Biomedical Sciences, Buffalo, New York

33.9a Barbiturates and Similarly Acting Substances, 33.9b Benzodiazepine Receptor Agonists and Antagonists, 33.10a Calcium Channel Inhibitors

Jennifer J. Dunkin, Ph.D. Clinical Professor (Voluntary), Department of Psychiatry and Biobehavioral Sciences, University of California, School of Medicine, San Diego, California

55.2d Psychological Changes With Normal Aging

Walter Dunn, M.D., Ph.D. Assistant Clinical Professor, Department of Psychiatry, University of California, David Geffen School of Medicine, Los Angeles, California
33.2b Dopamine-Serotonin Antagonists, 33.3a Dopamine Partial Agonists

Dino Dvorak, Ph.D. Postdoctoral Fellow; Senior Director, Data Science and Platform Technologies, Center for Neural Science, New York University, Grossman School of Medicine; Gilgamesh Pharmaceuticals Inc., New York, New York
1.23 Basic Systems Neuroscience

Zabrina Ebert, D.O. Chief Resident, Department of Psychiatry and Behavioral Medicine, Medical College of Wisconsin Affiliated Hospitals, Milwaukee, Wisconsin
32.17 Acceptance and Commitment Therapy

Helen Link Egger, M.D. Chief Medical Officer, Little Otter Health; Adjunct Associate Professor at Duke University, School of Medicine/Duke University Medical Center, Department of Psychiatry and Behavioral Sciences, Durham, North Carolina
35.2 Psychiatric Assessment of Preschool Children

Stuart J. Eisendrath, M.D. Professor of Psychiatry Emeritus, Department of Psychiatry, University of California, School of Medicine, San Francisco, California
19 Factitious Disorder

John D. Elsworth, Ph.D. Senior Research Scientist, Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut
1.7 Biogenic Amine Neurotransmitters

Steven A. Epstein, M.D. Physician Executive Director/Professor, Department of Psychiatry, MedStar Health/Georgetown University School of Medicine, Washington, DC

27.1 History and Current Trends

David Erritzoe, M.D., Ph.D., M.R.C.Psych. Clinical Senior Lecturer and Consultant Psychiatrist, Centres for Neuropsychopharmacology and Psychedelic Research, Department of Brain Sciences, Division of Psychiatry, Imperial College London, London, United Kingdom
33.14b MDMA, Psilocybin, Ayahuasca, and Ibogaine

Rodrigo Escalona, M.D. Professor and Attending Psychiatrist, Department of Psychiatry and Behavioral Sciences, University of New Mexico School of Medicine and New Mexico VA Health Care System, Albuquerque, New Mexico
12.2 Phenomenology of Schizophrenia

Javier I. Escobar, M.D., M.Sc. Professor Emeritus, Departments of Psychiatry and Family Medicine, Rutgers University, Robert Wood Johnson Medical School, Piscataway, New Jersey; Professor, Departments of Psychiatry and Health Humanities and Society, Florida International University, Herbert Wertheim College of Medicine, Miami, Florida; Associate Dean for Global Health, Office of Global Health, Rutgers University, Robert Wood Johnson Medical School, Piscataway, New Jersey
9.1 Present and Future of Classification Systems for Mental Disorders, 9.2 The Classification of Mental Disorders in the International Classification of Diseases (ICD-11), 18 Somatic Symptom and Related Disorders

Zelde Espinel, M.D., M.P.H. Assistant Professor of Psychiatry, Psychiatry and Behavioral Sciences, University of Miami Leonard M. Miller School of Medicine, Miami, Florida
33.11b Cholinesterase Inhibitors and Memantine

Spencer Eth, M.D. Professor and Chief of Mental Health, Miami VA Medical Center, University of Miami Leonard M. Miller School of Medicine, Miami, Florida
58.1 Clinical-Legal Issues in Psychiatry

Harris A. Eyre, M.B.B.S., Ph.D. Fellow in Brain Health, Center for Health and Bioscience, Baker Institute for Public Policy, Rice University, Houston, Texas
55.2b Complementary and Integrative Geriatric Psychiatry

Tanya Fabian, Pharm.D., Ph.D. Associate Professor and Director of Pharmacy, Department of Pharmacy and Therapeutics and Psychiatry, University of Pittsburgh, School of Medicine and University of Pittsburgh Medical Center Western Psychiatric Hospital, Pittsburgh, Pennsylvania
10.2 Delirium

Nathan Fairman, M.D., M.P.H. Associate Health Sciences Clinical Professor, Department of Psychiatry and Behavioral Sciences, University of California-Davis School of Medicine, Sacramento, California
55.6c Ethical Issues

Scott C. Fears, M.D., Ph.D. Professor of Clinical Health Sciences, Department of Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
1.19 Gene Mapping Investigations of Psychiatric Disorders

Adriana Feder, M.D. Professor, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, New York
14.4 Anxiety Disorders: Neurobiology and Neuroscience

Michael Feldmeier, M.D. Psychiatrist, Department of Psychiatry, University of California, David Geffen School of Medicine, Los Angeles, California
54.14 Internet Gaming Disorder in Youth, 54.15 Social Media and Youth

André A. Fenton, Ph.D. Professor of Neural Science, Center for Neural Science, New York University, Grossman School of

Medicine/Faculty of Arts and Science, New York, New York
1.23 Basic Systems Neuroscience

Francisco Fernandez, M.D. Founding Dean, Professor Emeritus, Department of Psychiatry, University of Texas Rio Grande Valley, School of Medicine, Harlingen, Texas
2.10 Neuropsychiatric Aspects of Prion Disease

Prudence W. Fisher, Ph.D. Associate Professor of Clinical Psychiatric Social Work (in Psychiatry)/Research Scientist, Department of Psychiatry/Child & Adolescent Psychiatry, Columbia University, Vagelos College of Physicians & Surgeons/New York State Psychiatric Institute, New York, New York
35.1 Psychiatric Examination of the Infant, Child, and Adolescent

Alastair J. Flint, M.B. Professor of Psychiatry, Department of Psychiatry, University Health Network/University of Toronto, Toronto, Ontario, Canada
55.4c Antianxiety Drugs

Edna B. Foa, Ph.D. Professor, Department of Psychiatry, Perelman School of Medicine, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine, Philadelphia, Pennsylvania
14.6 Anxiety Disorders: Cognitive-Behavioral Therapy

Laura J. Fochtmann, M.D., M.B.I. State University of New York, Distinguished Service Professor, Department of Psychiatry, Pharmacological Sciences, and Biomedical Informatics, Stony Brook University, Renaissance School of Medicine, Stony Brook, New York
7.3 Practice Guidelines in Psychiatry, 12.17 Other Psychotic Disorders

Peter Fonagy, O.B.E., F.Med.Sci., F.B.A., F.Ac.S.S. Professor of Psychoanalysis and Developmental Science, Division of Psychology and Language Sciences, University College London, London, United Kingdom

32.14 Mentalization-Based Treatment

Brent P. Forester, M.D., M.Sc. Chief, Division of Geriatric Psychiatry, McLean Hospital; Senior Medical Director, Value-Based Care Solutions, Population Health Management, Mass General Brigham; Associate Professor of Psychiatry, Harvard University, Harvard Medical School, Boston, Massachusetts
55.3e Geriatric Mood Disorders

Kathryn Forneris, D.O., M.P.H. Resident Physician, Department of Psychiatry, Huntsman Mental Health Institute/ University of Utah, Spencer Fox Eccles School of Medicine, Salt Lake City, Utah
54.12 Impact on Parents of Raising a Child with Psychiatric Illness and/or Developmental Disability

Bradley Freeman, M.D. Associate Professor of Clinical Psychiatry, Department of Psychiatry and Behavioral Sciences, Vanderbilt University, School of Medicine/Medical Center, Nashville, Tennessee
54.2 Child Maltreatment

Wanda P. Fremont, M.D. Professor of Psychiatry and Family Medicine, Department of Psychiatry, State University of New York, Upstate Medical University, Alan and Marlene Norton College of Medicine, Syracuse, New York
54.11 Impact of Terrorism and School Shootings on Children

Paul Frewen, Ph.D., C.Psych. Associate Professor, Department of Psychiatry, Psychology, and Neuroscience, Western University, Canada, London, Ontario, Canada
20 Dissociative Disorders

Paul J. Frick, Ph.D. Professor, Department of Psychology, Louisiana State University, Baton Rouge, Louisiana
45 Disruptive Behavior Disorders in Children and Adolescents

Mark A. Frye, M.D. Psychiatrist, Mayo Clinic, Alix School of Medicine, Rochester, Minnesota
33.10c Carbamazepine, 33.10e Valproate

Kenneth Fung, M.D., F.R.C.P.C., M.Sc. Professor and Director of Global Mental Health, Department of Psychiatry, Toronto Western Hospital, University Health Network/University of Toronto, Toronto, Ontario, Canada
4.2 Transcultural Psychiatry

Margo C. Funk, M.D., M.A., F.A.C.L.P. Vice Chair for Education, Residency Program Director, Director of Cardiovascular Psychiatry, Department of Psychiatry, Brigham and Women's Hospital, Boston, Massachusetts
27.2 Cardiovascular Disorders

Owen Gaasedelen, Ph.D. Neuropsychologist, Independent Practice, Albuquerque, New Mexico
7.4 Neuropsychological Assessment of Adults

Isaac Galatzer-Levy, Ph.D. Research Assistant Professor, Department of Psychiatry, New York University, Grossman School of Medicine, New York, New York
5.2 Statistics and Experimental Design

Martha C. Gamboa, M.D. Assistant Professor of Psychiatry and Behavioral Sciences Department of Psychiatry, New York Medical College/Westchester Medical Center, Valhalla, New York
27.14 Psychiatric Care of the Burned Patient

Michael D. Garrett, M.D. Professor Emeritus of Clinical Psychiatry, Division of Psychiatry, State University of New York, Downstate Health Sciences University, College of Medicine/Medical Center, Brooklyn, New York
32.6 Individual Psychodynamic Psychotherapy and Cognitive-Behavioral Therapy for Psychosis

Robert Garrett, M.D. Adjunct Assistant Professor in Psychiatry, Department of Psychiatry, University of Texas Southwestern Medical School, Dallas, Texas
55.4f Electroconvulsive Therapy and Neurostimulation Treatments

Christina Kitt Garza, M.D. Assistant Professor of Psychiatry, Department of Psychiatry, Columbia University Irving Medical Center/Columbia University Vagelos College of Physicians and Surgeons, New York, New York
32.3 Psychoanalysis and Psychoanalytic Psychotherapy

Jennifer R. Gatchel, M.D., Ph.D. Assistant Professor of Psychiatry, Harvard University, Harvard Medical School, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts
55.3e Geriatric Mood Disorders

Nori Geary, Ph.D. Professor (Retired), Department of Psychiatry, Weill Cornell Medical College, New York, New York
1.17 Basic Science of Appetite

Marie Anne Gebara, M.D. Assistant Professor of Psychiatry, Department of Psychiatry, University of Pittsburgh Medical Center/University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
10.2 Delirium

Dylan G. Gee, Ph.D. Associate Professor, Departments of Psychology and Psychiatry, Yale University, School of Medicine, New Haven, Connecticut
14.5 Neuroimaging and the Neuroanatomical Circuits Implicated in Anxiety Disorders

Cynthia Geppert, M.D., Ph.D., D.P.S., M.A., M.P.H., M.S.B., M.S.J., F.A.C.L.P., D.F.A.P.A., F.A.S.A.M., H.E.C-C. Senior Ethicist and Director of Ethics Education, VA National Center for Ethics in Health Care; Professor, Departments of Psychiatry and Internal Medicine;

Director of Ethics Education, University of New Mexico School of Medicine; Adjunct Professor of Bioethics, Alden March Bioethics Institute, Albany, New York
25 Adjustment Disorders

Ruth S. Gerson, M.D. Clinical Associate Professor, Department of Child and Adolescent Psychiatry, New York University Grossman School of Medicine, New York, New York
35.4 Psychiatric Emergencies in Children and Adolescents

Omar Ghosn, M.D. Assistant Clinical Professor of Psychiatry, Division of Geriatric Psychiatry, University of California, School of Medicine, San Diego, California
55.3j Alcohol and Substance Abuse in Older Adults

Scott Giacomucci, D.S.W., L.C.S.W., B.C.D., C.G.P., F.A.A.E.T.S., T.E.P. Director, Founder, and Owner; Research Associate and Adjunct Professor, Phoenix Center for Experiential Trauma Therapy, Bryn Mawr College Graduate School of Social Work and Social Research, Philadelphia. Pennsylvania
32.22 Psychodrama, Sociodrama, Sociometry, and Sociatry

Tresha A. Gibbs, M.D. Assistant Clinical Professor of Child and Adolescent Psychiatry, Department of Psychiatry, New York University Grossman School of Medicine, New York, New York
34.2 Child Development

Walter S. Gilliam, Ph.D. Executive Director and Richard D. Holland Presidential Chair in Early Childhood Development, Buffet Early Childhood Institute, University of Nebraska, Omaha, Nebraska
35.1 Psychiatric Examination of the Infant, Child, and Adolescent

Brian Giunta, M.D., Ph.D. Associate Professor, Department of Psychiatry and Behavioral Neurosciences, University of South Florida, Morsani School of Medicine, Tampa, Florida
2.10 Neuropsychiatric Aspects of Prion Disease

Albert Gjedde, M.D., D.Sc. Emeritus Professor of Neurobiology and Pharmacology, Department of Neuroscience, University of Copenhagen, Copenhagen, Denmark
12.9 Molecular Brain Imaging in Schizophrenia

Stephen J. Glatt, Ph.D. Professor, Department of Psychiatry and Behavioral Sciences; Professor, Department of Neuroscience and Physiology; Professor, Department of Public Health and Preventive Medicine; Director, Psychiatric Genetic Epidemiology & Neurobiology Laboratory (PsychGENe Lab), State University of New York, Upstate Medical University, Alan and Marlene Norton College of Medicine, Syracuse, New York
55.2f Genetics of Late-Life Neurodegenerative Disorders

Mary Margaret Gleason, M.D. Kay W. Abiouness Professor of Pediatric Psychiatry, Department of Pediatrics, Eastern Virginia Medical School/Children's Hospital of The King's Daughters, Norfolk, Virginia
49.1 Reactive Attachment Disorder and Disinhibited Social Engagement Disorder

Sam Gnanapragasam, B.Sc., M.B.B.S., M.R.C.Psych. NIHR Academic Clinical Fellow in Psychiatry, Mental Health & Psychological Sciences, King's College London, London, United Kingdom
60 World Aspects of Psychiatry

Irene Gonsalvez, M.D. Associate Psychiatrist, Department of Psychiatry, Brigham and Women's Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
2.9 Neuropsychiatric Aspects of Other Infectious Diseases (Non-HIV) Araceli Gonzalez, Ph.D. Associate Professor, Department of Psychology, California State University, Long Beach, Long Beach, California

51.4 Selective Mutism

Sylvia Gonzalez Cruz, M.D. Psychiatrist, Psychotherapist, Adjunct Faculty, Center for Psychoanalytic Studies, Houston, Texas
6.1 Psychoanalytic Theories and Treatment: Perspective from North America and Great Britain

Jessica Goodman, Ph.D. Senior Instructor, Department of Psychiatry, University of Rochester, School of Medicine and Dentistry, Rochester, New York
55.4j Family Intervention and Therapy With Older Adults

Hilary Gould, Ph.D. Assistant Clinical Professor, Department of Psychiatry, University of California, School of Medicine, San Diego, California
55.3j Alcohol and Substance Abuse in Older Adults, 55.5 Financial Issues in the Delivery of Geriatric Psychiatric Care

Eric Granholm, Ph.D. Professor of Psychiatry, Department of Psychiatry, University of California, School of Medicine, San Diego, California
55.4i Cognitive-Behavioral Therapy

John A. Gray, M.D., Ph.D. Associate Professor of Neurology, Center for Neuroscience, University of California-Davis, School of Medicine, Sacramento, California
1.11 Intraneuronal Signaling

Julie Graziane, M.D. Assistant Professor, Department of Psychiatry and Behavioral Health, Pennsylvania Psychiatric Institute/Penn State University, College of Medicine, Hershey, Pennsylvania
10.3 Major Neurocognitive Disorders (Dementia)

Benjamin D. Greenberg, M.D., Ph.D. Professor, Department of Psychiatry and Human Behavior, Butler Hospital/VA Providence Healthcare System/Brown University, Warren Alpert Medical School, Providence, Rhode Island
33.20c Neurosurgical Treatments

Harvey Roy Greenberg, M.D. Clinical Professor of Psychiatry, Albert Einstein College of Medicine at Yeshiva University, Bronx, New York.
16 Pathological and Problem Gambling: Gambling Disorder

Mindy Greenstein, Ph.D. Director, Psychological Consultation, MaxFint, Inc., New York, New York
27.9 End-of-Life and Palliative Care

Paul Richard Greenwood, L.L.B. (Hons.) Deputy District Attorney San Diego (Retired); CEO, Greenwood Law Corp, San Diego, California
55.6e The Legal and Ethical Analysis of Older Adult Abuse

George T. Grossberg, M.D. Professor and Director, Department of Psychiatry and Behavioral Neuroscience, Division of Geriatric Psychiatry, Saint Louis University, School of Medicine, St. Louis, Missouri
55.6a Psychiatric Aspects of Long-Term Care

Sandeep Grover, M.B.B.S., M.D. Professor of Psychiatry, Department of Psychiatry, Post Graduate Institute of Medical Education and Research, Chandigarh, Chandigarh, India
33.19c Biologic Therapies in India

Gerhard Gründer, M.D. Professor of Psychiatry, Department for Molecular Neuroimaging, Central Institute of Mental Health, Mannheim, Germany
12.9 Molecular Brain Imaging in Schizophrenia

Adrienne Grzenda, M.D., Ph.D., M.S. Health Sciences Clinical Assistant Professor, Department of Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
5.1 Quantitative and Experimental Methods in Psychiatry: Epidemiology

Christina Guest, M.D. Los Angeles County and University of Southern California, Child and Adolescent Psychiatry Fellow, Division of Psychiatry and Behavioral Science, University of Southern California, Keck School of Medicine, Los Angeles, California
54.15 Social Media and Youth

Rachel Guetta, B.A. Clinical Psychology Ph.D. Candidate, Department of Psychology and Neuroscience, Duke University, School of Medicine, Durham, North Carolina
32.11 Dialectical Behavior Therapy

Rishab Gupta, M.B.B.S., M.D. Associate Psychiatrist/Instructor in Psychiatry, Department of Psychiatry, Brigham & Women's Faulkner Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
2.9 Neuropsychiatric Aspects of Other Infectious Diseases (Non-HIV)

Raquel E. Gur, M.D., Ph.D. Professor, Department of Psychiatry, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine, Philadelphia, Pennsylvania
12.8 Functional Brain Imaging in Schizophrenia

Ruben C. Gur, Ph.D. Professor, Psychiatry, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine, Philadelphia, Pennsylvania
12.8 Functional Brain Imaging in Schizophrenia

Oye Gureje, Ph.D., D.Sc., F.R.C.Psych., F.W.A.C.P. Professor of Psychiatry, WHO Collaborating Centre for Research and Training in Mental Health, Neuroscience and Substance Abuse, Department of Psychiatry, College of Medicine, University of Ibadan, Ibadan, Nigeria
33.19b Biologic Therapies in Africa

Debra A. Gusnard, M.D. Retired, Department of Radiology and Psychiatry, Washington University in St. Louis, School of Medicine, St. Louis, Missouri
1.29 Neuropsychiatry of Self

Robert W. Guynn, M.D. Professor Emeritus, Department of Psychiatry and Behavioral Sciences, University of Texas Health Science Center, McGovern Medical School, Houston, Texas
32.10 Interpersonal Psychotherapy

Kathleen Y. Haaland, Ph.D., A.B.P.P.-C.N. Professor, Department of Psychiatry and Behavioral Sciences, University of New Mexico, School of Medicine/Health Sciences Center, Albuquerque, New Mexico
7.4 Neuropsychological Assessment of Adults

Habibolah Khazaie, M.D. Clinical Professor of Psychiatry, Department of Psychiatry, Division of Sleep Disorders Research Center, Farabi Hospital/Kermanshah University of Medical Sciences, Kermanshah, Iran
23 Sleep Disorders

Saria El Haddad, M.D. Instructor, Department of Psychiatry, Harvard University, Harvard Medical school, Boston, Massachusetts
33.17c Pharmacologic Treatment of Sexual Dysfunction

Danella Hafeman, M.D., Ph.D. Assistant Professor, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
50.2 Early-Onset Bipolar Disorder

Nekisa Haghighat, M.D., M.P.H. Resident Physician, Department of Psychiatry and Neuroscience, University of California, School of Medicine, Riverside, California
33.7a Pimavanserin

Wayne D. Hall, Ph.D. Emeritus Professor, The National Centre for Youth Substance Use Research, The University of Queensland, Queensland, Australia
11.5 Cannabis-Related Disorders

Michael Hann, M.D., M.B.A., M.S., C.P.E., F.A.C.H.E., F.A.P.A. Chief Medical Officer, Department of Psychiatry, Brook Lane Health Services, Hagerstown, Maryland
55.3j Alcohol and Substance Abuse in Older Adults, 55.5 Financial Issues in the Delivery of Geriatric Psychiatric Care

Helena B. Hansen, M.D., Ph.D. Professor of Psychiatry, Department of Psychiatry, University of California, David Geffen School of Medicine, Los Angeles, California
7.10 Cultural Competency in the Organization and Delivery of Psychiatric Care

Jessica Harder, M.D. Neuropsychiatrist, Department of Psychiatry, Brigham and Women’s Hospital, Boston, Massachusetts
2.9 Neuropsychiatric Aspects of Other Infectious Diseases (Non-HIV)

Ebrahim Haroon, M.D. Associate Professor, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia
1.13 Immune–Brain Interactions in Psychiatry

Ansar M. Haroun, M.D. (Retired) Clinical Professor of Psychiatry, and Pediatrics and Adjunct Professor of Law, Departments of Psychiatry, Pediatrics, and Law, University of California, School of Medicine and University of San Diego School of Law; Supervising Psychiatrist, Department of Forensic Psychiatry, San Diego Superior Court, San Diego, California
55.6b Forensic Aspects, 55.6e The Legal and Ethical Analysis of Older Adult Abuse

Philip D. Harvey, Ph.D. Leonard M. Miller Professor of Psychiatry and Behavioral Sciences, Department of Behavioral Sciences, University of Miami Leonard M. Miller School of Medicine, Miami, Florida
12.10 Neurocognition in Schizophrenia, 33.2a Dopamine Antagonists

Lily T. Hechtman, M.D., F.R.C.P., A.B.P.N. Professor of Psychiatry and Pediatrics, Division of Child Psychiatry, Montreal Children's Hospital, McGill University Health Center, McGill University Medical School Montreal, Quebec, Canada
44.1 Attention-Deficit/Hyperactivity Disorder

Nicholas D. Henkel, Ph.D. Graduate Research Assistant, Department of Neurosciences, University of Toledo, College of Medicine and Life Sciences, Toledo, Ohio
12.6 Cellular and Molecular Neuropathology of Schizophrenia

Robert Hindman, Ph.D. Faculty, Beck Institute, Bala Cynwyd, Pennsylvania
32.9 Cognitive Behavior Therapy

Max Hirshkowitz, Ph.D. Retired Full Professor, Department of Medicine, Baylor University, College of Medicine, Houston, Texas
23 Sleep Disorders

J. Gregory Hobelmann, M.D., M.P.H. CO-CEO, Ashley Addiction Treatment, Havre De Grace, Maryland
27.15 Management of Chronic Pain

Gil D. Hoftman, M.D., Ph.D. Assistant Professor of Psychiatry, Division of Child and Adolescent Psychiatry, Resnick Neuropsychiatric Hospital; Assistant Professor of Psychiatry and Biobehavioral Sciences, Division of Child and Adolescent Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human

Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
36 Genetics in Child Psychiatry

Eric Hollander, M.D. Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry, Albert Einstein College of Medicine, New York, New York
33.8a α_2*-Adrenergic Receptor Agonists: Clonidine, Clonidine Extended Release, Guanfacine, and Guanfacine Extended Release, 33.8b β-Adrenergic Receptor Antagonists*

Lindsay E. Holly, Ph.D. Assistant Professor, Department of Psychology, Marquette University, Milwaukee, Wisconsin
32.24 Evaluating Psychotherapy: Research Methods, Findings, and Future Directions

Paul E. Holtzheimer, M.D., M.S. Professor, Department of Psychiatry and Surgery, Dartmouth College, Geisel School of Medicine, Hanover, New Hampshire
33.5d Monoamine Oxidase Inhibitors

Vivian Hook, Ph.D. Distinguished Professor of Pharmaceutical Sciences, Pharmacology, and Neurosciences, Division of Pharmaceutical Sciences, University of California, School of Medicine, San Diego, California
55.4d Antipsychotic Drugs

Dina Hooshyar, M.D., M.P.H. Director, Veterans Health Administration National Center on Homelessness Among Veterans; Associate Professor, Department of Psychiatry, University of Texas Southwestern, Medical School, Dallas, Texas
12.15 Recovery in Schizophrenia

Rory P. Houghtalen, M.D. Clinical Professor of Psychiatry, Department of Psychiatry, University of Rochester, School of Medicine and Dentistry, Rochester, New York

7.1 Psychiatric Interview, History, and Mental Status Examination of the Adult Patient

Michael F. Hoyt, Ph.D. Independent Practice, Mill Valley, California
32.13 Single-Session Therapy

Jeffrey Hsu, M.D. Assistant Professor, Department of Psychiatry and Behavioral Sciences, The Johns Hopkins Hospital/Johns Hopkins University School of Medicine, Baltimore, Maryland
2.8 Neuropsychiatric Aspects of HIV Infection and AIDS

Jonathan D. Huppert, Ph.D. Professor of Psychology, Sam and Helen Beber Chair of Clinical Psychology, Department of Psychology, The Hebrew University of Jersualem, Jerusalem, Israel
14.6 Anxiety Disorders: Cognitive-Behavioral Therapy

Mustafa M. Husain, M.D. Professor of Psychiatry, Neurology and Bio-medical Engineering, Fellow, Peter O'Donnell Brain Institute (POBI), University of Texas Southwestern, Medical Center, Dallas, Texas; Adjunct Professor of Psychiatry and Neurology, Member, Duke Institute of Brain Sciences (DIBS), Duke University, School of Medicine, Durham, North Carolina
55.4f Electroconvulsive Therapy and Neurostimulation Treatments

Kumail Hussain, M.D. Child and Adult Psychiatrist, Clarity Clinic Arlington Heights, PLLC, Arlington Heights, Illinois
33.2c Dopamine Blockers and Neuromotor Adverse Effects

Philippe Hwang, M.B., B.Ch., B.A.O., M.Sc. Psychiatry Resident Physician, Department of Psychiatry, University of Ottawa, The Ottawa Hospital/Children's Hospital of Eastern Ontario/Royal Ottawa Mental Health Centre, Ottawa, Ontario, Canada
44.1 Attention-Deficit/Hyperactivity Disorder

Brian Iacoviello, Ph.D. Assistant Professor, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, New

York
14.4 Anxiety Disorders: Neurobiology and Neuroscience

Rocco A. Iannucci, M.D. Instructor in Psychiatry, Division of Alcohol, Drugs and Addiction, McLean Hospital/Harvard University, Harvard Medical School, Belmont, Massachusetts
11.3 Stimulant-Related Disorders

Roya Ijadi-Maghsoodi, M.D., M.S.H.P.M. Assistant Professor-in-Residence, Department of Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
54.8 School Consultation and Collaborating With the Educational System

Evan Iliakis, B.A., M.D./Ph.D. Candidate, Department of Neuroscience, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine, Philadelphia, Pennsylvania
32.7 Treatment of Borderline Personality Disorder

Ali S. Imami, M.B.B.S., M.S. Graduate Research Assistant, Department of Neurosciences, University of Toledo, College of Medicine and Life Sciences, Toledo, Ohio
12.6 Cellular and Molecular Neuropathology of Schizophrenia

Brian Isakson, Ph.D. Professor, Department of Psychiatry and Behavioral Sciences, University of New Mexico School of Medicine, Albuquerque, New Mexico
11.8 Tobacco-Related Disorders

Anna Ivanenko, M.D., Ph.D. Professor of Clinical Psychiatry and Behavioral Sciences, Division of Child and Adolescent Psychiatry, Ann and Robert H. Lurie Children’s Hospital of Chicago/Northwestern University, Feinberg School of Medicine, Chicago, Illinois
54.13 Pediatric Sleep Disorders

Elena I. Ivleva, M.D., Ph.D. Associate Professor of Psychiatry, Director of Early Psychosis Clinical and Research Program, Department of Psychiatry, University of Texas Southwestern, Medical School, Dallas, Texas
12.16 Psychosis as a Defining Dimension in Schizophrenia

Julienne Jacobson, M.D. Clinical Associate Professor of Psychiatry and Behavioral Sciences and Pediatrics, Psychiatry and the Behavioral Sciences, Children's Hospital Los Angeles/University of Southern California, Keck School of Medicine, Los Angeles, California
54.3 Children's Reaction to Illness and Hospitalization

Robert J. Jaffe, M.D. Assistant Professor, Departments of Psychiatry and Pediatrics, Icahn School of Medicine at Mount Sinai, New York, New York
34.2 Child Development

Neeta Jain, M.D. Clinical Assistant Professor of Psychiatry, Division of Psychiatry and Psychology, Mayo Clinic of Arizona/Mayo Clinic, Alix School of Medicine, Scottsdale, Arizona
30.8 Physician and Medical Student Mental Health

Jimmy E. Jakobsson, Ph.D. Postdoctoral Research Associate in Radiology, Mallinckrodt Institute of Radiology, Washington University in St. Louis, School of Medicine, St. Louis, Missouri
12.9 Molecular Brain Imaging in Schizophrenia

Philip G. Janicak, M.D. Adjunct Professor of Psychiatry, Department of Psychiatry and Behavioral Sciences, Northwestern University, Feinberg School of Medicine, Chicago, Illinois
33.2c Dopamine Blockers and Neuromotor Adverse Effects

Oluwole O. Jegede, M.D., M.P.H. Assistant Professor of Psychiatry, Division of Addiction Psychiatry, Yale University School of Medicine, New Haven, Connecticut

33.13a.2 Opioid Receptor Antagonists: Naltrexone and Nalmefene

Dilip V. Jeste, M.D. Distinguished Professor, Department of Psychiatry and Neurosciences, University of California, School of Medicine, San Diego, California
55.1 Introduction to Geriatric Psychiatry, 55.6i Positive Psychiatry of Aging

Dylan J. Jester, Ph.D., M.P.H. Biostatistician, War Related Illness and Injury Study Center (WRIISC), VA Palo Alto, Palo Alto, California
55.1 Introduction to Geriatric Psychiatry

Jason K. Johannesen, Ph.D. Assistant Professor, Adjunct, Department of Psychiatry, Yale University, School of Medicine, New Haven, Connecticut
1.26 Electroencephalography in Psychiatry

Melissa B. Jones, M.D. Assistant Professor, Menninger Department of Psychiatry and Behavioral Sciences, Baylor University, College of Medicine, Houston, Texas
2.5 Neuropsychiatric Consequences of Traumatic Brain Injury

Ricardo E. Jorge, M.D. Professor, Beth K. and Stuart C. Chair in Brain Injury Medicine, Department of Psychiatry and Behavioral Science, Baylor University, College of Medicine, Houston, Texas
2.5 Neuropsychiatric Consequences of Traumatic Brain Injury

Laura M. Juliano, Ph.D. Professor, Department of Psychology, American University, Washington, DC
11.4 Caffeine-Related Disorders

Rahil R. Jummani, M.D. Clinical Associate Professor of Child and Adolescent Psychiatry, Department of Child and Adolescent Psychiatry, Child Study Center/Hassenfeld Children's Hospital at NYU Langone/New York University, Grossman School of Medicine, New York, New York

47 Tic Disorders

Alexandra Junewicz, M.D. Clinical Assistant Professor, Department of Child and Adolescent Psychiatry, New York University, Grossman School of Medicine, New York, New York
35.4 Psychiatric Emergencies in Children and Adolescents

Arie Kaffman, M.D., Ph.D. Assistant Clinical Professor of Psychiatry, Department of Psychiatry, Newington VA/Yale University, School of Medicine, New Haven, Connecticut
1.20 Epigenetics in Psychiatry: The Promise for New Biomarkers and Treatments

Sudhir Kakar, Ph.D. President, Delhi Institute of Psychoanalysis, Delhi, India
6.2 Erik H. Erikson

Amir Kalali, M.D. Chairman, CNS Summit, San Diego, California
33.1b Drug Development and Approval Process in the United States

Gen Kanayama, M.D., Ph.D. Research Associate in Psychiatry, Department of Psychiatry, McLean Hospital/Harvard University, Harvard Medical School, Belmont, Massachusetts
11.11 Anabolic-Androgenic Steroid-Related Disorders

John M. Kane, M.D. Professor of Psychiatry and Molecular Medicine, Department of Psychiatry, Zucker Hillside Hospital, Hofstra University/Northwell Health, Donald and Barbara Zucker School of Medicine, Hempstead, New York
12.12 Schizophrenia: Pharmacologic Treatment

Tuana Kant, M.Sc. Clinical Research Analyst, Molecular Brain Science, Neurogenetics Department, Centre for Addiction and Mental Health, University of Toronto, Toronto, Ontario, Canada
42.1 Language Disorder, 42.3 Speech Sound Disorder, 42.4 Stuttering

Adam I. Kaplin, M.D., Ph.D. Adjunct Faculty, Departments of Psychiatry and Neurology, Johns Hopkins University, School of Medicine, Baltimore, Maryland
1.9 Novel Neurotransmitters

Shweta Kapoor, M.D., Ph.D. Senior Associate Consultant and Assistant Professor of Psychiatry, Department of Psychiatry and Psychology, Mayo Clinic/Mayo Clinic, Alix School of Medicine, Scottsdale, Arizona
30.7 Psychiatry and Spirituality

Helmet T. Karim, Ph.D. Assistant Professor of Psychiatry and Bioengineering, Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
55.3d Anxiety Disorders in Older Adults

Ethan F. Karsen, M.D. Staff Psychiatrist, Department of Psychiatry and Behavioral Sciences, NorthShore University Health System, Evanston, Illinois
33.5d Monoamine Oxidase Inhibitors

Mirelle Kass, B.A. Research Projects Coordinator, Center for the Developing Brain, Child Mind Institute, New York, New York
42.2 Social (Pragmatic) Communication Disorder

Sheryl Kataoka, M.D., M.S.H.S. Professor Emeritus, Department of Psychiatry, Division of Population Behavioral Health, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
54.8 School Consultation and Collaborating With the Educational System

Jeffrey W. Katzman, M.D. Professor, University of New Mexico School of Medicine, Department of Psychiatry, University of New Mexico Health Science Center, Albuquerque, New Mexico; Adjunct

Professor, Department of Psychiatry, Yale University, School of Medicine, Silver Hill Hospital, New Canaan, Connecticut
25 Adjustment Disorders

M. Sagman Kayatekin, M.D. Medical Director, Professionals Program, Menninger Department of Psychiatry and Behavioral Sciences, Baylor University, College of Medicine, The Menninger Clinic, Houston, Texas
57.2 Examining Professional Patients

David L. Kaye, M.D. Professor of Psychiatry, Department of Psychiatry, University at Buffalo, Jacobs School of Medicine and Biomedical Sciences, Buffalo, New York
53.1 Psychodynamic Psychotherapy (Child Psychiatry)

George Alan Keepers, M.D. Carruthers Professor and Chair of Psychiatry, Department of Psychiatry, Oregon Health & Science University, School of Medicine, Portland, Oregon
57.1 Graduate Psychiatric Education

Samuel J. Keith, M.D. Milton Rosenbaum Professor of Psychiatry, Emeritus, Department of Psychiatry, University of New Mexico School of Medicine, Albuquerque, New Mexico
12.2 Phenomenology of Schizophrenia

Kimberley M. Kendall, B.Sc. (Hons.), M.B.B.Ch., Ph.D., M.R.C.Psych. Wales Clinical Academic Track Psychiatrist, Centre for Neuropsychiatric Genetics and Genomics, Cardiff University, Cardiff, United Kingdom
12.4 Genetics of Schizophrenia

Alvin Keng, M.D., F.R.C.P.C. Assistant Professor, Division of Geriatric Psychiatry, Department of Psychiatry, Baycrest Centre for Geriatric Care/University of Toronto, Toronto, Ontario, Canada
55.4k Group Therapy

James L. Kennedy, M.D., F.R.C.P.C., F.R.S.C. Professor, Department of Psychiatry; Department of Molecular Sciences, Centre for Addiction and Mental Health, University of Toronto, Toronto, Ontario, Canada

42.1 Language Disorder, 42.3 Speech Sound Disorder, 42.4 Stuttering

Sidney H. Kennedy, M.D., F.R.C.P.C., F.R.C.Psych. Professor, Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada

13.6 Mood Disorders: Pharmacologic Treatment of Depression and Bipolar Disorders

Paul J. Kenny, Ph.D. Ward-Coleman Professor and Chair, Nash Family Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, New York

1.22 Animal Models in Psychiatry

Otto F. Kernberg, M.D. Emeritus Professor of Psychiatry, Weill Cornell Medical College, Westchester Division, New York/Presbyterian Hospital, White Plains, New York

3.6 Neuroscience of Psychoanalytic Object Relations Theory

Amir A. Khan, M.D. Staff Psychiatrist/Behavioral Health Lead, Department of Behavioral Health, Corporal Michael J. Crescenz Department of Veterans Affairs Medical Center, Philadelphia, Pennsylvania

33.6b Nefazodone

Ravenna Khanna, M.D. Resident Physician, Department of Dermatology, Howard University College of Medicine, Washington, DC

27.12 Psychocutaneous Disorder

Nayla M. Khoury, M.D., M.P.H. Assistant Professor/Chief of Child and Adolescent Psychiatry Outpatient Clinic, Department of

Psychiatry, State University of New York, Upstate Medical University, Alan and Marlene Norton College of Medicine, Syracuse, New York
54.11 Impact of Terrorism and School Shootings on Children

Jihye Kim, M.D. Instructor, Department of Psychiatry, Weill Cornell Medical College and New York-Presbyterian/Weill Cornell Medical Center, New York, New York
1.10 Neurotrophic Factors

Soo-Jeong Kim, M.D. Associate Professor of Psychiatry and Behavioral Sciences, Division of Child and Adolescent Psychiatry, Seattle Children's Autism Center/University of Washington, School of Medicine, Seattle, Washington
39 Intellectual Disability

Young Shin Kim, M.D., M.S., M.P.H., Ph.D. Professor, Department of Psychiatry and Behavioral Sciences, University of California, School of Medicine, San Francisco, California
42.2 Social (Pragmatic) Communication Disorder

Ryan J. Kimmel, M.D. Professor, Department of Psychiatry and Behavioral Sciences, University of Washington School of Medicine, Seattle, Washington
14.2 Clinical Features of the Anxiety Disorders

Eva R. Kimonis, Ph.D., M.S. Professor of Psychology, School of Psychology, University of New South Wales, Sydney, New South Wales, Australia
45 Disruptive Behavior Disorders in Children and Adolescents

Robert A. King, M.D. Professor of Child Psychiatry, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut
35.1 Psychiatric Examination of the Infant, Child, and Adolescent

Laurence J. Kirmayer, M.D. James McGill Professor, Division of Social and Transcultural Psychiatry, McGill University, Montreal, Quebec, Canada
29.1 Cultural Concepts of Distress

Elizabeth R. Kitt, M.S., M.Phil. Graduate Student, Department of Psychology, Yale University, School of Medicine, New Haven, Connecticut
14.5 Neuroimaging and the Neuroanatomical Circuits Implicated in Anxiety Disorders

Cary Kogan, Ph.D., M.S.C.P. Professor of Clinical Psychology, School of Psychology, University of Ottawa, Ottawa, Ontario, Canada
33.5b $5HT_{1A}$ *Receptor Partial Agonists (Buspirone)*

Steve Koh, M.D., M.P.H., M.B.A. Chief, General Psychiatry Division; Clinical Professor, Department of Psychiatry, University of California, School of Medicine, San Diego, California
55.3j Alcohol and Substance Abuse in Older Adults, 55.5 Financial Issues in the Delivery of Geriatric Psychiatric Care

Maulika Kohli, M.S. Doctoral Candidate, Department of Psychiatry, San Diego State University/University of California, School of Medicine, Joint Doctoral Program in Clinical Psychology, San Diego, California
55.3a Assessment of Functioning

Robert Kohn, M.D. Professor, Practice of Epidemiology, Brown University, Providence, Rhode Island
4.2 Transcultural Psychiatry

Brandon A. Kohrt, M.D., Ph.D. Professor of Psychiatry, Global Health, and Anthropology, Center for Global Mental Health Equity, George Washington University School of Medicine and Health Sciences, Washington, DC

29.1 Cultural Concepts of Distress

Alexander Kolevzon, M.D. Professor of Psychiatry and Pediatrics, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, New York
34.2 Child Development

Susan G. Kornstein, M.D. Professor of Psychiatry and Obstetrics and Gynecology; Executive Director, Institute for Women's Health, Virginia Commonwealth University School of Medicine, Richmond, Virginia
33.6a Trazodone, 33.6b Nefazodone

Anna Moukouri Kouoh, C.R.N.P. Nurse Practitioner, Psychiatry Department, Johns Hopkins Hospital/John Hopkins University, School of Medicine, Baltimore, Maryland
2.8 Neuropsychiatric Aspects of HIV Infection and AIDS

Emiko Koyama, Ph.D. Postdoctoral Research Fellow/Technical Staff I, Molecular Brain Science/Molecular Pathology of Psychiatric Disorders, Centre for Addiction and Mental Health, University of Toronto/Center for Brain Science, RIKEN, Toronto, Ontario, Canada; Wakō-shi, Saitama, Japan
42.1 Language Disorder, 42.3 Speech Sound Disorder, 42.4 Stuttering

Jennifer L. Kruse, M.D. Associate Professor of Psychiatry, Department of Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
7.6 Medical Assessment and Laboratory Testing in Psychiatry

John H. Krystal, M.D. Robert L. McNeil, Jr., Professor of Translational Research, Professor of Psychiatry, Neuroscience, and Psychology; Chair, Department of Psychiatry; Co-Director, Yale Center for Clinical Investigation, Yale University, School of Medicine;

Chief of Psychiatry and Behavioral Health, Yale-New Haven Hospital, New Haven, Connecticut
1.1 The Neuroscience of Psychiatry, 1.25 Nuclear Magnetic Resonance Imaging and Spectroscopy: Basic Principles and Recent Findings in Neuropsychiatric Disorders, 1.27 Radiotracer Imaging with Positron Emission Tomography and Single Photon Emission Computed Tomography: Fundamental Principles, Methodology and Role in Neuropsychiatric Research

Marek Kubicki, M.D., Ph.D. Professor of Psychiatry and Radiology, Psychiatry and Radiology, Brigham and Women's Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
12.7 Structural Brain Imaging in Schizophrenia

Helen H. Kyomen, M.D., M.S. Clinical Assistant Professor, Department of Psychiatry, Boston University, Aram V Chobanian and Edward Avedisian School of Medicine; Adjunct Clinical Assistant Professor, Department of Psychiatry, Tufts University, School of Medicine; Lecturer, Part-Time, Department of Psychiatry, Harvard University, Harvard Medical School, Boston, Massachusetts
55.5 Financial Issues in the Delivery of Geriatric Psychiatric Care, 55.6d Gender Issues

Beth Ann Labardi, M.D. Clinical Assistant Professor of Psychiatry, Psychiatry and Behavioral Sciences, VA Puget Sound Health Care System/University of Washington School of Medicine, Seattle, Washington
55.3b Psychiatric Problems in the Medically Ill Geriatric Patient

Simon Lafrenière, M.D., M.Sc. Psychiatrist/Clinical instructor of psychiatry, Division of Psychiatry and Neurosciences, Institut universitaire en santé mentale de Québec /Université Laval, Quebec City, Quebec, Canada
33.5a.1 Serotonin Reuptake Inhibitors (SRIs)

James H. Lake, M.D. Adjunct Fellow, National Institute of Complementary Medicine, Health Research Institute, Western Sydney University, Sydney, Australia
30.4 Complementary, Alternative, and Integrative Approaches in Mental Health Care

H. Richard Lamb, M.D. Professor Emeritus of Psychiatry and the Behavioral Sciences, University of Southern California, Keck School of Medicine, Los Angeles, California
56.8 Criminalization of Persons With Serious Mental Illness

Eugene Laska, Ph.D. Research Professor, Department of Psychiatry and Division of Biostatistics, Department of Population Health, New York University Grossman School of Medicine, New York, New York
5.2 Statistics and Experimental Design

Tarannum Lateef, M.D., M.P.H. Associate Professor of Pediatrics and Neurology, Division of Neurology, George Washington University, School of Medicine and Health Sciences, Washington, DC; Pediatric Specialists of Virginia and Children's National Health System, Woodbridge, Virginia
2.11 Neuropsychiatric Aspects of Headache

Megan E. Lavery, Psy.D. Bariatric Psychologist, Department of Bariatric Surgery/Embedded Psychology, Christiana Care, Wilmington, Delaware
27.4 Psychosomatic Medicine: Obesity

Helen Lavretsky, M.D., M.S. Professor In-Residence of Psychiatry, Department of Psychiatry and Biobehavioral Sciences, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
55.2b Complementary and Integrative Geriatric Psychiatry

Lawrence W. Lazarus, M.D. Private Practice, Adult, Geriatric and Forensic Psychiatry, Santa Fe, New Mexico, San Francisco, California
55.4h Individual Psychotherapy

Ellen E. Lee, M.D. Assistant Professor and Division Chief of Geriatric Psychiatry, Psychiatry, University of California, School of Medicine, San Diego, California
55.1 Introduction to Geriatric Psychiatry

Francis S. Lee, M.D., Ph.D. Chair and Professor, Department of Psychiatry, Weill Cornell Medical College and New York-Presbyterian/Weill Cornell Medical Center, New York, New York
1.10 Neurotrophic Factors

Kelly C. Lee, Pharm.D., M.A.S., B.C.P.P. Professor of Clinical Pharmacy, Skaggs School of Pharmacy and Pharmaceutical Sciences, University of California, School of Medicine, San Diego, California
55.4d Antipsychotic Drugs

Susan W. Lehmann, M.D. Professor of Psychiatry and Behavioral Sciences, Division of Geriatric Psychiatry and Neuropsychiatry, Johns Hopkins University School of Medicine, Baltimore, Maryland
55.3g Delirium

Sean R. LeNoue, M.D. Medical Director of Outpatient Services, Rogers Behavioral Health, Nashville, Tennessee
54.5 Adolescent Substance Use Disorders

Gregory B. Leong, M.D. Clinical Professor of Psychiatry, Department of Psychiatry and the Behavioral Sciences, University of Southern California, Keck School of Medicine, Los Angeles, California
58.1 Clinical-Legal Issues in Psychiatry

Bernard Lerer, M.D. Professor, Department of Psychiatry, Hadassah Medical Center, Hebrew University, Jerusalem, Israel
33.15b Thyroid Hormones

Alan J. Lerner, M.D. Director, Brain Health and Memory Center, Neurology Department, University Hospitals Cleveland Medical Center, Cleveland, Ohio
2.12 Neuropsychiatric Aspects of Neuromuscular Diseases

Nigel Lester, M.D. Director of Mental Health, Palm Health; Professor of Wellbeing, Anthropedia Foundation, St. Louis, Missouri
26 Personality Disorders

Janni Leung, Ph.D. Research Fellow of Epidemiology, National Centre for Youth Substance Use Research, The University of Queensland, Australia
11.5 Cannabis-Related Disorders

Bennett L. Leventhal, M.D. Irving B. Harris Professor of Child and Adolescent Psychiatry, Emeritus, University of Chicago, Division of Biological Sciences, Pritzker School of Medicine, Chicago, Illinois
42.2 Social (Pragmatic) Communication Disorder

Adam B. Lewin, Ph.D., A.B.P.P. Professor and Division Chief, Pediatric Neuropsychiatry, University of South Florida, Morsani College of Medicine, Tampa, Florida
51.1 Obsessive-Compulsive Disorder in Childhood

Bradley Lewis, M.D., Ph.D. Associate Professor of Health Humanities and Cultural Studies, Gallatin School of Individualized Study, New York University, Grossman School of Medicine, New York, New York
32.15 Narrative Psychiatry

David A. Lewis, M.D. Chair of Psychiatry and Distinguished Professor of Psychiatry and Neuroscience, Department of

Psychiatry, University of Pittsburgh, School of Medicine, Pittsburgh, Pennsylvania
1.2 Functional Neuroanatomy

Dorothy Otnow Lewis, M.D., F.A.C.P. Retired Clinical Professor of Psychiatry, Yale Child Study Center, Yale University, School of Medicine, New Haven, Connecticut
28.2 Adult Antisocial Behavior, Criminality, and Violence

Stephen F. Lewis, B.S., M.D. Professor, Staff Psychiatrist, Department of Psychiatry and Behavioral Sciences, University of New Mexico School of Medicine, Albuquerque, New Mexico
12.2 Phenomenology of Schizophrenia

Roberto Lewis-Fernández, M.D., M.T.S. Professor of Clinical Psychiatry at Columbia University, Vagelos College of Physicians and Surgeons; Director of the New York State Center of Excellence for Cultural Competence; Director of the Hispanic Treatment Program; and Research Area Leader for Anxiety, Mood, Eating and Related Disorders at New York State Psychiatric Institute, Psychiatry (Columbia) and Anxiety, Mood, Eating and Related Disorders (NYS Psychiatric Institute), Columbia University, Vagelos College of Physicians and Surgeons and NYS Psychiatric Institute, New York, New York
20 Dissociative Disorders, 29.1 Cultural Concepts of Distress, 29.2 Cultural Assessments in Psychiatry

Julio Licinio, M.D., Ph.D., M.B.A., M.S. State University of New York, Distinguished Professor, Department of Psychiatry and Behavioral Sciences, State University of New York, Upstate Medical University, Alan and Marlene Norton College of Medicine, Syracuse, New York
1.21 Pharmacogenetics

Yeun J. Lim, M.D. Resident Physician, Department of Psychiatry, University of California, David Geffen School of Medicine, Olive View

Psychiatry Residency Program, Los Angeles, California
54.15 Social Media and Youth

Christine Lochner, Ph.D. Professor of Clinical Psychology, SAMRC Unit on Risk and Resilience in Mental Disorders, Department of Psychiatry, Stellenbosch University, Cape Town, South Africa
15 Obsessive-Compulsive and Related Disorders

Richard J. Loewenstein, M.D. Adjunct Professor, Department of Psychiatry, University of Maryland School of Medicine, Baltimore, Maryland
20 Dissociative Disorders

John Lotfi, M.D., J.D. Resident Physician, Department of Psychiatry, Mather Hospital, Port Jefferson, New York
1.16 Pain Systems: Interface with Affective and Motivational Mechanisms

Carlos López-Jaramillo, M.D., Ph.D. Professor of Psychiatry, Department of Psychiatry, School of Medicine, Universidad de Antioquia, Medellin, Colombia
9.2 The Classification of Mental Disorders in the International Classification of Diseases (ICD-11)

Luminita Luca, M.D., Ph.D. Attending Psychiatrist, Department of Psychiatry and Behavioral Sciences, University of Miami Leonard M. Miller School of Medicine, Miami, Florida
33.11b Cholinesterase Inhibitors and Memantine

Loredana Lucarelli, Psy.D. Chair Professor in Dynamic and Developmental Psychopathology, Department of Pedagogy, Psychology, Philosophy, University of Cagliari, Cagliari, Italy
46 Feeding and Eating Disorders of Infancy and Early Childhood

John Luo, M.D. Health Sciences Clinical Professor of Psychiatry, Department of Psychiatry and Human Behavior, University of

California Irvine Medical Center/University of California Irvine Health/University of California, School of Medicine, Irvine, California
30.9 Computers in Psychiatry

Sean X. Luo, M.D., Ph.D. Assistant Professor of Clinical Psychiatry, Department of Psychiatry, Columbia University, Vagelos College of Physicians and Surgeons, New York, New York
11.9 Opioid Use and Related Disorders: From Neuroscience to Treatment

Anne Bodmer Lutz, B.S.N., M.D. Executive Director of The Institute for Solution-Focused Therapy and Assistant Professor, Psychiatry: Child Psychiatry Division, Institute for Solution-Focused Therapy, University of Massachusetts, T.H. Chan School of Medicine, Worcester, Massachusetts
32.12 Solution-Focused Brief Therapy

Amanda E. Lyall, Ph.D. Assistant Professor, Department of Psychiatry, Brigham and Women's Hospital, Massachusetts General Hospital, Harvard University, Harvard Medical School, Boston, Massachusetts
12.7 Structural Brain Imaging in Schizophrenia

Stanley Lyndon, M.D. Associate Neuropsychiatrist, Center for Brain/Mind Medicine, Brigham and Women's Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
2.2 Neuropsychiatric Aspects of Cerebrovascular Disorders

Frank P. Macmaster, Ph.D. Vice President, Research and Innovation, IWK Health, Halifax, Nova Scotia, Canada
37 Neuroimaging in Psychiatric Disorders of Childhood

Vladimir Maletic, M.D., M.S. Clinical Professor of Psychiatry, Department of Psychiatry, University of South Carolina, School of Medicine, Columbia, South Carolina, and Greenville, South Carolina
13.8 Mood Disorders: Neurobiology

Daniel Mamah, M.D., M.P.E. Professor, Department of Psychiatry, Washington University in St. Louis, School of Medicine, St. Louis, Missouri
12.3 Global Burden of Schizophrenia

Alice R. Mao, M.D. Professor of Psychiatry and Behavioral Sciences, Child and Adolescent Psychiatry, Texas Children's Hospital, Baylor University, College of Medicine, Houston, Texas
54.12 Impact on Parents of Raising a Child with Psychiatric Illness and/or Developmental Disability

Stephen R. Marder, M.D. Daniel X. Freedman Professor of Psychiatry, Department of Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, and VA Greater Los Angeles, Los Angeles, California
33.2b Dopamine-Serotonin Antagonists, 33.3a Dopamine Partial Agonists

Russell L. Margolis, M.D. Professor of Psychiatry and Neurology, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland
2.6 Neuropsychiatric Aspects of Movement Disorders

John J. Mariani, M.D. Associate Professor of Clinical Psychiatry, Division on Substance Use Disorders, New York State Psychiatric Institute/CUIMC, New York, New York
11.10 Sedative-, Hypnotic-, or Anxiolytic-Related Disorders

Humberto Marin, M.D. Professor of Psychiatry, Department of Psychiatry and UBHC, Rutgers University, Robert Wood Johnson Medical School, Piscataway, New Jersey
9.1 Present and Future of Classification Systems for Mental Disorders

John C. Markowitz, M.D. Professor of Clinical Psychiatry; Research Psychiatrist, Department of Psychiatry, Columbia University, Vagelos College of Physicians and Surgeons; New York State Psychiatric Institute, New York, New York
13.4 Mood Disorders: Intrapsychic and Interpersonal Aspects

Charles R. Marmar, M.D. Littauer Professor and Chair, Department of Psychiatry, New York University, Grossman School of Medicine, New York, New York
17 Post-Traumatic Stress Disorder

María Marquine, Ph.D. Associate Professor, Department of Medicine, University of California, School of Medicine, San Diego, California
55.6g HIV and Aging

Laura Marsh, M.D. Professor, Menninger Department of Psychiatry and Department of Neurology, Baylor University, College of Medicine/Michael E. DeBakey Veterans Affairs Medical Center, Houston, Texas
2.6 Neuropsychiatric Aspects of Movement Disorders

Dori Marshall, M.D. Clinical Associate Professor of Psychiatry, Department of Psychiatry, University at Buffalo, Jacobs School of Medicine and Biomedical Sciences, Buffalo, New York
33.9a Barbiturates and Similarly Acting Substances, 33.9b Benzodiazepine Receptor Agonists and Antagonists, 33.10a Calcium Channel Inhibitors

Andrés Martin, M.D., Ph.D. Riva Ariella Ritvo Professor, Child Study Center, Yale University, School of Medicine, New Haven, Connecticut
53.6 Inpatient Psychiatric, Partial Hospitalization, and Residential Treatment for Children and Adolescents

Nancy Martin, M.D. Emergency Psychiatrist, Presbyterian Behavioral Health, Albuquerque, New Mexico
30.3 Physical Violence on Adults

Ardis C. Martin, M.D. Child, Adolescent, and Adult Psychiatrist, True InSight Psychiatric, Private Practice, Martinez, California
34.3 Adolescent Development

Caridad Ponce Martinez, M.D. Assistant Professor, Department of Psychiatry, University of Massachusetts, T.H. Chan School of Medicine, Worcester, Massachusetts
33.17c Pharmacologic Treatment of Sexual Dysfunction

Ruben G. Martinez, Ph.D. Postdoctoral Fellow, Department of Psychiatry, University of California, David Geffen School of Medicin, Los Angeles, California
51.3 Separation Anxiety, Generalized Anxiety, and Social Anxiety

Graeme F. Mason, Ph.D. Professor, Departments of Radiology and Biomedical Imaging, Psychiatry, and Biomedical Engineering, Yale University, School of Medicine, New Haven, Connecticut
1.25 Nuclear Magnetic Resonance Imaging and Spectroscopy: Basic Principles and Recent Findings in Neuropsychiatric Disorders

Christopher E. Mason, Ph.D. Professor of Genomics, Physiology, and Biophysics, Physiology and Biophysics, Weill Cornell Medical College, New York, New York
1.18 Genome, Transcriptome, and Proteome: The Molecular Genetics, Biochemistry, and Multi-Omics Underlying the Neurobiology of Mental Disorders

Chacku Mathai, A.A.S. Director, OnTrackNY Healthy Transitions SAMHSA Grant Department, Center for Practice Innovations at Columbia University, New York, New York
12.15 Recovery in Schizophrenia

Anu A. Matorin, M.D. Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Ben Taub Hospital Harris Health/Baylor University, College of Medicine, Houston, Texas
8 Clinical Manifestations of Psychiatric Disorders

Sarah Mattson, Ph.D. Professor and Neuropsychologist, Department of Psychology, Center for Behavioral Teratology, San Diego State University, San Diego, California
2.13 Psychiatric Aspects of Child Neurology

Jeffrey E. Max, M.D., M.B.B.Ch. Professor of Psychiatry, Division of Child and Adolescent Psychiatry, University of California, School of Medicine, San Diego; Rady Children's Hospital, San Diego, California
2.13 Psychiatric Aspects of Child Neurology

Tina L. Mayes, Ph.D. Staff Psychologist, Geriatric Mental Health Clinic, San Diego VA Healthcare System/University of California, School of Medicine, San Diego, California
55.2d Psychological Changes With Normal Aging

Ruth McCann, M.D. Fellow in Neuropsychiatry and Behavioral Neurology, Department of Psychiatry, Brigham and Women's Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
2.9 Neuropsychiatric Aspects of Other Infectious Diseases (Non-HIV)

Kristine L. Mccaslin, Psy.D. Assistant Professor of Psychiatry, Division of Psychology, University of Texas Southwestern, Medical School, Dallas, Texas
6.3 Other Psychodynamic Schools

James T. McCracken, M.D. Professor of Psychiatry and Biobehavioral Sciences, Division of Child and Adolescent Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California

36 Genetics in Child PsychiatryRobert E. McCullumsmith, M.D., Ph.D. Chair of Department of Neurosciences, Department of Neurosciences, University of Toledo, College of Medicine and Life Sciences/ProMedica Neurosciences Institute, Toledo, Ohio

12.6 Cellular and Molecular Neuropathology of Schizophrenia

Courtney R. McDermott, B.A. Doctoral Candidate in Neuroscience, Neuroscience and Cell Biology, Rutgers University, Robert Wood Johnson Medical School, Piscataway, New Jersey

1.4 Neural Development and Neurogenesis

James J. McGough, M.D., M.S. Professor of Clinical Psychiatry and Biobehavioral Sciences, Division of Child and Adolescent Psychiatry, Resnick Neuropsychiatric Hospital/University of California, David Geffen School of Medicine, Los Angeles, California

44.2 Adult Manifestations of Attention-Deficit/Hyperactivity Disorder

Daniel McFarland, D.O., M.S. Associate Professor/Director of Psycho-Oncology, Departments of Psychiatry and Internal Medicine/Division of Hematology and Oncology, University of Rochester, School of Medicine and Dentistry/Wilmot Cancer Center, Rochester, New York

27.8 Psycho-Oncology

John S. McIntyre, M.D. Clinical Professor of Psychiatry, Department of Psychiatry, University of Rochester, School of Medicine and Dentistry, Rochester, New York

7.1 Psychiatric Interview, History, and Mental Status Examination of the Adult Patient, 7.3 Practice Guidelines in Psychiatry

Nicole C.R. McLaughlin, Ph.D. Associate Professor, Research Scholar Track, Neuropsychology, Department of Psychiatry and

Human Behavior, Butler Hospital/Brown University, Warren Alpert Medical School, Providence, Rhode Island
33.20c Neurosurgical Treatments

John R. McQuaid, Ph.D. Chief of Psychology, Psychology Service, VA Palo Alto Health Care System, Palo Alto, California; Vice Chair, Psychiatry and Behavioral Sciences, Weill Institute for Neurosciences, University of California, School of Medicine, San Francisco, California; Associate Chief of Staff for Health Equity, Office of the Chief of Staff, San Francisco VA Health Care System, San Francisco, California
13.7 Mood Disorders: Psychotherapy, 55.4i Cognitive-Behavioral Therapy

Paul D. Meesters, M.D. Geriatric psychiatrist, Education and Research, Mental Health Services, GGZ Friesland, Leeuwarden, The Netherlands
55.3h Schizophrenia and Other Psychotic Disorders

Darlene S. Melchitzky, M.S. Research Principal, Department of Psychiatry, University of Pittsburgh, Medical Center, Pittsburgh, Pennsylvania
1.2 Functional Neuroanatomy

Samantha Meltzer-Brody, M.D., M.P.H. Assad Meymandi Distinguished Professor and Chair, Department of Psychiatry, University of North Carolina, School of Medicine, Chapel Hill, North Carolina
33.17a Sex Differences in Psychopharmacology

Mario F. Mendez, M.D., Ph.D. Professor of Neurology and Psychiatry and Clinical Neurosciences, Department of Neurology, University of California, David Geffen School of Medicine and VA Greater Los Angeles Healthcare System, Los Angeles, California
2.4 Neuropsychiatric Aspects of Epilepsy and Psychogenic Nonepileptic Seizures

Steven Mennerick, Ph.D. John P. Feighner Professor of Neuropsychopharmacology, Department of Psychiatry, Washington University in St. Louis, School of Medicine, St. Louis, Missouri
1.5 Cellular and Synaptic Basis of Neural Signaling

James R. Merikangas, M.D. Clinical Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry, George Washington University, School of Medicine and Health Sciences, Washington, DC
2.11 Neuropsychiatric Aspects of Headache

Kathleen Ries Merikangas, Ph.D. Distinguished Investigator, Intramural Research Program, National Institute of Mental Health, Bethesda, Maryland
2.11 Neuropsychiatric Aspects of Headache, 13.2 Mood Disorders: Epidemiology, 14.1 Anxiety Disorders: Introduction and Overview, 14.3 Epidemiology of Anxiety Disorders

Jonathan Michel Metzl, M.D., Ph.D. Professor, Chair, Department of Medicine, Health, and Society, Vanderbilt University, School of Medicine, Nashville, Tennessee
7.10 Cultural Competency in the Organization and Delivery of Psychiatric Care

Edwin Jens Mikkelsen, M.D. Associate Professor of Psychiatry, Harvard University, Harvard Medical School, Boston, Massachusetts
48 Elimination Disorders

Andrew H. Miller, M.D. Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia
1.13 Immune–Brain Interactions in Psychiatry

Barbara L. Milrod, M.D. Professor of Psychiatry, Albert Einstein College of Medicine, New York, New York
13.4 Mood Disorders: Intrapsychic and Interpersonal Aspects

Alireza Minagar, M.D., M.B.A. Retired Neurologist, University of Maryland Global Campus, Bioinformatics, Shreveport, Louisiana
2.10 Neuropsychiatric Aspects of Prion Disease

Daniel Minkin Levy*, M.D. Resident Physician, Women's Department, Jerusalem Mental Health Center, Jerusalem, Israel
33.1c Classification of Psychotropics: Neuroscience-Based Nomenclature (NbN), 33.19a Essential List of Medicines

Wendy G. Mitchell, M.D. Professor, Clinical Neurology, Department of Neurology, University of Southern California, Keck School of Medicine, Children's Hospital Los Angeles, Los Angeles, California
41 Developmental Coordination Disorder

Ramon Mocellin, M.B.B.S., M.Sc., F.R.A.N.Z.C.P. Consultant Neuropsychiatrist and Psychogeriatrician, Delmont Consulting Suites, Delmont Private Hospital, Glen Iris, Victoria, Australia
2.14 Neuropsychiatry of Neurometabolic and Neuroendocrine Disorders

F. Gerard Moeller, M.D. Professor, Department of Psychiatry, Virginia Commonwealth University, School of Medicine, Richmond, Virginia
24.1 Intermittent Explosive Disorder, 24.2 Pyromania, 24.3 Kleptomania

Janna K. Moen, B.A., Ph.D. Postdoctoral Research Fellow, Nash Family Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, New York
1.22 Animal Models in Psychiatry

E. Mohandas, M.B.B.S., M.D. Chief Consultant in Psychiatry, Sun Medical and Research Centre, Kerala, India
33.19c Biologic Therapies in India

Ramin Mojtabai, M.D., Ph.D., M.P.H. Professor, Department of Mental Health, Bloomberg School of Public Health and Department of Psychiatry and Behavioral Sciences, Johns Hopkins University, School of Medicine, Baltimore, Maryland
12.17 Other Psychotic Disorders

David J. Moore, Ph.D. Professor of Psychiatry, Department of Psychiatry, University of California, School of Medicine//HIV Neurobehavioral Research Program, San Diego, California
55.3a Assessment of Functioning

Raeanne C. Moore, Ph.D. Associate Professor, Psychiatry, University of California, School of Medicine, San Diego, California
55.6g HIV and Aging

Timothy H. Moran, Ph.D. Paul R. McHugh Professor of Motivated Behaviors, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland
1.17 Basic Science of Appetite

Joshua C. Morganstein, M.D. Professor of Psychiatry, Psychiatry, Uniformed Services University of the Health Sciences, F. Edward Hébert School of Medicine, Bethesda, Maryland
30.6 Disaster Psychiatry: Disasters, Terrorism, and War

Stephen J. Morse, J.D., Ph.D. Ferdinand Wakeman Hubbell Professor of Law and Professor of Psychology and Law in Psychiatry, Law School and Department of Psychiatry, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine, Philadelphia, Pennsylvania
4.1 Neurocentrism: Implications for Addiction and the Courtroom

Nidal Moukaddam, M.D., Ph.D. Associate Professor, Department of Psychiatry and Behavioral Sciences, Baylor University, College of Medicine, Houston, Texas
56.1 Public and Community Psychiatry, 56.2 Reforming Health Care

Khaled Moussawi, M.D., Ph.D. Assistant Professor of Psychiatry and Neurology, Department of Psychiatry, University of Pittsburgh, School of Medicine, Pittsburgh, Pennsylvania
1.31 Neuroscience of Substance Use Disorders

Cynthia Mulder, L.C.S.W.S. Psychoanalyst, Clinical Assistant Professor, Menninger Department of Psychiatry and Behavioral Sciences, Baylor University, College of Medicine; Faculty, Center for Psychoanalytic Studies, Houston, Texas
6.1 Psychoanalytic Theories and Treatment: Perspective from North America and Great Britain

Grace Murray, B.A. Business Office Manager, Gunderson Personality Disorders Institute, McLean Hospital, Belmont, Massachusetts
32.7 Treatment of Borderline Personality Disorder

John D. Murray, Ph.D. Associate Professor of Psychiatry, Department of Psychiatry, Yale University, School of Medicine, New Haven, Connecticut
1.24 Computational Modeling Approaches to Psychiatry

James W. Murrough, M.D., Ph.D. Associate Professor, Department of Psychiatry and Neuroscience, Icahn School of Medicine at Mount Sinai, New York, New York
14.4 Anxiety Disorders: Neurobiology and Neuroscience

Drew Musa, C.P.S. Peer Specialist, Bronx, New York
12.15 Recovery in Schizophrenia

Philip R. Muskin, M.D., M.A., D.L.F.A.P.A., L.F.A.C.L.P. Professor of Psychiatry, Psychiatry/Consultation-Liaison Psychiatry, Columbia University Irving Medical Center/Columbia University, Vagelos College of Physicians and Surgeons, New York, New York
32.3 Psychoanalysis and Psychoanalytic Psychotherapy

Srinivas B. Muvvala, M.D., M.P.H. Associate Professor, Department of Psychiatry, Yale University, School of Medicine, New Haven, Connecticut
33.13a.2 Opioid Receptor Antagonists: Naltrexone and Nalmefene

Ashwini Nadkarni, M.D. Associate Vice Chair, Wellness and Assistant Medical Director, Brigham Psychiatric Specialties Group; Instructor, Harvard University, Harvard Medical School, Department of Psychiatry, Brigham and Women's Hospital, Boston, Massachusetts
27.3 Gastrointestinal Disorders

David Naimark, M.D. Forensic Psychiatrist, Adult Behavioral Health Services, County of San Diego Health & Human Services Agency, San Diego, California
55.6b Forensic Aspects, 55.6e The Legal and Ethical Analysis of Older Adult Abuse

William E. Narrow, M.D., M.P.H. Associate Professor, Department of Psychiatry and Behavioral Sciences, Johns Hopkins Bayview Medical Center/Johns Hopkins University School of Medicine, Baltimore, Maryland
5.1 Quantitative and Experimental Methods in Psychiatry: Epidemiology

J. Craig Nelson, M.D. Professor Emeritus, Department of Psychiatry and Behavioral Sciences, Weill Institute of Neurosciences/University of California, School of Medicine, San Francisco, California
33.5a.3 Tricyclics and Tetracyclics

Charles B. Nemeroff, M.D., Ph.D. Matthew P. Nemeroff Professor and Chair, Department of Psychiatry and Behavioral Sciences, University of Texas, Dell Medical School, Austin, Texas
1.8 Neuropeptides: Biology, Regulation and Role in Neuropsychiatric Disorders

Ariana Nesbit, M.D., M.B.E. Assistant Consulting Professor, Department of Psychiatry and Behavioral Sciences, Central Regional Hospital/Duke University, School of Medicine, Durham, North Carolina; Deputy Chief Medical Officer, Central Regional Hospital, Butner, North Carolina
55.6b Forensic Aspects, 55.6e The Legal and Ethical Analysis of Older Adult Abuse

Mark P. Nespeca, M.D. Clinical Professor of Neuroscience and Pediatrics, Departments of Neurosciences and Pediatrics, Rady Childrens Hospital San Diego, University of California, School of Medicine, San Diego, California
2.13 Psychiatric Aspects of Child Neurology

Randolph M. Nesse, M.D. Professor Emeritus of Psychiatry, Professor Emeritus of Psychology, Department of Psychiatry, University of Michigan, Medical School, Ann Arbor, Michigan
4.3 Evolutionary Foundations for Psychiatric Research and Practice

Paul S. Nestadt, M.D. Associate Professor of Psychiatry, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland
27.10 Stress and Psychiatry

D. Jeffrey Newport, M.D., M.S., M.Div. Professor of Psychiatry & Behavioral Sciences and Women’s Health, Departments of Psychiatry and Behavioral Sciences and Women’s Health, University of Texas, Dell Medical School, Austin, Texas
33.15a Melatonin Receptor Agonists

Dorian S. Newton, Ph.D. Psychologist and Psychoanalyst, Oakland, California
6.2 Erik H. Erikson

Sarah A. Nguyen, M.D. Assistant Clinical Professor, Department of Psychiatry and Biobehavioral Sciences, University of California,

David Geffen School of Medicine, Los Angeles, California
55.2b Complementary and Integrative Geriatric Psychiatry

Sharon Nichols, Ph.D. Research Scientist, Department of Neurosciences, University of California, School of Medicine, San Diego, California
2.13 Psychiatric Aspects of Child Neurology

Frank John Ninivaggi, M.D. Assistant Clinical Professor of Child Psychiatry, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut
28.1 Malingering, 28.3 Borderline Intellectual Functioning and Academic or Educational Problem

Wanjikũ F.M. Njoroge, M.D. Assistant Professor/Associate Chair of Diversity, Equity, Inclusion, Department of Psychiatry/Department of Child and Adolescent Psychiatry and Behavioral Sciences, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine/Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
54.17 Racism and Discrimination's Impact on the Health and Well-Being of Developing Children and Adolescents

Hannah O. Nordberg, M.A. Student, Department of Psychology, Southern Methodist University, Dallas, Texas
27.5 Respiratory Disorders

Erika L. Nurmi, M.D., Ph.D. Associate Professor of Psychiatry and Biobehavioral Sciences, Division of Child and Adolescent Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
36 Genetics in Child Psychiatry

David Nutt, F.R.C.P., F.R.C.Psych., F.B.Ph.S., F.Med.Sci., D.Laws. Edmond J. Safra Professor of Neuropsychopharmacology, Division

of Psychiatry, Imperial College London, London, United Kingdom
33.14b MDMA, Psilocybin, Ayahuasca, and Ibogaine

Jennifer A. O'Day, M.D. Psychopharmacology Consultant, Department of Psychiatry, California Department of State Hospitals, Los Angeles, California
33.7a Pimavanserin

Andres A. Avellaneda Ojeda, M.D. Associate professor of Psychiatry, Menninger Department of Psychiatry, Baylor University, College of Medicine, Houston, Texas
8 Clinical Manifestations of Psychiatric Disorders

Nora C. Oberfield, M.D. Assistant Professor of Psychiatry at Columbia University Medical Center, Child and Adolescent Psychiatry, Columbia University, Vagelos College of Physicians and Surgeons, New York, New York
7.11 Medical Error

Taylor A. Ochalek, Ph.D. Postdoctoral Fellow, Department of Pharmacology and Toxicology, Virginia Commonwealth University, School of Medicine, Richmond, Virginia
24.1 Intermittent Explosive Disorder, 24.2 Pyromania, 24.3 Kleptomania

Michael Ogata, M.D. Teaching Faculty, Inpatient Psychiatry, Department of Psychiatry, Mission Community Hospital Psychiatry Residency Program, Panorama City, California
54.14 Internet Gaming Disorder in Youth

Ejine Okoroafor, M.D., F.A.P.A. Medical Director, Central Point Psychiatry, Mental Health OP Clinic, Las Vegas, Nevada
27.14 Psychiatric Care of the Burned Patient

Stephanie S. O'Malley, Ph.D. Elizabeth Mears and House Jameson Professor of Psychiatry and Deputy Chair for Clinical Research,

Department of Psychiatry, Yale University, School of Medicine, New Haven, Connecticut
33.13a.2 Opioid Receptor Antagonists: Naltrexone and Nalmefene

Lauren M. Osborne, M.D. Associate Professor and Vice Chair for Clinical Research; Associate Professor, Department of Obstetrics and Gynecology; Department of Psychiatry, Weill Cornell Medical College, New York, New York
30.1 Psychiatry and Reproductive Medicine

Hanadi Ajam Oughli, M.D. Health Sciences Assistant Clinical Professor, Department of Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
55.2b Complementary and Integrative Geriatric Psychiatry

Fred Ovsiew, M.D. Clinical Professor of Psychiatry and Behavioral Sciences, Psychiatry and Behavioral Sciences, Northwestern Memorial Hospital/Northwestern University, Feinberg School of Medicine, Chicago, Illinois
2.1 The Neuropsychiatric Approach to the Patient

Kyle Owen, D.O. Lead Psychiatrist—Consult Liaison service, Department of Psychiatry, Presbyterian Health System, Albuquerque, New Mexico
30.3 Physical Violence on Adults

Michael J. Owen, B.Sc. (Hons.), M.B., Ch.B., Ph.D., F.R.C.P.sych. Professor of Psychological Medicine, Division of Psychological Medicine and Clinical Neurosciences, Cardiff University, Cardiff, United Kingdom
12.4 Genetics of Schizophrenia, 1.8 Neuropeptides: Biology, Regulation and Role in Neuropsychiatric Disorders

Vanessa Padilla, M.D. Assistant Professor, Consultation-Liaison Psychiatry, Department of Clinical Psychiatry and Behavioral

Sciences, University of Miami Leonard M. Miller School of Medicine, Miami, Florida
56.6 Psychiatric Rehabilitation

Barton W. Palmer, Ph.D. Professor in Residence, Department of Psychiatry, University of California, School of Medicine, San Diego, California; Staff Psychologist, Mental Illness Research, Education, and Clinical Center and Division of Psychology, VA San Diego Healthcare System, San Diego, California
55.2e Neuropsychological Evaluation, 55.6i Positive Psychiatry of Aging

Maryland Pao, M.D. Clinical and Deputy Scientific Director, National Institute of Mental Health, Office of the Clinical Director, National Institutes of Health, Bethesda, Maryland
54.3 Children’s Reaction to Illness and Hospitalization

Leila Parand, M.D. Neurologist, Neurobehavior Specialist, Department of Neurology, University of California Health/David Geffen School of Medicine, Los Angeles, California
2.4 Neuropsychiatric Aspects of Epilepsy and Psychogenic Nonepileptic Seizures

Lawrence T. Park, A.M., M.D. Medical Director, Experimental Therapeutics and Pathophysiology Branch, National Institute of Mental Health, Bethesda, Maryland
33.4a Dopamine Receptor Agonists, 33.14a Esketamine and Ketamine

Nansook Park, Ph.D. Professor of Psychology, Psychology, University of Michigan, Medical School, Ann Arbor, Michigan
32.16 Positive Psychology

Marcella Pascualy, M.D. Associate Professor of Psychiatry, Psychiatry and Behavioral Sciences, University of Washington School of Medicine, Seattle, Washington

55.3b Psychiatric Problems in the Medically Ill Geriatric Patient

Caroly Sue Pataki, M.D. Health Sciences Clinical Professor, Department of Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
34.1 Introduction and Overview, 34.3 Adolescent Development, 35.2 Psychiatric Assessment of Preschool Children, 50.2 Early-Onset Bipolar Disorder, 54.14 Internet Gaming Disorder in Youth, 54.15 Social Media and Youth

Kartik Pattabiraman, M.D., Ph.D. Assistant Professor, Child Study Center, Yale New Haven Hospital, Yale University, School of Medicine, New Haven, Connecticut
1.3 Functional Genomics of Human Brain Development

Bindu D. Paul, Ph.D. Assistant Professor of Pharmacology, Psychiatry and Neuroscience, Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland
1.9 Novel Neurotransmitters

Holly L. Peay, Ph.D., M.S. Senior Research Scientist, Genomics and Translational Research Center, RTI International, Research Triangle Park, Durham, North Carolina
30.2 Genetic Counseling for Psychiatric Conditions

Dale Aaron Peeples, M.D. Associate Professor of Psychiatry, Department of Psychiatry and Health Behavior, Child and Adolescent Psychiatry Division, Augusta University, Medical College of Georgia, Augusta, Georgia
54.1 Adoption and Foster Care

Kevin Pelphrey, Ph.D. Harrison-Wood Jefferson Scholars Foundation Professor, Department of Neurology, University of Virginia, School of Medicine, Charlottesville, Virginia
43 Autism Spectrum Disorders

Max Pemberton, M.B.B.S., B.Sc., M.R.C.Psych. Specialty Trainee in General Adult and Old Age Psychiatry, Department of Psychiatry, Camden and Islington NHS Foundation Trust, London, United Kingdom
60 World Aspects of Psychiatry

Tara S. Peris, Ph.D. Professor and Vice Chair for Research, Department of Psychiatry and Biobehavioral Sciences, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
51.3 Separation Anxiety, Generalized Anxiety, and Social Anxiety

Bernice A. Pescosolido, Ph.D. Distinguished Professor, Sociology Department, Indiana University, School of Medicine, Indianapolis, Indiana
56.7 A Sociocultural Framework for Mental Health and Substance Abuse Service Inequities

Ninoska D. Peterson, Ph.D. Adjunct Assistant Professor, Bariatric and Metabolic Institute, Cleveland Clinic Lerner College of Medicine, Cleveland, Ohio
27.4 Psychosomatic Medicine: Obesity

Joanna Petrides, M.B.S., Psy.D. Associate Professor, Department of Family Medicine, Rowan-Virtua School of Osteopathic Medicine, Stratford, New Jersey
32.17 Acceptance and Commitment Therapy

Megan L. Petrik, Ph.D. Assistant Professor, Department of Medicine, University of Minnesota Medical School, Minneapolis, Minnesota
32.24 Evaluating Psychotherapy: Research Methods, Findings, and Future Directions

John Piacentini, Ph.D., A.B.P.P. Professor of Psychiatry and Biobehavioral Sciences, Division of Child and Adolescent Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
51.1 Obsessive-Compulsive Disorder in Childhood

Ralph L. Piedmont, Ph.D. Managing Director, Center for Professional Studies, Timonium, Maryland
6.4 Approaches Derived from Philosophy and Psychology

Katherine S. Pier, M.D. Addiction Psychiatrist, Addiction Medicine and Recovery Services and Department of Psychiatry, The Permanente Medical Group, San Francisco, California
33.13a.2 Opioid Receptor Antagonists: Naltrexone and Nalmefene, 33.13b Disulfiram and Acamprosate

Sandra S. Pimentel, Ph.D. Associate Professor, Chief of Child and Adolescent Psychology, Department of Psychiatry and Behavioral Sciences, Montefiore Medical Center/Albert Einstein College of Medicine, New York, New York
53.2 Cognitive-Behavioral Psychotherapy for Children and Adolescents

Eric M. Plakun, M.D. Medical Director and Chief Executive Officer, The Austen Riggs Center, Stockbridge, Massachusetts
32.4 Psychoanalytic Treatment of Anxiety, Obsessive-Compulsive and Trauma-Related Disorders

Sirisha Pochareddy, Ph.D. Administrative Director of Genome Sciences Core, Penn State College of Medicine, Hershey, Pennsylvania
1.3 Functional Genomics of Human Brain Development

Carol Ann Podgorski, Ph.D., M.P.H., M.S. Professor of Psychiatry, Department of Psychiatry, University of Rochester, School of

Medicine and Dentistry, Rochester, New York
55.4j Family Intervention and Therapy With Older Adults

Bruce G. Pollock, M.D., Ph.D., F.R.C.P.C. Peter and Shelagh Godsoe Endowed Chair in Late-Life Mental Health, Centre for Addiction and Mental Health; Professor of Psychiatry and Pharmacology, Temerty Faculty of Medicine, University of Toronto, Temerty, Toronto, Ontario, Canada
33.18b Biologic Therapies: Geriatric Psychopharmacology, 55.4a Geriatric Psychopharmacology: General Principles

Norman K. Pollock, Ph.D. Senior Research Scientist, Department of Pediatrics, Boston Medical Center/Boston University, Aram V Chobanian and Edward Avedisian, School of Medicine, Boston, Massachusetts
30.5 Micronutrient Monitoring and Supplementation in Psychiatric Illness

Maurizio Pompili, M.D., Ph.D. Full Professor and Chair of Psychiatry, Department of Neurosciences, Mental Health and Sensory Organs, Sant'Andrea Hospital, Sapienza University of Rome, Rome, Italy
13.5 Mood Disorders: Suicidal Behavior

Harrison G. Pope, Jr., M.D. Professor of Psychiatry, McLean Hospital, Belmont, Massachusetts/Harvard University, Harvard Medical School, Boston, Massachusetts
11.11 Anabolic-Androgenic Steroid-Related Disorders

Robert M. Post, M.D. Clinical Professor of Psychiatry, Department of Psychiatry, George Washington University, School of Medicine and Health Sciences, Washington, DC
33.10c Carbamazepine, 33.10d Lamotrigine, 33.10e Valproate

Seth Powsner, M.D. Professor, Department of Psychiatry and Emergency Medicine, Yale University, School of Medicine, New

Haven, Connecticut
19 Factitious Disorder

Jenessa S. Price, Ph.D. Associate Professor, Department of Surgery, Division of Transplant Surgery; Department of Psychiatry and Behavioral Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin
32.8 Behavior Therapy

Leslie S. Prichep, Ph.D. Chief Scientific Officer, BrainScope Company, Chevy Chase, Maryland; Professor of Psychiatry and Director of the Brain Research Laboratories (Retired), Department of Psychiatry, City University of New York, School of Medicine, New York, New York
7.7 Principles and Applications of Quantitative Electroencephalography in Psychiatry

Elizabeth J. Prince, D.O. Assistant Professor, Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland
27.10 Stress and Psychiatry

Jessica L. Principe, M.D., M.S. Resident Physician in Psychiatry, Department of Psychiatry, Brigham and Women’s Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
30.5 Micronutrient Monitoring and Supplementation in Psychiatric Illness

Joan Prudic, M.D. Clinical Professor of Psychiatry, Department of Psychiatry, Columbia University, Vagelos College of Physicians and Surgeons/Irving Medical Center, New York, New York
33.20a Electroconvulsive Therapy

Andrés J. Pumariega, M.D. Professor and Chief, Department of Psychiatry, Division of Child and Adolescent Psychiatry, University of Florida College of Medicine, Gainesville, Florida

53.7 Community-Based Treatment

Davin K. Quinn, M.D. Vice Chair, Adult Clinical Services, Department of Psychiatry and Behavioral Sciences, University of New Mexico School of Medicine, Albuquerque, New Mexico
19 Factitious Disorder

Avery Quynh, B.S. Staff Research Associate II, Department of Psychiatry, University of California, School of Medicine, San Diego, California
55.6h Technology for Seniors

Mark Ragins, M.D. Psychiatrist, Department of Student Health Services/Counseling and Psychological Services, California State University Long Beach, Long Beach, California
12.15 Recovery in Schizophrenia

Nusrat Rahman, Ph.D. Senior Researcher, Department of Research, American Psychiatric Association, Washington, DC
5.1 Quantitative and Experimental Methods in Psychiatry: Epidemiology

Charles L. Raison, M.D. Professor of Human Ecology and Psychiatry, Department of Psychiatry; Human Development and Family Studies, School of Medicine and Public Health; School of Human Ecology, University of Wisconsin, School of Medicine and Public Health, Madison, Wisconsin
1.13 Immune–Brain Interactions in Psychiatry, 13.8 Mood Disorders: Neurobiology

Tarek K. Rajji, M.D., F.R.C.P.C. Professor of Psychiatry, Geriatric Psychiatry Division, Centre for Addiction and Mental Health/Temerty Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada
55.4f Electroconvulsive Therapy and Neurostimulation Treatments

Seethalakshmi Ramanathan, M.D., M.P.A. Clinical Associate Professor of Psychiatry, Department of Psychiatry and Behavioral Sciences, State University of New York, Upstate Medical University, Alan and Marlene Norton College of Medicine, Syracuse, New York
55.2f Genetics of Late-Life Neurodegenerative Disorders

Natalia Ramos, M.D., M.P.H. Assistant Clinical Professor, Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
54.16 Gay, Bisexual, Transgender, Queer/Questioning, Intersex, and Asexual (LGBTQIA) Youth

Laura B. Ramsey, Ph.D. Associate Professor, Department of Pediatrics, Divisions of Clinical Pharmacology and Research in Patient Services, University of Cincinnati, College of Medicine and Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
33.18a Pediatric Psychopharmacology, 53.5 Pediatric Psychopharmacology

Mark M. Rasenick, Ph.D. Distinguished University of Illinois Chicago, Professor of Physiology and Biophysics and Psychiatry, University of Illinois College of Medicine, Research Career Scientist, Jesse Brown VA Medical Center, President/CSO Pax Neuroscience, Chicago, Illinois
33.1a General Principles of Psychopharmacology

Natalie Rasgon, M.D., Ph.D. Professor of Psychiatry and Behavioral Sciences, Psychiatry and Behavioral Sciences, Stanford University, School of Medicine, Palo Alto, California
27.7 Endocrine and Metabolic Disorders

Wegdan Rashad, M.D. Knowledge Translation Coordinator, Department of Psychiatry, Centre for Depression and Suicide Studies, St. Michael's Hospital, Toronto, Ontario, Canada
13.6 Mood Disorders: Pharmacologic Treatment of Depression and Bipolar Disorders

Lakshmi N. Ravindran, M.D., F.R.C.P.C. Assistant Professor of Psychiatry, Department of Psychiatry, Centre for Addiction and Mental Health/University of Toronto, Toronto, Ontario, Canada
14.7 Somatic Therapies for Anxiety Disorders

Elliott Rees, B.Sc. (Hons.), Ph.D. Dr of Psychiatric Genetics, Centre for Neuropsychiatric Genetics and Genomics, Division of Psychological Medicine and Clinical Neurosciences/Cardiff University, Cardiff, United Kingdom
12.4 Genetics of Schizophrenia

Ulrich Reininghaus, Ph.D. Heisenberg Professor Head of Department, Department of Public Mental Health, Central Institute of Mental Health, Mannheim, Germany
12.5 The Clinical Epidemiology of Psychosis Spectrum Disorder

Maya A. Reiter, M.S., Ph.D. Visiting Scholar, Department of Psychology, University of California, School of Medicine, San Diego, California
55.2d Psychological Changes With Normal Aging

Judith Restrepo, M.D. Associate Director Transplant Psychiatry, Consultation Liaison Psychiatry Service, Massachusetts General Hospital, Boston, Massachusetts
27.2 Cardiovascular Disorders

David C. Rettew, M.D. Clinical Faculty, Oregon Health & Science University, School of Medicine, Department of Psychiatry, Portland, Oregon; Medical Director, Lane County Behavioral Health, Eugene, Oregon
38 Temperament: Risk and Protective Factors for Child Psychiatric Disorders

Victor I. Reus, M.D. Distinguished Professor Emeritus, Department of Psychiatry and Behavioral Sciences, University of California,

School of Medicine, UCSF Weill Institute for Neurosciences, San Francisco, California
1.12 Psychoneuroendocrinology

Paula D. Riggs, B.A., M.A., M.D. Professor and Vice Chair, Faculty Affairs and Director, Division of Addiction Science Prevention and Treatment, Department of Psychiatry, University of Colorado, School of Medicine, Aurora, Colorado
54.5 Adolescent Substance Use Disorders

Zoltán Rihmer, M.D., Ph.D., D.Sc. Clinical Professor of Psychiatry, Department of Psychiatry and Psychotherapy, Semmelweis University and National Institute of Mental Health, Neurology and Neurosurgery, Budapest, Hungary
13.2 Mood Disorders: Epidemiology, 13.5 Mood Disorders: Suicidal Behavior

Thomas Ritz, Ph.D. Professor, Department of Psychology, Southern Methodist University, Dallas, Texas
27.5 Respiratory Disorders

Laura Weiss Roberts, M.D., M.A. Professor and Chairman, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, California
58.2 Ethics in Psychiatry

Xiomara Rocha-Cadman, M.D. Assistant Clinical Professor of Psychiatry, Division of Psychiatry, City of Hope Comprehensive Cancer Center, Duarte, California
27.9 End-of-Life and Palliative Care

Joshua J. Rodgers, M.D. Assistant Clinical Professor, Department of Psychiatry, University of Colorado School of Medicine, Aurora, Colorado; Chief Medical Officer, Community Reach Center, Westminster, Colorado; Director, Behavioral Neurology and

Neuropsychiatry, Baylor University, College of Medicine, Houston, Texas
1.14 Chronobiology, Circadian Rhythm, and Psychiatry, 2.15 Catatonia, 2.7 Neuropsychiatric Aspects of Multiple Sclerosis and Other Demyelinating Disorders

Ana Rodriguez-Villa, M.D., M.B.A. Staff Psychiatrist, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts; McLean Hospital, Belmont, Massachusetts
32.7 Treatment of Borderline Personality Disorder

Christian Romanchek, M.D. Resident Physician, Department of Psychiatry, The Johns Hopkins Hospital, Baltimore, Maryland
27.11 Psychiatric Morbidity Following Critical Illness

Alasdair G. Rooney, MB.ChB., M.D., Ph.D. Consultant Neuropsychiatrist, Scottish Neurobehavioural Rehabilitation Service, Royal Edinburgh Hospital, NHS Lothian; Centre for Clinical Brain Sciences, The University of Edinburgh, Edinburgh, Scotland
2.3 The Neuropsychiatry of Brain Tumors

David R. Rosenberg, M.D. Professor and Chair of the Department of Psychiatry and Behavioral Neurosciences, Wayne State University, School of Medicine, Detroit, Michigan
37 Neuroimaging in Psychiatric Disorders of Childhood

M. Zachary Rosenthal, Ph.D. Associate Professor, Department of Psychiatry and Behavioral Science, Duke University, School of Medicine/Medical Center, Durham, North Carolina
32.11 Dialectical Behavior Therapy

Stefan B. Rowny, M.D., M.F.A. Attending Psychiatrist, Assistant Professor, Department of Psychiatry, New York State Psychiatric Institute/Columbia University, Vagelos College of Physicians and Surgeons/Irving Medical Center, New York, New York
33.20b Brain Stimulation Methods

Peter Roy-Byrne, M.D. Professor, Department of Psychiatry, University of Washington School of Medicine, Seattle, Washington
14.2 Clinical Features of the Anxiety Disorders

David R. Rubinow, M.D. Research Professor, Departments of Psychiatry and Medicine, University of North Carolina School of Medicine, Chapel Hill, North Carolina
33.17b Reproductive Hormonal Therapy: Theory and Practice

Katrina A. Rufino, Ph.D. Associate Professor in Psychology, Department of Social Sciences, University of Houston– Downtown, Senior Research Scientist, Department of Psychiatry and Behavioral Sciences, The Menninger Clinic/Baylor University, College of Medicine, Houston, Texas
31.2 Suicide Treatment

Pedro Ruiz, M.D. Professor of Psychiatry, Department of Psychiatry, University of Texas Health Science Center, McGovern Medical School, Houston, Texas
8 Clinical Manifestations of Psychiatric Disorders, 60 World Aspects of Psychiatry

Samir A. Sabbag, M.D. Assistant Professor, Adult and Geriatric Psychiatry, Community Hospital of Monterey Peninsula, Monterey, California
33.11b Cholinesterase Inhibitors and Memantine

Ewurama Sackey, M.D. Child and Adolescent Psychiatry Fellow, Department of Psychiatry and Biobehavioral Sciences, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
54.17 Racism and Discrimination’s Impact on the Health and Well-Being of Developing Children and Adolescents

Joel I. Sadavoy, M.D., F.R.C.P.(C) Professor and Medical Director, Psychiatry (Reitman Centre), University of Toronto and Psychiatrist in Chief and inaugural Pencer Chair in Applied General Psychiatry at Mount Sinai Hospital, Toronto, Ontario, Canada
55.4g Psychosocial Factors in Psychotherapy of the Older Adults, 55.4h Individual Psychotherapy

Joseph R. Sadek, Ph.D., A.B.P.P.-C.N. Associate Professor, Psychiatry and Behavioral Sciences, University of New Mexico, School of Medicine and New Mexico VA Health Care System, Albuquerque, New Mexico
7.4 Neuropsychological Assessment of Adults

Virginia A. Sadock, M.D. Professor of Psychiatry, Department of Psychiatry, New York University, Grossman School of Medicine; Attending Physician, Department of Psychiatry, NYU Langone Hospital Center, New York, New York
21.1 Normal Human Sexuality and Sexual Dysfunctions

Benjamin J. Sadock, M.D. Menas S. Gregroy Professor of Psychiatry, Department of Psychiatry, New York University Grossman School of Medicine; Attending Physician, Department of Psychiatry, NYU Langone Hospital Center; Attending Physician, Bellevue Hospital, New York, New York
7.2 The Psychiatric Report and Outline for a Psychiatric Examination

Carl Salzman, M.D. Professor of Psychiatry, Department of Psychiatry, Beth Israel Deaconess Hospital and Massachusetts Mental Health Center, Harvard University, Harvard Medical School, Boston, Massachusetts
55.4b Antidepressants and Mood Stabilizers

Gerard Sanacora, M.D., Ph.D. George D. Gross and Esther S. Gross Professor of Psychiatry, Yale University School of Medicine, Director of Yale Depression Research, Department of Psychiatry, Co-Director, Yale-New Haven Hospital Interventional Psychiatry Services, New Haven, Connecticut

1.25 Nuclear Magnetic Resonance Imaging and Spectroscopy: Basic Principles and Recent Findings in Neuropsychiatric DisordersJohn Sargent, M.D. Director, Division of Child and Adolescent Psychiatry, Tufts Medical Center, Boston, Massachusetts

53.4 Family Therapy

Sally L. Satel, M.D. Lecturer, Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut

4.1 Neurocentrism: Implications for Addiction and the Courtroom

Stephen M. Saunders, Ph.D. Professor of Psychology, Psychology Department, Marquette University, Milwaukee, Wisconsin

32.24 Evaluating Psychotherapy: Research Methods, Findings, and Future Directions

Radu V. Saveanu, M.D. Professor and Executive Vice Chair, Department of Psychiatry and Behavioral Sciences, University of Miami Leonard M. Miller School of Medicine, Miami, Florida

33.6c Mirtazapine, 56.6 Psychiatric Rehabilitation

Gauri Savla, Ph.D. Clinical Psychologist, Private Practice, Gauri Savla, Encinitas, California

55.2e Neuropsychological Evaluation

Andrew J. Saxon, M.D. Professor, Department of Psychiatry and Behavioral Sciences, University of Washington School of Medicine/VA Puget Sound Health Care System, Seattle, Washington

33.13a.1 Opioid Maintenance Treatments: Methadone and Buprenorphine

Ayal Schaffer, M.D., F.R.C.P.C. Professor, Department of Psychiatry, Sunnybrook Health Sciences Centre, University of Toronto, Toronto, Ontario, Canada

13.6 Mood Disorders: Pharmacologic Treatment of Depression and Bipolar Disorders

Alan F. Schatzberg, M.D. Kenneth T. Norris, Jr., Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, School of Medicine, Palo Alto, California
33.5a.4 Dopamine-Noradrenaline Reuptake Inhibitors (Bupropion), 33.16 Combination Pharmacotherapy

Steven C. Schlozman, M.D. Associate Professor, Department of Psychiatry, Dartmouth College, Geisel School of Medicine, Hanover, New Hampshire
53.8 The Treatment of Adolescents

Peter J. Schmidt, M.D. Chief, Section on Behavioral Endocrinology, National Institute of Mental Health, Intramural Research Program, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland
33.17b Reproductive Hormonal Therapy: Theory and Practice

Benjamin N. Schneider, M.D. Associate Professor of Psychiatry and Biobehavioral Sciences, Department of Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior, University of California, David Geffen School of Medicine, Los Angeles, California
51.3 Separation Anxiety, Generalized Anxiety, and Social Anxiety

Edward J. Schreiber, T.E.P. Psychodrama Director and Adjunct Professor, Zerka Foundation, Amherst, Massachusetts, and Lesley University, Cambridge, Massachusetts
32.22 Psychodrama, Sociodrama, Sociometry, and Sociatry

Matthew Alan Schreiber, M.D., Ph.D. Assistant Professor, Department of Psychiatry and Behavioral Sciences, University of Washington, School of Medicine, Seattle, Washington

55.3b Psychiatric Problems in the Medically Ill Geriatric Patient

Marc A. Schuckit, M.D. Distinguished Professor of Psychiatry, University of California, School of Medicine, San Diego, California
11.2 Alcohol-Related Disorders

Kenneth M. Schwartz, M.D., F.R.C.P.C. Assistant Professor of Medicine, Department of Psychiatry, Baycrest Center for Geriatric Care, Toronto, Ontario, Canada
55.4k Group Therapy

Nicholas P. Schweizer, Ed.D., L.C.A.D.C., L.C.P.C. Program Manager, Department of Psychiatry, Johns Hopkins Hospital, Johns Hopkins University, School of Medicine, AIDS Psychiatry Service, Baltimore, Maryland
2.8 Neuropsychiatric Aspects of HIV Infection and AIDS

Vanessa Scott, B.S. Staff Research Associate, Psychiatry, University of California, School of Medicine/San Diego Health, San Diego, California
55.6h Technology for Seniors

Thomas W. Sedlak, M.D., Ph.D. Assistant Professor, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University, School of Medicine, Baltimore, Maryland
1.9 Novel Neurotransmitters

Mary Schwab Seligman, M.D., M.A.R., Ph.D. Professor of Psychiatry, Psychology, Epidemiology, Nursing, Biostatistics, and Clinical and Translational Science, Department of Psychiatry, University of Pittsburgh School of Medicine and Medical Center, Pittsburgh, Pennsylvania
35.1 Psychiatric Examination of the Infant, Child, and Adolescent

Nenad Sestan, M.D., Ph.D. Harvey and Kate Cushing Professor of Neuroscience, Department of Neuroscience, Yale University, School

of Medicine, New Haven, Connecticut
1.3 Functional Genomics of Human Brain Development

Daniel D. Sewell, M.D. Professor Emeritus, Department of Psychiatry, University of California, School of Medicine, San Diego, California
55.6f Geriatric Psychiatry: Sexuality and Aging

Sandra B. Sexson, M.D. Professor and Chief, Child, Adolescent and Family Psychiatry, Department of Psychiatry and Health Behavior, Augusta University, Medical College of Georgia, Augusta, Georgia
54.1 Adoption and Foster Care

Olivia Shadid, M.D. Child and Adolescent Psychiatry Fellow, Department of Psychiatry and Behavioral Sciences, University of New Mexico School of Medicine, Albuquerque, New Mexico
54.18 Forensic Evaluations of Child and Adolescent Migrants

Arya Shah, M.D. Resident, Department of Psychiatry, Brigham and Women's Hospital, Boston, Massachusetts
58.3 Correctional Psychiatry

Asim A. Shah, M.D. Professor & Executive Vice Chair, Menninger Department of Psychiatry, Baylor University, College of Medicine, Houston, Texas
8 Clinical Manifestations of Psychiatric Disorders, 56.1 Public and Community Psychiatry, 56.2 Reforming Health Care

Talya Shahal, M.D. Clinical Instructor in Psychiatry, Department of Psychiatry, Veterans Administration Boston Healthcare System/Harvard University, Harvard Medical School, Boston, Massachusetts
55.3e Geriatric Mood Disorders

Arieh Y. Shalev, M.D. Adjunct Professor of Psychiatry, Department of Psychiatry, New York University, Grossman School of Medicine, New York, New York
17 Post-Traumatic Stress Disorder

Gabrielle Shapiro, M.D., D.F.A.A.C.A.P., D.F.A.P.A. Clinical Professor of Psychiatry, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, New York
34.2 Child Development

Michael Shapiro, M.D. Clinical Associate Professor of Psychiatry, Division of Child and Adolescent Psychiatry, Department of Psychiatry/University of Florida College of Medicine, Gainesville, Florida
53.1 Psychodynamic Psychotherapy (Child Psychiatry)

Paul Shapshak, Ph.D. Professor, Internal Medicine, University of South Florida, Tamp, Florida
2.10 Neuropsychiatric Aspects of Prion Disease

Amir Sharafkhaneh, M.D., Ph.D. Professor of Medicine, Department of Medicine, Section of Pulmonary, Critical Care and Sleep Medicine, Michael E. DeBakey VA Medical Center, Baylor University, College of Medicine, Houston, Texas
23 Sleep Disorders

Neha Sharma, D.O. Associate Professor of Psychiatry, Child and Adolescent Psychiatry Fellowship Program Director, Department of Psychiatry, Division of Child and Adolescent Psychiatry, Tufts University, School of Medicine/Medicine—Tufts Medical, Boston, Massachusetts
53.4 Family Therapy

Shweta Sharma, Psy.D. Assistant Professor, Menninger Department of Psychiatry and Behavioral Sciences, Baylor University College of Medicine, Houston, Texas

6.1 Psychoanalytic Theories and Treatment: Perspective from North America and Great Britain

Jess P. Shatkin, M.D., M.P.H. Professor and Vice Chair for Education, Department of Child and Adolescent Psychiatry and Pediatrics, New York University Grossman School of Medicine, New York, New York
54.13 Pediatric Sleep Disorders

Martha E. Shenton, Ph.D. Professor, Psychiatry and Radiology, Brigham and Women's Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
12.7 Structural Brain Imaging in Schizophrenia

Edward Shorter, Ph.D., F.R.S.C. Jason A Hannah Professor of the History of Medicine/Professor of Psychiatry, Temerty Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada
59 History of Psychiatry

Rajeet Shrestha, M.D. Assistant Professor, Psychiatry, Department of Psychiatry, University Hospitals Cleveland Medical Center/Case Western Reserve University, School of Medicine, Cleveland, Ohio
2.12 Neuropsychiatric Aspects of Neuromuscular Diseases

Shawn Singh Sidhu, M.D. Associate Professor of Psychiatry, Department of Psychiatry, Division of Child and Adolescent Psychiatry, University of California, School of Medicine, San Diego, California
54.18 Forensic Evaluations of Child and Adolescent Migrants

Carole E. Siegel, Ph.D. Research Professor of Psychiatry, Psychiatry and Population Health, New York University, Grossman School of Medicine, New York, New York
5.2 Statistics and Experimental Design, 7.10 Cultural Competency in the Organization and Delivery of Psychiatric Care

Daniel J. Siegel, M.D. Executive Director, Mindsight Institute, Santa Monica, California; Clinical Professor of Psychiatry, University of California, David Geffen School of Medicine, Founding Co-Director, Mindful Awareness Research Center at UCLA, Los Angeles, California
3.1 Contributions of the Psychological Sciences: Sensation, Perception, and Cognition

Linmarie Sikich, M.D., M.A. Associate Clinical Professor of Psychiatry and Behavioral Health, Division of Child and Family Mental Health and Community Psychiatry, Duke University School of Medicine, Durham, North Carolina
52 Early-Onset Psychotic Disorders

John C. Silbereis, Ph.D. Fellow, Department of Neuroscience, Yale University School of Medicine, New Haven, Connecticut
1.3 Functional Genomics of Human Brain Development

David A. Silbersweig, M.D. Stanley Cobb Professor of Psychiatry; Chairman, Department of Psychiatry, Brigham and Women's Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
1.29 Neuropsychiatry of Self

Samuel Justin Sinclair, Ph.D. Assistant Professor, Department of Psychiatry, Harvard University, Harvard Medical School; Director of the Psychological Assessment and Research Service (PARSe), Brigham and Women's Hospital, Boston, Massachusetts
7.8 Psychiatric Rating Scales

Manpreet Kaur Singh, M.D., M.S. Associate Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, School of Medicine, Palo Alto, California
33.4b Amphetamines, Methylphenidate, Atomoxetine, and Modafinil, 50.2 Early-Onset Bipolar Disorder

Patrick D. Skosnik, Ph.D. Professor, Northeastern University, Bouvé College of Health Sciences, Schools of Nursing and Pharmacy/Pharmaceutical Sciences, Boston, Masachusetts
1.26 Electroencephalography in Psychiatry

Mark Slifstein, Ph.D. Professor of Psychiatry, Director of Research PET, Department of Psychiatry and Behavioral Health, Stony Brook University, Renaissance School of Medicine, Stony Brook, New York
1.27 Radiotracer Imaging with Positron Emission Tomography and Single Photon Emission Computed Tomography: Fundamental Principles, Methodology and Role in Neuropsychiatric Research

Gary W. Small, M.D. Professor, Chair, Behavioral Health Physician-in-Chief, Department of Psychiatry and Behavioral Health, Hackensack Meridian School of Medicine, Hackensack University Medical Center, Hackensack Meridian Health, Hackensack, New Jersey
55.3f Alzheimer Disease and Other Neurocognitive Disorders

Tawny L. Smith, Pharm.D., B.C.P.P. Associate Professor, Department of Psychiatry and Behavioral Sciences, University of Texas, Dell Medical School, Austin, Texas
33.15a Melatonin Receptor Agonists

Yvette Smolin, M.D., M.Ed. Director of Consultation-Liaison Psychiatry, Department of Psychiatry, Westchester Medical Center/New York Medical College, Valhalla, New York
27.14 Psychiatric Care of the Burned Patient

Ingrid Söchting, Ph.D., R.Psych., C.G.P. Clinic Director and Clinical Professor, Psychology and Psychiatry, University of British Columbia, Vancouver, British Columbia, Canada
55.4k Group Therapy

Takahiro Soda, M.D., Ph.D. Assistant Professor of Psychiatry, Department of Psychiatry, Division of Child and Adolescent

Psychiatry, University of Florida, College of Medicine/University of Florida Health, Gainesville, Florida
54.7 Ethical Issues in Child and Adolescent Psychiatry

LalithKumar Solai, M.D. Professor of Psychiatry/Vice-Chair, Clinical Services, Department of Psychiatry and Behavioral Sciences, Medical University of South Carolina, College of Medicine, Charleston, South Carolina
10.2 Delirium

Adrian N. Sondheimer, M.D. Clinical Assistant Professor, Psychiatry Department, University at Buffalo, Jacobs School of Medicine and Biomedical Sciences, Buffalo, New York
54.7 Ethical Is 1.3 Functional Genomics of Human Brain Developmenthiatry

Reneé M. Sorrentino, M.D. Clinical Assistant Professor, Part-time, Department of Psychiatry, Massachusetts General Hospital/Harvard University, Harvard Medical School, Boston, Massachusetts
21.3 Paraphilic Disorders

Traci J. Speed, M.D., Ph.D. Assistant Professor, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland
27.10 Stress and Psychiatry

Henry I. Spitz, M.D., D.F.A.P.A., D.F.A.G.P.A. Clinical Professor of Psychiatry, Department of Psychiatry, Columbia University, Vagelos College of Physicians and Surgeons, New York, New York
32.20 Family and Couples Therapy, 32.21 Group Psychotherapy

Susan Spitz, A.C.S.W., C.G.P. Clinical Instructor of Psychiatry, Columbia University, Vagelos College of Physicians and Surgeons, New York, New York
32.20 Family and Couples Therapy

Stephen M. Stahl, M.D., Ph.D., D.Sc. (Hon.) Adjunct Professor of Psychiatry, Department of Psychiatry, University of California, School of Medicine, San Diego, California
33.7a Pimavanserin

Dan J. Stein, M.D., Ph.D. Professor and Chair, Department of Psychiatry and Neuroscience Institute, Groote Schuur Hospital/University of Cape Town, Cape Town, South Africa
15 Obsessive-Compulsive and Related Disorders

Murray B. Stein, M.D., M.P.H. Distinguished Professor of Psychiatry and Public Health, Department of Psychiatry, University of California, School of Medicine, San Diego, California
14.7 Somatic Therapies for Anxiety Disorders

Erika Steinbrenner, M.D. Psychiatrist, Imagine Healthcare, Chicago, Illinois
32.18 Hallucinogen-Assisted Psychotherapy

Kayla D. Stone, Ph.D. Postdoctoral Associate, Department of Psychiatry, Cumming School of Medicine, Alberta Children’s Hospital / University of Calgary, Calgary, Alberta, Canada
37 Neuroimaging in Psychiatric Disorders of Childhood

Cynthia M. Stonnington, M.D. Professor of Psychiatry, Psychiatry and Psychology, Mayo Clinic, Scottsdale, Arizona
30.8 Physician and Medical Student Mental Health

Martin T. Strassnig, M.D. Adjunct Associate Professor of Psychiatry, Psychiatry and Behavioral Sciences, University of Miami Leonard M. Miller School of Medicine, Miami, Florida
33.2a Dopamine Antagonists

Jeffrey R. Strawn, M.D. Professor of Psychiatry, Pediatrics and Clinical Pharmacology; Co-Director, Center for Clinical and Translational Science and Training, Department of Psychiatry &

Behavioral Neuroscience, University of Cincinnati College of Medicine, Cincinnati, Ohio
33.18a Pediatric Psychopharmacology, 53.5 Pediatric Psychopharmacology

Joan M. Striebel, M.D. Assistant Clinical Professor, Department of Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
33.7a Pimavanserin

Shannon F. Stromberg, M.D. Medical Director and Chief of Psychiatry, Psychiatry and Behavioral Health Program, Presbyterian Healthcare System and Medical Group, Albuquerque, New Mexico
30.3 Physical Violence on Adults

Mandayam Sujata, M.D. Staff Psychiatrist, Department of Psychiatry, Western Psychiatric Hospital of UPMC, Pittsburgh, Pennsylvania
10.2 Delirium

Joji Suzuki, M.D. Director, Division of Addiction Psychiatry, Brigham and Women's Hospital, Boston, Massachusetts
11.1 Substance Use Disorders: Introduction, 11.6 Hallucinogen-Related Disorders

D.W. Svenson, M.A. Doctoral Candidate, Psychology/Behavioral, Cognitive Neuroscience, Wayne State University, School of Medicine/College of Liberal Arts and Sciences, Detroit, Michigan
11.7 Inhalant-Related Disorders

Dragan M. Svrakic, M.D., Ph.D. Professor, Department of Psychiatry, Washington University in St. Louis, School of Medicine; Staff Psychiatrist, VA Medical Center, St. Louis, Missouri
3.6 Neuroscience of Psychoanalytic Object Relations Theory

Rex M. Swanda, Ph.D., A.B.P.P.-C.N. Clinical Assistant Professor, Department of Psychiatry and Behavioral Sciences, University of New Mexico, School of Medicine, Albuquerque, New Mexico
7.4 Neuropsychological Assessment of Adults

Mary Margaret Sweeney, Ph.D. Assistant Professor, Department of Psychiatry and Behavioral Sciences, Behavioral Pharmacology Research Unit, Johns Hopkins University School of Medicine, Baltimore, Maryland
11.4 Caffeine-Related Disorders

Roxy Szeftel, M.D. Clinical Professor, Department of Psychiatry and Biobehavioral Sciences, University of California, David Geffen School of Medicine, Los Angeles, California
54.14 Internet Gaming Disorder in Youth, 54.15 Social Media and Youth

Zebulon Taintor, M.D. Adjunct Professor, Department of Psychiatry, New York University, Grossman School of Medicine, New York, New York
7.9 Electronic Media in Psychiatry

Carol A. Tamminga, M.D. Professor and Chair, Department of Psychiatry, University of Texas Southwestern, Medical School, Dallas, Texas
12.1 Introduction and Overview, 12.16 Psychosis as a Defining Dimension in Schizophrenia

Evan Taniguchi, M.D. Acting Assistant Professor, Department of Psychiatry and Behavioral Sciences/Department of Psychiatry and Behavioral Medicine, University of Washington, School of Medicine/Seattle Children's Hospital, Seattle, Washington
39 Intellectual Disability

Erica Taylor, M.D., M.P.H. Psychiatrist, Assistant Professor, Department of Psychiatry, MD Anderson Cancer Center, Houston,

Texas
56.3 The Role of the Hospital in the Care of Persons with Mental Illness

Michael E. Thase, M.D. Professor, Department of Psychiatry, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine and Corporal Michael J. Crescenz Veterans Affairs Medical Center, Philadelphia, Pennsylvania
13.7 Mood Disorders: Psychotherapy, 13.8 Mood Disorders: Neurobiology, 33.5a.2 Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs) 33.6c Mirtazapine

Mikiko Thelwell, M.D., M.P.H. Resident, Department of Psychiatry, University of Pennsylvania, Raymond and Ruth Perelman School of Medicine, Philadelphia, Pennsylvania
54.16 Gay, Bisexual, Transgender, Queer/Questioning, Intersex, and Asexual (LGBTQIA) Youth

Michelle M. Theodory, B.A. Post-baccalaureate IRTA, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland
14.3 Epidemiology of Anxiety Disorders

Margo L. Thienemann, M.D. Clinical Professor of Psychiatry, Department of Psychiatry and Behavioral Sciences, Stanford University, School of Medicine, Palo Alto, California
53.3 Group Psychotherapy

Giulio Tononi, M.D., Ph.D. Professor of Psychiatry, Department of Psychiatry, University of Wisconsin, School of Medicine and Public Health, Madison, Wisconsin
1.15 Basic Science of Sleep

Marika Toscano, M.D. Physician, Department of Obstetrics and Gynecology, University of Rochester Medical Center, Rochester, New York

30.1 Psychiatry and Reproductive Medicine

*Deceased.

Preface

The Comprehensive Textbook of Psychiatry was conceived in the 1960s when Harold Kaplan, MD, saw the need for a scholarly textbook in the style of the great medical textbooks. He published the first edition in 1967. Then, it was one volume with about 600 pages. However, as you see, it has grown considerably!

Much of the book's growth occurred under the remarkable careers of Benjamin and Virginia Sadock, both psychiatrists at the New York University School of Medicine, who coedited many of the volumes with Dr. Kaplan and then took on the book's leadership after Dr. Kaplan's death in 1998. They continued updating and revising the book through the 10th edition, published in 2017.

Over the book's course, they oversaw an expansion to two volumes and more than 5,000 pages, with more than 600 contributors. This growth reflects the fantastic expansion of the field of psychiatry, with advances in neuroscience, pharmacology, psychological theory and practice, cultural psychiatry, sociology, and many other affiliated areas. To accommodate this, the Sadocks organized the book into different subject area sections, each with an expert contributing editor.

With the Sadocks' retirement, the publishers sought a new set of editors who would respect the mission of these books. We are honored to have been chosen and appreciate the faith the Sadocks have put in us to continue their wonderful tradition. Long-time consumers of the Kaplan and Sadock series (one of us remembers buying the fifth edition during residency [RB]) and then the Sadock and Sadock series of books, we understand all too well the care and thought that has gone into both the organization and writing of these volumes. With that in mind, we have chosen an incremental approach. Thus, whereas some previous editions saw dramatic changes in subject matter or organization, this book will look similar to the last volume, at least superficially. Some chapters have been added and some removed, but the organization remains unchanged. The reader will find a few notable exceptions to this rule, where advances had outpaced the previous edition's approach. For example, readers will find significant changes in the organization and chapters in our biologic treatments section and the cultural and global psychiatry content.

The most significant change is the knowledge contained. Psychiatry is moving ever-increasingly, making this an exciting time to be in the field. We asked each author to update their content and review the latest research in their field. At times this has meant adding or replacing authors. Indeed, a sad part of our jobs was learning of the passing of several distinguished authors. This unfortunate experience was perhaps made more common during this ongoing pandemic. In many cases, the new authors retained much of the format and detail from the previous volumes and acknowledged their predecessors' work in their new chapters.

One practical update is in psychiatric classification. Both the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM) and the World Health Organization's International Classification of Diseases (ICD) have had updates since the last edition of this textbook. In the case of the DSM, the change is relatively modest, representing a textual revision of the fifth edition (DSM-5-TR). The ICD has undergone a more significant revision, updating much of the descriptions and nomenclature for many diseases to reflect advancing medical science. The WHO approved ICD-11 in 2019 and committed to transitioning to the newer system in 2022. For mental health professionals, the most significant change is in their efforts to align ICD with DSM, with more similar terminology and approaches to mental diseases than the previous versions. This revision will simplify things, particularly for hospital systems that rely on the ICD for classification and billing. However, the United States has classically been slow to adopt ICD changes, taking about 10 years for the last one. The United States hopes to transition to the newer nomenclature by 2025, although its full adoption may take longer. You can read more about these approaches and the results in this book's section on Classification in Psychiatry.

The book's many other revisions are too many to relate here, but they will be evident as you read it. Hopefully, readers will also appreciate the book's continued attempt, long championed by the Sadocks, to keep the book readable. As editors, we agree with the maxim, usually attributed to Einstein, that "If you can't explain it simply, you don't understand it well enough." However, we are also mindful of the other Einstein attribution, "Everything should be made as simple as possible, but no simpler." With that in mind, our contributors and we worked hard to make the book as readable as possible while maintaining its high scientific rigor. We wanted this book to be more than a compendium of facts, but rather something we would want to sit down and read—if not cover to cover, then at least through an entire chapter. Being the first to read the book as we edited it, we believe the many authors who contributed to this work have done an awe-inspiring job achieving that. We learned a great deal and enjoyed doing it. At least most of the time.

One aspect of the challenge to balance rigor and readability is the decision to omit within-text citations and limit the references. This approach has been a longstanding policy of this and many other standard textbooks; however, it made many of our authors uncomfortable. Their concern is that readers will see their chapter as unscientific "pop science" or just their opinion. Some even worried about ethical considerations: whether it would appear that they were presenting the work of others as if it was theirs. We trust that the readers will understand otherwise. We all intend each chapter to be a rigorous review of existing literature. Usually, a complete reflection of the many sources contributing to each chapter would require hundreds, if not thousands, of citations and references, making the result unwieldy. We trust that the readers will understand that each chapter represents the authors' synthesis of the many sources they reviewed to create a coherent work. Each chapter does list critical references at the end for further study. However, in most cases, many more references than we can include contribute to the ideas and facts in a chapter. We accept that this is the nature of works that attempt to review massive fields of study. Hopefully, readers will appreciate the reasons for and results of this approach. If you do not, please understand that this decision was ours alone.

The limitation in this approach, we realize, is somewhat mitigated by the connected world we live in, where interested readers can quickly and easily search for relevant papers online—accessibility likely to be broadened by the advances in artificial intelligence. Such intelligent systems are already producing reviews of complicated subjects, albeit with mixed results. Will that field advance so dramatically that we will not need further editions of this book? We doubt it. When we reflect on the most important influences in our education as psychiatrists, we do not recount the countless computer screens we have viewed. Instead, we remember the fantastic psychiatrists and other experts who taught us throughout our training and careers. We are delighted to say that we had the opportunity to include some of them in this book. Although the written word will never equal the power of a human relationship, we hope that the chance to sit down and read the thoughts of the many expert minds found here will be an experience we all can appreciate long into the future.

OUR MISSION STATEMENT

Our mission is to educate mental health and related professionals in contemporary psychiatry.

We emphasize the word "educate." Today, there is no end to information sources. What we seek here is not one more repository of facts but rather a system of education that is complete, authoritative, and accessible. This book represents a crucial part of that mission, being the most comprehensive of the books. However, it is part of a series of books devoted to psychiatric education. Also included are the *Synopsis of Psychiatry*, a distillation of this book into a single volume, and the *Concise Textbook of Psychiatry*, which further reduces the *Synopsis*, concentrating on the most clinically relevant sections of the book. Also related are books devoted to subspecialties in psychiatry, most notably the *Concise Textbook of Child and Adolescent Psychiatry*, edited by child psychiatrist Caroly Pataki, M.D. We are considering other specialty volumes as well. Finally, the *Study Guide and Self-Examination Review of Psychiatry* are written by Eric Williams, M.D., and Lindsay Moskowitz, M.D., both respected educators. That volume, used independently or alongside the *Synopsis*, represents a further example of our commitment to education. One of the best ways to learn new material is through self-assessment, and we produced the *Study Guide* with that purpose in mind.

Acknowledgments

Over time, thousands of psychiatric, mental health, and other experts have contributed to this book. Many are long gone, but they have put their mark on the current volume, and we appreciate them all. We also thank the hundreds of authors who often endured work pressures, the pandemic, and our nagging as they took on the challenge of summarizing their fields. They put in an incredible effort, the results are remarkable, and we gratefully thank them all.

We give special thanks to the section editors of this book. A book of this size is well beyond our abilities to review as thoroughly as we would wish, and these editors took on the lion’s share of the oversite in their sections. These editors include Iqbal “Ike” Ahmed, M.D., Gaston Baslet, M.D., Carlyle Chan, M.D., Dilip Jeste, M.D., John Krystal, M.D., Roberto Lewis-Fernández, M.D., Kathleen Merikangas, Ph.D., Christine Yu Moutier, M.D., Caroly Pataki, M.D., Joji Suzuki, M.D., Carol Tamminga, M.D., Sasson Zemach, M.D., and Joseph Zohar, M.D. It would be a wild understatement to say that we could not have done this without them, and we owe them all a lasting debt of gratitude.

We owe a similar debt to the publishing team at Wolters Kluwer. Particular thanks go to Chris Teja, our Acquisitions Editor; Anne Malcolm, the Associate Director for Content Development; Ariel S. Winter, our Development Editor; and most of all, Sean Hanrahan and Erin Hernandez, Editorial Coordinators, who had the dubious pleasure of being in almost daily communication with us.

We want to acknowledge our respective institutions and universities, The Menninger Clinic, The Baylor College of Medicine, and the University of Central Florida, for their enduring support in our careers.

Finally, we remain always thankful to Ben and Virginia Sadock, who are wonderful people and great scholars, for creating what we consider the finest textbooks in psychiatry and trusting us to continue the tradition.

Foreword

A BRIEF HISTORY

Harvey Cushing (1869–1939), the father of modern neurosurgery wrote a biography of Sir William Osler for which he won a Pulitzer Prize. In that book he described Osler's writing of his famous *Textbook of Medicine*. Osler devoted his life to that magnum opus which prompted Cushing to write the following: *The birth of a successful textbook, like that of a child, may hold its authors in unexpected bondage*. That saying resonated with us.

The first edition of the *Comprehensive Textbook of Psychiatry* (CTP) was published in 1967, over 55 years ago. Now in its 11th edition, it is the most widely used psychiatric textbook in this country and around the world, translated into several languages. The book has been well received not only by mental health professionals but also by reviewers. The *Journal of the American Medical Association* published many reviews of the book using terms like "well-organized, up to date, comprehensive" among other laudatory phrases. It has been called "a university without walls."

A foreword is rarely written by an author or editor of a previous edition of a book. So, we were surprised, pleased, and honored to be offered this opportunity by the editors. It gave us a chance to reflect on our work. To help us we decided to review the forewords written by others and the prefaces written by us. This would help jog our memories. We decided to take excerpts from some of the forewords to let the reader know how the editions evolved and how the issues facing the field changed over these many years.

The book began as the brainchild of Harold Kaplan, M.D. (1928–1998) who wanted to develop a textbook in psychiatry that would rival the great textbooks of medicine like *Nelson's Textbook of Pediatrics* or the *Cecil Textbook of Medicine*. He eventually achieved this objective but not before several rejections. One major medical publishing house rejected the project commenting that "trying to get a group of psychiatrists to collaborate would be like trying to herd cats." Years later, that same publisher said it was the biggest mistake they had ever made. One editor did accept the proposal, Chuck Reville at Williams & Wilkins (now Wolters Kluwer).

Unfortunately, Harold passed away in 1998 after the sixth edition was published, and we dedicated the seventh edition to him:

> In addition to his academic career, Dr. Kaplan was a clinical psychiatrist who maintained a large and active practice. He believed strongly in the art and science of psychotherapy, and although trained as a psychoanalyst, he followed no particular school. He was eclectic in the true sense of the word; he applied the best of each school in his work with patients. His vast clinical experience allowed him to create a textbook of value to basic behavioral scientists and more importantly, to clinicians.
>
> As an editor, Dr. Kaplan was a hard task master who demanded perfection. He encouraged each contributor, exhorted them when necessary, and expected and received their best work.

In Harold's last sixth edition, the following was written about the editor to be.

> In all our previous books, she (VS) served as an assistant to the editors and actively participated in every editorial decision. Her enthusiasm, sensitivity, comprehension, and depth of psychiatric knowledge were of immeasurable importance. She has ably represented not only the viewpoint of women in medicine but has also made many contributions to the content of this textbook.

The text could not have come into being or have continued without our contributors. We ended each preface thanking them for their cooperation and participation. As each edition appeared and the reputation of the text became more apparent, it was easier to recruit contributors. We sought experts in their respective fields who were often persons who developed or originated an area of study. Aaron Beck is one example. Having developed cognitive behavioral therapy, he wrote the chapter on CBT for the textbook. Arvid Carlsson, the Nobel laureate who discovered dopamine was another.

Our practice was to invite contributors and stay in touch with them by telephone. That contact with them was effective in getting them to complete their sections on time, a major concern for editors of a multi-authored textbook. And those phone calls enabled us to get to know our contributors personally, a rewarding and valuable fringe benefit of editing this book.

To date over 2,000 psychiatrists, psychologists and behavioral scientists have written sections for the book. Some are long gone but their work lives on in the various editions of the book that can be accessed via the internet. We consider many of their contributions to be classics.

As the book expanded we added a third editor, Pedro Ruiz, (1936–2023) a close personal and professional associate, to the ninth edition. At the time he was Professor of Psychiatry at the University of Texas Medical School at Houston and President of the World Psychiatric Association. His participation immeasurably enhanced and facilitated our work.

The first Foreword did not appear until the fourth edition. It was written by Robert Cancro, M.D., who was at the time Professor and Chairman of the Department of Psychiatry at New York University. He analyzed the prior editions. The first brought structure and discipline into the field; the second and third increased our understanding of clinical psychiatry by including basic science; and the fourth integrated the application of neuroscience as crucial to understanding the problems of patients. He went on.

> It is awkward for this writer to acknowledge the debt to Harold Kaplan and Benjamin Sadock, because, in addition to being colleagues they are personal friends and members of the same faculty. It is an irony of Western culture that one can acknowledge indebtedness to a stranger more easily than to those who are near and dear. The time and effort demanded of them to make this book possible is known to only a handful of people.

In the eighth edition, John Nemiah (1918–2009), at the time Professor of Psychiatry at Harvard Medical School and long-standing editor of the *American Journal of Psychiatry* commented on an issue that is still present: the conflict between a psychoanalytic and psychodynamic approach versus a biologic approach to understanding human behavior. He was prescient when he wrote the following.

> Psychiatry has been reassessing its position. It is fortunate that the current self-reflection coincides with recent major advances in knowledge of the biological side of psychiatric illness and human behavior. The understanding of brain function is beginning to approximate the sophistication of psychological observations and theories, inspiring the hope that psychiatrists are coming closer to substantial correlations between those two complementary approaches. Already, the contributions of psychopharmacology have made it possible for psychiatrists to alleviate the symptoms of major psychoses that were generally beyond the reach of their skills. Biological knowledge, in other words, is beginning to restore balance that has too long tipped steeply toward psychology. There is danger in this too - a danger that the balance dip too far in the other direction and that psychiatrists forget the important gains that have been made in the psychological and social understanding of human behavior.

For the ninth edition of the textbook, Robert Michels, M.D., then University Professor of Medicine and Psychiatry at Weill Cornell Medical College, wrote the foreword. He entitled his contribution *The Future of Psychiatry*. He was concerned about the social and economic structure of the health care system, as are we. He covered broad areas: medicine in general; science and research; education and many others. A brief excerpt of his many interests follows.

> The social and economic structure of the healthcare system has lagged behind the development of knowledge and is currently the limiting factor in the quality of care available to most patients. The future promises a continuing growth of our knowledge and, particularly, an increased rate of its translation to clinically relevant tools. However, developments in the healthcare system are more difficult to predict and more problematic. Psychiatry is increasingly recognized as a full participant in medicine and health care and is unlikely to return to its former marginal status, as represented in the past by the asylum, the stigma associated with mental illness, and the woeful underfunding of psychiatric services. However, we continue to grapple for a more rational and effective healthcare system in the United States, and although the urgency is increased, the outcome is uncertain. The magnitude

of the problem suggests that larger social and political forces will determine the course, and the psychiatric profession will have to struggle merely to participate in the dialogue.

Psychiatry for the future will evolve in the context of the future use of these–of medicine, of the other mental health professions, of the scientific basis of psychiatric practice, of the healthcare system, of education, and of the organization of the profession. Each will change, and as it is so often said, the future is, therefore, hard to predict.

For the last edition the foreword was written by Herbert Pardes, M.D. At the time he was the Professor of Psychiatry and Dean of the Columbia College of Physicians and Surgeons. His interests were in the recent history of psychiatry, especially legislation that made mental health “more visible, accessible and patient oriented.” He mentioned the benefits that accrued to the mentally ill from the Community Mental Health Act of 1963 that led to deinstitutionalization and community health centers. His foreword emphasized emerging research into the cause and treatment of mental illness, and he regretted the trend to defund research and treatment programs. He focused on problems that exist to this day where psychiatry has a vital role to play.

A multitude of factors, that is, veterans’ problems, increased suicide, increased cost of comorbid psychiatric and nonpsychiatric conditions, mass violence along with recognition of the overwhelming numbers of individuals who both need care yet are winding up in prisons and jails, has given mental health unprecedented visibility.

The many editions of CTP reviewed here are a living history of psychiatry in the last half-century. There have been so many changes during this period, in the delivery of care, in our understanding of what causes mental illness, in treatment methods and in methods of investigation. Neuroscience, which occupied no more than 200 pages in the first edition is now covered in almost 1,000 pages. The first edition was about 1,600 pages in length, the last edition had close to 5,000 pages. Such was and is, the expansion of knowledge. Despite this, psychiatry is a frontier science with large gaps still to be filled. The connectome which has as its goal the mapping of more than 86 billion neurons of the brain is in its infancy. It may hold the clue that finally explains psychiatric disorders. New editions of this textbook will record these events.

One of the insights we had in reviewing the editions was an awareness of how much we missed Harold. Thinking about him 25 years after his death brought back many memories. It was more than a work relationship—it was a friendship of long standing. We went on vacations with our families while working at the same time.

This has been a labor of love, but after more than 50 years of working on this textbook it was time to release ourselves from bondage. The search for new editors to carry on our work resulted in the choice of Robert Boland, M.D. and Marcia Verduin, M.D., distinguished academicians. We had the opportunity to give them some advice, but they produced the current edition on their own. We are pleased to see that they organized the book based upon the solid foundation of the previous edition.

We said goodbye to “our child” with, as in all partings, feelings of sadness. But we take comfort that the book is in very excellent hands. They have done a superb job and we wish them both many more editions of this classic textbook.

Benjamin Sadock, M.D. and Virginia Sadock, M.D.

Neural Sciences

1.1 The Neuroscience of Psychiatry

John H. Krystal, M.D.

This section of the *Textbook* contains a remarkable collection of 30 chapters that provide an overview of the landscape of the current understanding of the neuroscience foundations of psychiatry. The brain is the principal organ of psychiatry, so understanding brain science is the starting point for a comprehensive knowledge of the field. These chapters bear careful reading as they reflect the first indications of the emergence of explanatory science within psychiatry. This progress arises from the application of technologies that have transformed our understanding of the brain and brain-behavior relationships, such as optogenetics, DREADDs, and CRISPR. It also arises from the maturation of fields, such as cognitive neuroimaging and psychiatric genetics, transforming them from intellectual curiosities to strategies to answer important questions about human behavior and mental illness.

What are the signs of this progress? The last issue of *The Comprehensive Textbook in Psychiatry* appeared in 2009. Thus a quote attributed to Bill Gates, known as “Gates Law” applies, “most people overestimate what they can achieve in a year, but underestimate what they can achieve in ten years.” There are many inspiring stories. With respect to etiology, advances in genome sequencing have enabled the discovery of growing numbers of rare gene variants that contribute significantly to the genetic risk for autism and schizophrenia. We are now beginning to understand in what regions of the brain and in which cell types these genes are preferentially expressed, as well as when in development, these genes are critically engaged. This knowledge establishes a foundation for understanding when, where, and how the development of the brain goes awry to give rise to the pathophysiology of psychiatric disorders. With the emergence of spatial transcriptomics, we will soon resolve our molecular understanding of pathophysiology to cells embedded in specific microcircuits within particular brain regions. As we have seen for Mendelian disorders, such as spinal muscular atrophy, identification of the molecular etiology may set the stage for disease-modifying interventions, such as gene therapy. With respect to pathophysiology, optogenetic studies in animals, neuroimaging studies in humans, and a new generation of intracortical physiology and stimulation studies have provided deep new insights into how depression and other psychiatric disorders might be expressed at the level of neural circuits. These “raw data” provide the basis for computational neuroscience studies that rigorously describe for the first time the relationships between the activity of neurons and networks or networks and behavior. In turn, these insights are providing a basis for a growing array of neurostimulation treatments for mood disorders. At the same time, some transformative advances in treatments, such as the discovery of the rapid antidepressant effects of ketamine and the psychedelics, have stimulated basic science advances that shed new light on the neurobiology of stress. In fact, since the last edition of this textbook, the FDA has approved the first two mechanistically novel antidepressants in over 50 years, Esketamine (treatment-resistant depression and depression in the context of increased suicide risk) and brexanolone (postpartum depression).

Why do psychiatrists need to understand neuroscience to practice their art? Psychiatry is moving away from viewing individual psychiatric patients solely as representative of static diagnostic categories, as might be reflected in the *Diagnostic and Statistical Manual*. One might predict that as psychiatrists become increasingly comfortable incorporating an understanding of the neurobiology of psychiatric disorders into their clinical formulations of individual patients, it will enrich their understanding of their patients and suggest new opportunities to enhance treatment.

CASE STUDY

The author will illustrate this point by referring to a case conference in which he participated, which he first presented in a blog to the American College of Neuropsychopharmacology in January 2012. The Yale Psychiatry Residents invited the author to interview a patient and then present his formulation to their group. The patient was a young man who suffered from long-standing psychotic symptoms. He met diagnostic criteria for schizophrenia, exhibiting many domains of preserved intellectual capacity but noted problems with sustained attention and memory. He also exhibited low levels of affective blunting but impairments in many social and functional domains. Upon interview, he also vividly described a childhood pattern of accentuated attention to nonsocial environmental details, and he both described and displayed perseverative tendencies and mild irritability when challenged. He also mentioned that both the diagnoses of schizophrenia and bipolar disorder ran in his family. With regard to treatment, he felt that clozapine was the most effective medication prescribed for him. In addition, he was treated with anticonvulsants, lamotrigine, and valproate.

How could psychiatrists understand the appearance of features of autism spectrum disorder (ASD) and his family history of both schizophrenia and bipolar disorder?

This patient presented opportunities to reflect on challenges in our diagnostic schema. Bleuler suggested that autistic thinking was a core feature of schizophrenia, but this feature is no longer included in the diagnosis of schizophrenia. Yet, a growing number of rare gene variants with relatively large effects on the risk for schizophrenia also contribute to the risk for ASD. Overlap of schizophrenia and ASD symptoms might be an illustration of pleiotropy. Similarly, recent large-scale GWAS studies report regions of the genome that appear to convey relatively modest increases in the risk for both schizophrenia and bipolar disorder. Thus, genetics provides some clues that may help to guide thinking about the features of the presentation of individual patients that conflict with the diagnostic categories of DSM-IV.

Why would someone add the antipsychotics lamotrigine and valproate to enhance clozapine treatment of schizophrenia?

Currently, there is a small evidence base to guide the pharmacotherapy of clozapine-resistant schizophrenia symptoms. The author was reminded of the evidence in animals and humans that lamotrigine, by itself or in combination with clozapine, attenuates some of the effects of psychotogenic NMDA receptor antagonists. Subsequently, lamotrigine was not found generally effective as an antipsychotic augmentation strategy unless patients had symptoms that had been highly resistant to treatments, including clozapine. Further, anticonvulsants like lamotrigine might protect against the seizure risk associated with pharmacotherapy with higher clozapine doses. Thus, there was a rationale for adding lamotrigine to clozapine in this case. However, the same could not be said for valproate. Psychiatrists discussed the pharmacoepidemiologic data describing common coprescription of valproate and antipsychotic medications for schizophrenia despite the lack of compelling efficacy data for valproate in this adjunctive role.

The invitation from the residents to interview a patient in front of them and to present a “biopsychosocial” formulation was embedded in an unspoken question. What do we mean by the “bio” component of the biopsychosocial formulation? Historically, the biologic domain was represented by general knowledge of psychopharmacology, medicine, and clinical neurology. Basic neuroscience was not included. In fact, historically, neuroscience education was not required in the psychiatry residency. To put this question another way, does it make a difference to a practicing psychiatrist to be a student of genetics and translational neuroscience? In the case that I discussed, the answer turned out to be absolutely! In fact, it seemed that the author’s background in neuroscience informed nearly every aspect of the interview, including the questions that the author asked, the hypotheses that he generated about the patient, and his thoughts about the treatment plan. While it was not yet clear to the author how his knowledge of the genetics of schizophrenia would guide the treatment of this patient, it was not hard to see how keeping abreast of developments in neuroscience might someday make this possible. There is also a growing appreciation that neurobiologic data, along with other types of data, will inform the development of more systematized personalized medicine approaches in psychiatry to improve the matching of individual patients to specific treatments.

REVIEW OF THE NEUROSCIENCE CHAPTERS

To facilitate this type of interplay between neuroscience and clinical psychiatry, the authors structured this section of the *Textbook* to cover the waterfront of progress in neuroscience that was most relevant to psychiatry. Experts in the field were asked to provide chapters that would be rigorous but accessible to clinicians. The section builds from elemental questions, that is, genetics, the properties of neurons, the basics of chemical neurotransmission, cortical networks, and network functions, and the pathophysiology of psychiatric disorders. The topics covered are broad, but some topics were not included. Similarly, the reviews provide depth, but hopefully not at the expense of accessibility. The Neuroscience Section of the Textbook is organized into five thematic subsections that are described briefly below.

The first subsection begins with three chapters that describe the organization and development of the brain. The first chapter (Chapter 1.2) in this subsection introduces the reader to core themes related to the overall structural organization of the brain, while the second and third chapters (Chapters 1.3 and 1.4) introduce the reader to molecular and cellular mechanisms governing the development of what is arguably one of the most complex structures in the universe.

The next seven chapters provide an overview of the basic signaling mechanisms that underlie communication and plasticity within the brain. Chapter 1.5 introduces readers to core cellular and synaptic mechanisms underlying neural communication. The next five chapters review the principal classes of chemical neurotransmission in the brain, including amino acid neurotransmitters (Chapter 1.5), monoamine neurotransmitters (Chapter 1.7), neuropeptides (Chapter 1.6), neurotrophic factors (Chapter 1.7), and novel neurotransmitters (Chapter 1.8). Intraneuronal signaling, the mechanisms through which the effects of transmitters and drugs are transduced chemically within neurons, are reviewed in Chapters 1.9 and 1.10.

Homeostatic and appetitive mechanisms are covered in the five chapters in the third subsection. These chapters cover topics that are implicated in nearly every psychiatric condition, such as psychoneuroendocrinology (Chapter 1.12), immune-brain interactions (Chapter 1.13), chronobiology (Chapter 1.14), sleep and insomnia (Chapter 1.15), pain (Chapter 1.16), and appetite (Chapter 1.17).

The fourth subsection covers a wide range of topics that are sometimes referred to as “the ’omics.” Chapter 1.18 introduces the reader to the relationship between genetics and brain biology, that is, the genome (the sources of genetic variation), the transcriptome (the levels of gene expression), and the proteome (the levels of various proteins). The following chapters in this subsection address particular aspects of psychiatric risk and resilience, including genomics (Chapter 1.19) and epigenomics (Chapter 1.20). Epigenomics is a topic of growing interest with regard to psychiatry biomarker development as epigenomic modifications provide a path for various environmental exposures (stress, abused substances, rewarding stimuli) to produce lasting changes in gene expression without altering the DNA sequence. Chapter 1.21 reviews the challenging area of pharmacogenomics, that is, the effort to find genomic predictors for the safety and effectiveness of psychiatric treatments. Lastly, for this subsection, animal models for psychiatric disorders are reviewed in chapter 1.22. Animal models, also known as animal research platforms, provide unique opportunities to test causal hypotheses related to brain structure, chemistry, and function. As a result, they are a critical component of the translational neuroscience mission in psychiatry.

The last 10 chapters in Section 1 cover special topics in systems, cognitive, and behavioral neuroscience. Chapter 1.23 covers basic issues in systems neuroscience. Chapter 1.24 addresses the important area of computational modeling, and it provides a foundation for the emerging focus on computation in psychiatry, that is, “computational psychiatry.” Chapters 1.25 to 1.28 present the key techniques for studying human cortical circuit function and chemistry, including nuclear magnetic resonance (sMRI, fMRI, dwMRI/DTI, MRS), cortical electrophysiology (EEG, MEG), and radiotracer imaging (PET, SPECT). Neuroscience is also informing our understanding of our sense of self (Chapter 1.29). The last two chapters in this section address learning theory and its application to the study of addiction (Chapters 1.30 and 1.31).

CONCLUSIONS

The information conveyed in the following 30 chapters provides evidence that psychiatric neuroscience is progressing at a dizzying pace. Nonetheless, in the final analysis, psychiatrists must be humble with regard to our current understanding of the biology and treatment of psychiatric disorders. The brain is unimaginably complicated. To quote chapter 1.3, it has “approximately 86 billion neurons connected by hundreds of thousands of kilometers of myelinated axons and several hundred trillion to well over a quadrillion synapses, along with a roughly equal number of glial cells.” Fundamental aspects of the pathophysiology of neuropsychiatric disorders remain beyond our grasp. Although some parts of the psychiatric community are put off by the growing complexity of neuroscience, others are attracted to the increasing explanatory power of this work. Although cautious in applying neuroscience advances to patients, psychiatry probably overestimates our knowledge and underestimates the challenges faced in trying to understand the etiology, pathophysiology, treatment, and prevention of neuropsychiatric disorders. Nonetheless, psychiatrists have a clinical, scientific, and humanistic imperative to continue to advance our understanding of the neurobiology of psychiatric disorders and to see that this knowledge improves the clinical practice of psychiatry.

Before closing, the author wishes to acknowledge the outstanding quality of the chapters in this Section as well as the wonderful collaboration with Mr. Sean Hanrahan and Dr. Robert Boland in shaping this Section. The author had the pleasure of reading these chapters several times and, with each repetition, learned more. He thanks the authors of these chapters for helping to inform you about some of the most exciting advances in all of science and for making this process so enjoyable.

1.2 Functional Neuroanatomy

DARLENE S. MELCHITZKY, M.S., AND DAVID A. LEWIS, M.D.

The broad range of affective, cognitive, and behavioral characteristics of humans arise as a consequence of specific patterns of activation in networks of neurons that are distributed across the central nervous system (CNS). These patterns of activation are mediated by the connections among specific brain structures. Consequently, understanding the neurobiologic bases for the disturbances in affective, cognitive, and behavioral processes present in psychiatric disorders requires an appreciation of the major principles governing the functional organization of these structures and their connections in the human brain. This chapter reviews some of these anatomic principles and illustrates them in the functional circuitry of neural systems that are of particular relevance to psychiatric disorders.

PRINCIPLES OF BRAIN ORGANIZATION

Cells

The human brain contains approximately 10^{11} nerve cells or *neurons*. In general, neurons are composed of four morphologically identified regions (Fig. 1.2–1): (1) the cell body, or *soma*, which contains the nucleus and can be considered the metabolic center of the neuron; (2) the *dendrites*, processes that arise from the cell body, branch extensively, and serve as the major recipient zones of input from other neurons; (3) the *axon*, a single process that arises from a specialized portion of the cell body (the *axon hillock*) and conveys information to other neurons; and (4) the *axon terminals*, fine branches near the end of the axon that form contacts (*synapses*) generally with the dendrites or the cell bodies of other neurons, release neurotransmitters, and provide a mechanism for interneuronal communication.

Most neurons in the human brain are considered to be multipolar in that they give rise to a single axon and several dendritic processes. Although there are numerous classification schemes for neurons in different brain regions, almost all neurons can be considered to be either projection or local circuit neurons. *Projection neurons* have long axons and convey information from the periphery to the brain (sensory neurons), from one brain region to another, or from the brain to effector organs (motor neurons). In contrast, *local circuit neurons* or *interneurons* have short axons and process information within distinct regions of the brain.

Neurons can also be classified according to the neurotransmitters they contain; for example, the neurons of the substantia nigra are often classified by their dopamine content. However, some neurons may contain more than one substance used for neurotransmission. Identification of neurons by their neurotransmitter content in anatomic studies provides a means for correlating the structure of a neuron with certain aspects of its function. However, neurotransmitters have defined effects on the activity of neurons, whereas complex brain functions, such as those disturbed in psychiatric disorders, are mediated by the coordinated activity of ensembles of neurons. Thus, the effects of neurotransmitters (or of pharmacologic agents that mimic or antagonize the action of neurotransmitters) on behavioral, emotional, or cognitive states must be viewed within the context of the neural circuits that they influence.

In addition to neurons, the brain contains several types of *glial* cells (Table 1.2–1). *Astrocytes* are the most numerous class of glial cells and are classified as either protoplasmic or fibrous. Protoplasmic astrocytes are large cells located exclusively in the gray matter with many fine and elaborate processes. In contrast, fibrous astrocytes are smaller with less complex processes and reside exclusively in the white matter. Protoplasmic astrocytes have been demonstrated to serve a number of functions, including participation in the formation of the blood–brain barrier, removal of glutamate and γ-aminobutyric acid (GABA) from the synaptic cleft, and buffering of the extracellular potassium (K^+) concentration.

FIGURE 1.2–1. Drawing of the major features of a typical neuron, oligodendrocyte, and astrocyte. **A, B:** The main features of neurons include a cell body, dendrites, a principal axon, and axon terminals. The principal axon is myelinated by neighboring oligodendrocytes. **C:** Axon terminals branch off axons and form synapses with postsynaptic neurons via the release of neurotransmitters stored in synaptic vesicles. **D:** Fine astrocytic processes surround synapses and regulate neurotransmission, while astrocytic endfeet contact blood vessels and regulate blood flow. (Adapted with permission from Gilman S, Winans-Newman S. *Manter and Gatz's Essentials of Clinical Neuroanatomy and Neurophysiology*. 10th ed. FA Davis Co; 2003:2.)

The close contact of their processes with neurons and blood vessels suggests that protoplasmic astrocytes may help support the energy requirements of neurons. For example, distinctive processes of protoplasmic astrocytes called endfeet line the basal lamina of blood vessels. These endfeet appear to extract glucose from the blood and convert it to lactate which is then released for neurons to uptake and use as an energy substrate. The endfeet may also play a role in the regulation of cerebral blood flow leading protoplasmic astrocytes to be referred to as a neurovascular bridge. In addition to these regulatory functions, protoplasmic astrocytes are involved in synaptic neurotransmission in two distinct ways. First, perisynaptic astrocytic processes express a variety of neurotransmitter receptors, and these receptors are stimulated by the release of neurotransmitters from presynaptic axon terminals. The activated glial cell then releases gliotransmitters that can stimulate the postsynaptic neuron. Thus, the perisynaptic astrocyte is an active partner in synaptic transmission, creating what has been termed the tripartite synapse. This feature allows astrocytes to regulate both glutamatergic/excitatory as well as GABAergic/inhibitory neurotransmission. Second, neurotransmission is regulated by the structural network of astrocytes, which has been shown to comprise nonoverlapping domains of individual astrocytes. In the hippocampus and the cerebral cortex, individual astrocytes possess their own domain, with only their most distal processes interdigitating with processes of neighboring astrocytes. This pattern of organization creates distinct astrocytic domains, in which individual astrocytes modulate the activity of neurons and synapses.

Table 1.2–1. Glial Cells

	Protoplasmic Astrocytes	Fibrous Astrocytes	Oligodendrocytes	Schwann Cells	Microglia
Location	Contact neuronal cell bodies, dendrites, and axons in gray matter; form a complete lining around the external surfaces of the CNS and around CNS blood vessels	Organized along white matter tracts; Endfeet contact blood vessels, ependymal, axons, and nodes of Ranvier	Myelinating oligodendrocytes form myelin sheaths around CNS axons; satellite oligodendrocytes surround CNS neuronal cell bodies	Form myelin sheaths around myelinated axons and ensheath unmyelinated axons	Gray and white matter of CNS
Function	Maintenance of extracellular ionic environment; secretion of gliotransmitters and growth factors; structural and metabolic support of neurons; regulation of blood flow	Support of axons in white matter	Myelinating oligodendrocytes—myelination; satellite oligodendrocytes—unknown	Myelination; biochemical and structural support of myelinated and unmyelinated axons	Scavenging and phagocytosis of debris after cell injury and death; synaptic pruning of dendritic spines during postnatal development; monitoring synaptic connections

Modified from Mihailoff GA, Haines DE. The cell biology of neurons and glia. In: Haines DE, Mihailoff GA. *Fundamental Neuroscience for Basic and Clinical Applications.* 5th ed. Elsevier; 2018:25.

The cell bodies of fibrous astrocytes are evenly distributed within the white matter, and unlike protoplasmic astrocytes, their processes overlap. Some processes form endfeet that contact blood vessels, ependymal cells, axons, and nodes of Ranvier. Fibrous astrocytes appear to play the traditional supportive role of neuroglia.

Oligodendrocytes and *Schwann cells*, found in the CNS and peripheral nervous system, respectively, are small cells that wrap their membranous processes around axons in a tight spiral. The resulting *myelin sheath* facilitates the conduction of action potentials along the axon. *Satellite oligodendrocytes* are found preferentially in gray matter, and their perineuronal location suggests that they may be involved in the regulation of the environment surrounding neurons.

The third class of glial cells, the *microglia*, is derived from macrophages and historically was thought to function solely as scavengers, eliminating the debris resulting from neuronal death and injury. However, studies over the last decade have demonstrated that microglia also regulate neurogenesis and synaptic function. For example, microglia are involved in the synaptic pruning of dendritic spines during postnatal development. In addition, microglia may have the ability to regulate the function of neuronal networks by constantly monitoring the status of synaptic connections and integrating new information when necessary.

Alterations in glial cells may contribute to the pathophysiology of psychiatric disorders. For example, stereologic studies of postmortem human brain tissue have revealed altered glial cell number in the dorsal prefrontal cortex of individuals with schizophrenia and in the subgenual medial prefrontal cortex in depressed individuals. Moreover, the decrease in cerebral blood flow in the prefrontal cortex of individuals with depression may be linked to a reduction in the amount of blood vessel coverage by astrocytic endfeet. Sleep disturbances can be comorbid with many psychiatric disorders, and thus clearance of neuronal and glial waste products through the glymphatic system during normal sleep may be impaired in these disorders. Although some putative susceptibility genes for schizophrenia are selectively expressed in glial cells, it is still unclear whether the alterations in glial cell number reflect the disease process or are a consequence of treating the disease.

Architecture

Neurons and their processes form groupings in many different ways, and these patterns of organization, or architecture, can be evaluated by several approaches. The pattern of distribution of nerve cell bodies, called *cytoarchitecture*, is revealed by aniline dyes called Nissl stains that stain ribonucleotides in the nuclei and the cytoplasm of neuronal cell bodies. The Nissl stains show the relative size and packing density of the neurons and, consequently, reveal the organization of the neurons into the different layers of the cerebral cortex. In certain pathologic states, such as Alzheimer disease (referred to as Major Neurocognitive Disorder due to Alzheimer type in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* [DSM-5]), neuronal degeneration and loss result in striking changes in the cytoarchitecture of some brain regions (Fig. 1.2–2).

Other types of histologic techniques, such as silver stains, selectively label the myelin coating of axons and consequently reveal the *myeloarchitecture* of the brain. For example, certain regions of the cerebral cortex—such as area MT, a portion of the temporal cortex involved in processing visual information—can be identified by a characteristic pattern of heavy myelination in the deep cortical layers. The progression of myelination is highly region specific, may not be complete for years after birth, and may be a useful anatomic indicator of the functional maturation of brain regions.

Immunohistochemical and other related techniques—which identify the location of neurotransmitters, their synthetic enzymes, or other molecules within neurons—can be used to determine the *chemoarchitecture* of the brain (Fig. 1.2–3B). In some cases, these techniques reveal striking regional differences in the chemoarchitecture of the brain that are difficult to detect in cytoarchitecture.

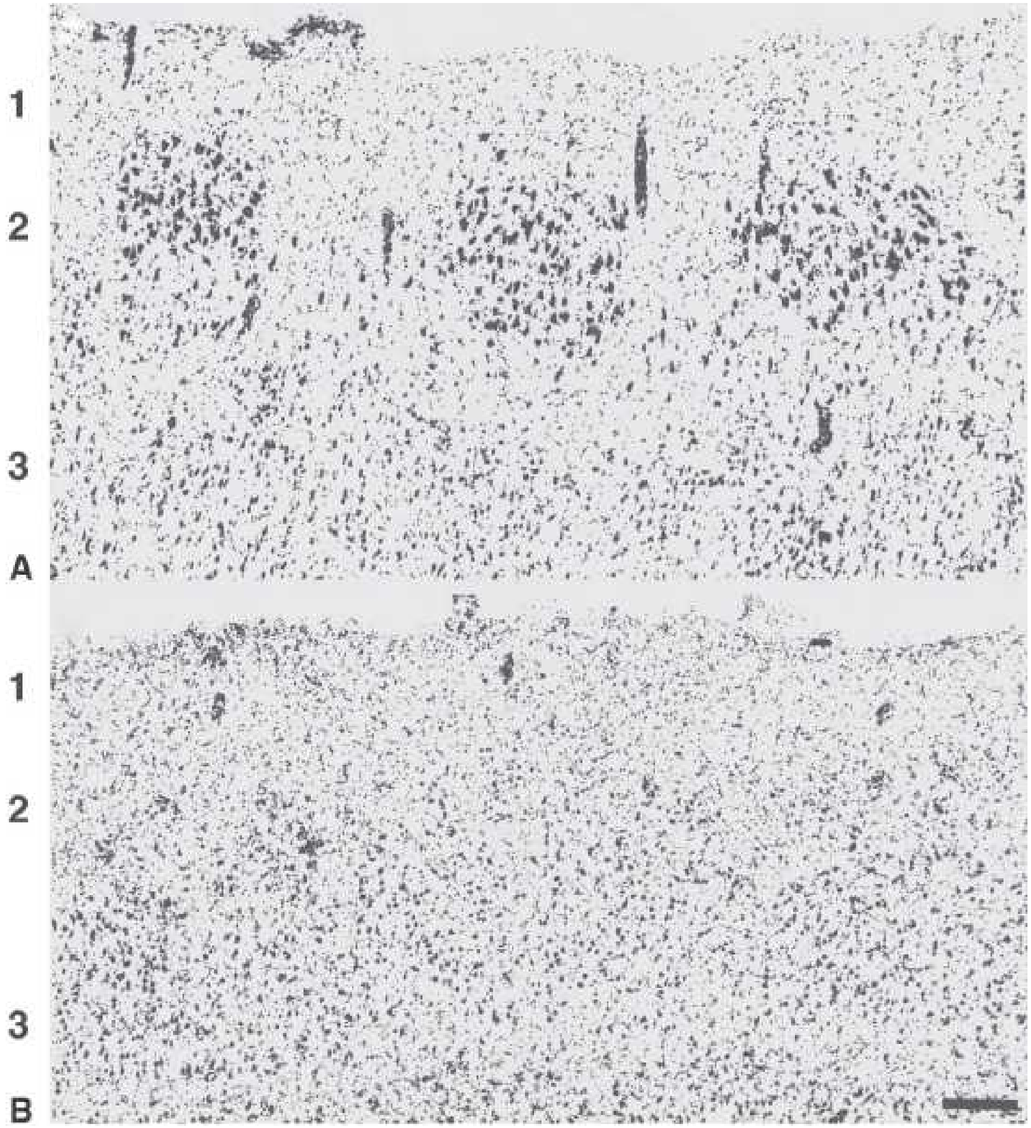

FIGURE 1.2–2. Nissl-stained sections of the superficial layers of the intermediate region of human entorhinal cortex. **A:** In the control brain, layer 2 contains clusters or islands of large, intensely stained neurons. **B:** In Alzheimer disease, these layer 2 neurons are particularly vulnerable to degeneration, and their loss produces a marked change in the cytoarchitecture of the region. Arabic numbers indicate the location of the cortical layers. Calibration bar (200 μm) applies to A and B.

Connections

Every function of the human brain is a consequence of the activity of specific neural circuits. The circuits form as a result of several developmental processes. First, each neuron extends an axon, either after it has migrated to its final location or, in some cases, before. The growth of an axon along distinct pathways is guided by molecular cues from its environment and eventually leads to the formation of synapses with specific target neurons. Although the projection of axons is quite precise, some axons initially produce an excessive number of axon branches, or *collaterals*, and contact a broader set of targets than are present in the adult brain. During later adolescence, the connections of particular neurons are focused by the pruning or elimination of axonal projections to inappropriate targets. The developmental timing of synaptic and axonal elimination seems to be highly specific across regions of the brain.

Within the adult brain, the connections among neurons or neural circuits follow several important principles of organization. First, many connections between brain regions are *reciprocal*. That is, each region tends to receive input from the regions to which it sends axonal projections. In some cases, the axons arising from one region may directly innervate the reciprocating projection neurons in another region; in other cases, local circuit interneurons are interposed between the incoming axons and the projection neurons that furnish the reciprocal connections. For some projections, the reciprocating connection is indirect, passing through one or more additional brain regions and synapses before innervating the initial brain region. In addition, connections within brain regions also display reciprocity. For example, in monkey prefrontal cortex, tract-tracing studies have shown that the axons and cell bodies of pyramidal neurons in layers 2 and 3 are arranged in a series of discrete stripes (Fig. 1.2–4). Reciprocity in this system is represented by the coregistration of anterogradely labeled axons and retrogradely labeled neurons within individual intrinsic and associational stripes. In addition, anterogradely labeled axon terminals form asymmetric synapses onto retrogradely labeled dendritic spines within individual stripes, providing further evidence of reciprocity in these connections.

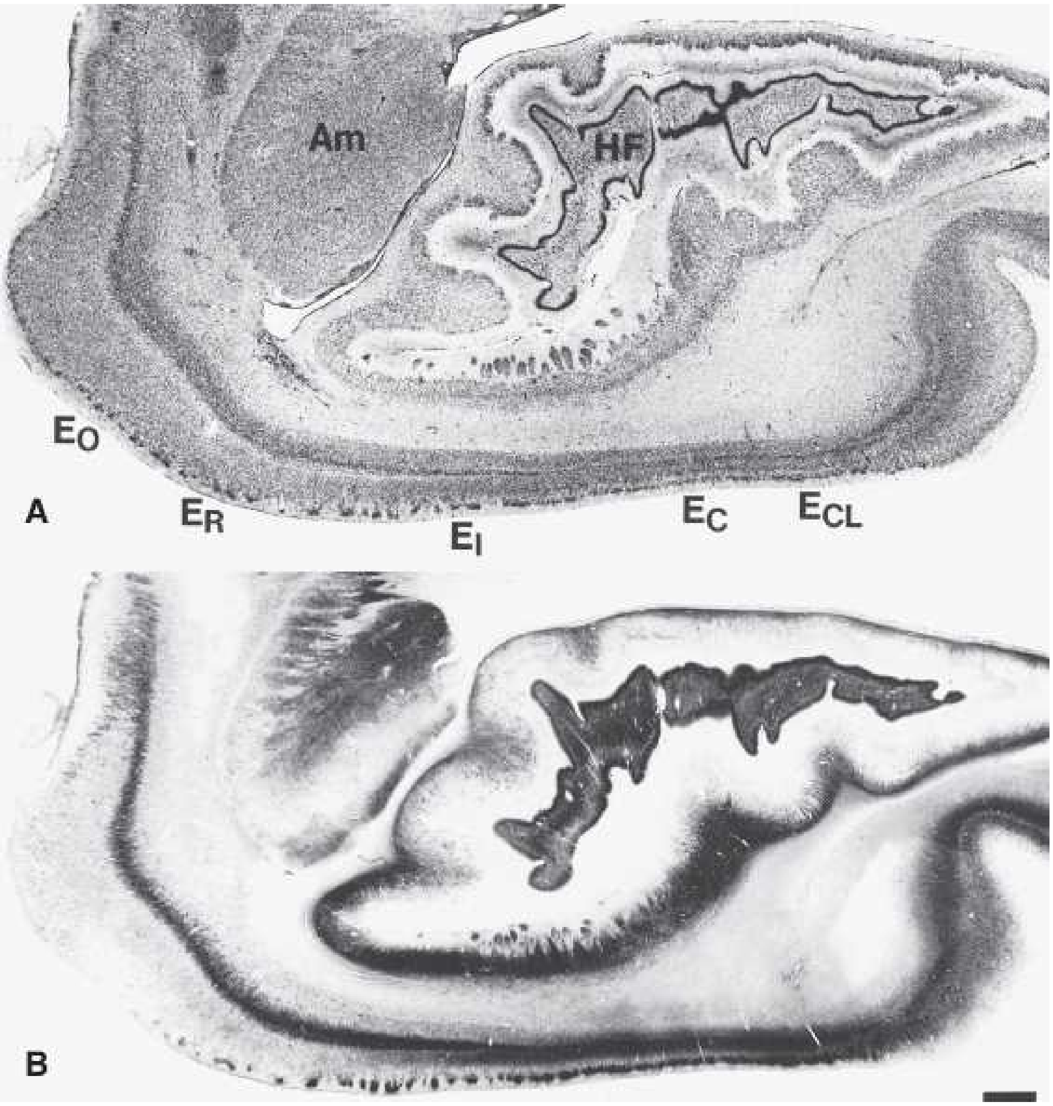

FIGURE 1.2–3. Adjacent sagittal sections through the medial temporal lobe of the human brain labeled to reveal the cytoarchitecture (**A**: Nissl stain) and chemoarchitecture (**B**: nonphosphorylated neurofilament protein immunoreactivity) of the entorhinal cortex. *Letters* indicate some of its subdivisions. Am, amygdala; HF, hippocampal formation. Calibration bar (2 mm) applies to both panels. (Reprinted with permission from Beall MJ, Lewis DA. Heterogeneity of layer II neurons in human entorhinal cortex. *J Comp Neurol*. 1992;321(2):241–266.)

Second, many neuronal connections are either divergent or convergent in nature. A *divergent* system involves the conduct of information from one neuron or a discrete group of neurons to a much larger number of neurons that may be located in diverse portions of the brain. The *locus coeruleus*, a small group of norepinephrine-containing neurons in the brainstem that sends axonal projections to the entire cerebral cortex and other brain regions, is an example of a highly divergent system. In contrast, the output of multiple brain regions may be directed toward a single area, forming a *convergent* system. Projection from multiple association areas of the cerebral cortex to the entorhinal region of the medial temporal lobe is an example of a convergent system. Connections within brain regions also display divergence and convergence (see Fig. 1.2–4). For example, in monkey prefrontal cortex, pyramidal neurons within an individual stripe have axons that project to several other stripes (divergence), and individual stripes receive input from more than one stripe (convergence). The divergence in this system may provide an anatomic substrate that would allow a spatially restricted input to recruit a group of neurons whose coordinated activation is necessary to generate a particular response. Convergence in this system could allow information from different modalities present in the array of stripes to be relayed to a single location, facilitating the integration of their information content.

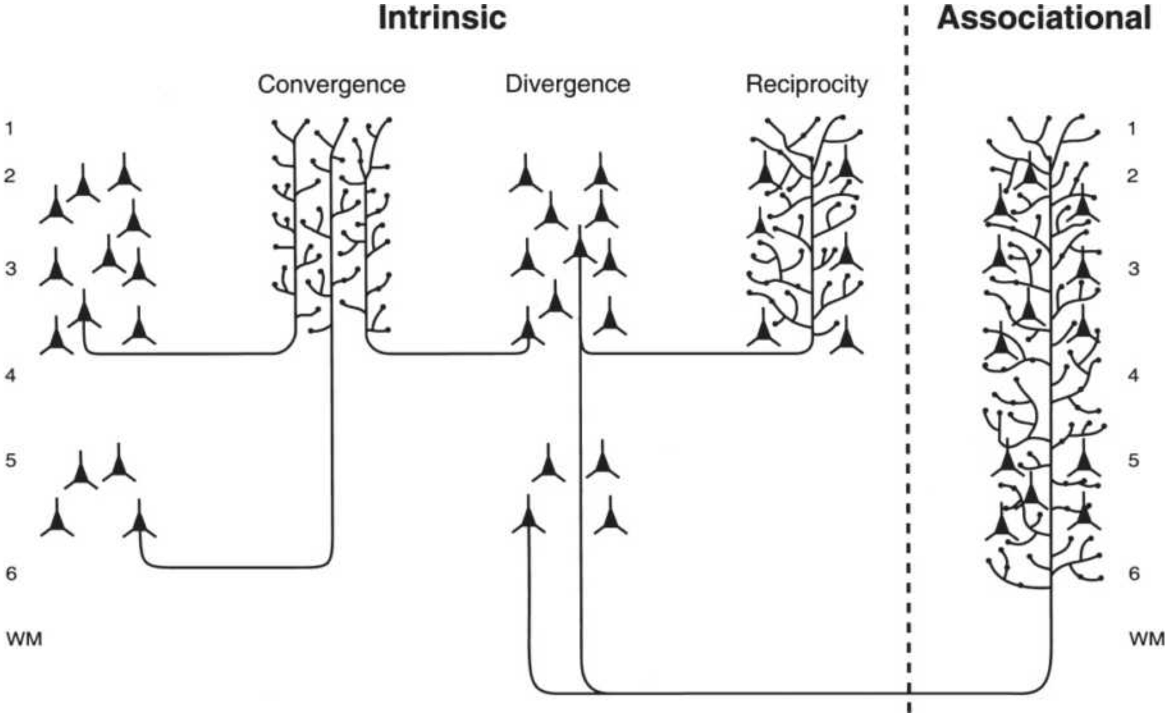

FIGURE 1.2–4. Schematic drawing comparing the spatial organization of intrinsic and associational connections and the reciprocity, convergence, and divergence in these connections in monkey prefrontal cortex. (Adapted with permission from Pucak ML, Levitt JB, Lund JS, Lewis DA. Patterns of intrinsic and associational circuitry in monkey prefrontal cortex. *J Comp Neurol*. 1996;376(4):614–630. Copyright © 1996 Wiley-Liss, Inc.)

Third, the connections among regions may be organized in a hierarchical or parallel fashion, or both. Visual input is conveyed in a serial or hierarchical fashion through several populations of neurons in the retina to the lateral geniculate nucleus, to the primary visual cortex, and then, progressively, to the multiple visual association areas of the cerebral cortex. Within the hierarchical scheme, different types of visual information (e.g., motion and form) may be processed in a parallel fashion through different portions of the visual system.

Finally, regions of the brain are specialized for different functions. Lesions of the left inferior frontal gyrus (Broca area) (Fig. 1.2–5) produce a characteristic impairment in speech production. Speech is a complex faculty. However, that depends not only on the integrity of Broca area but also on the distributed processing of information across numerous brain regions through divergent and convergent, serial, and parallel interconnections. Thus, the role of any particular brain region or group of neurons in the production of specific behaviors or in the pathophysiology of a given neuropsychiatric disorder cannot be viewed in isolation but must be considered within the context of the neural circuits connecting the neurons with other brain regions.

Distinctiveness of the Human Brain

Compared with the brains of other primate species, the human brain is substantially greater in size, with certain areas expanded disproportionately. The prefrontal cortex has been estimated to occupy only 3.5 percent of the total cortical volume in cats and 11.5 percent in monkeys but close to 30 percent of the much larger cortical volume of the human brain. Conversely, the relative representation of other regions is decreased in the human brain; for example, the primary visual cortex accounts for only 1.5 percent of the total area of the cerebral cortex in humans, but in monkeys, a much greater proportion (17 percent) of the cerebral cortex is devoted to this region. Thus, the distinctiveness of the human brain is attributable to its size and to the differential expansion of certain regions, particularly the areas of the cerebral cortex devoted to higher cognitive functions.

In addition, the expansion and differentiation of the human brain are associated with substantial differences in the organization of certain elements of neural circuitry. For example, compared with rodents, the dopaminergic innervation of the human cerebral cortex is much more widespread and regionally specific. The primary motor cortex and certain posterior parietal regions receive a dense dopamine innervation in monkeys and humans, but these areas receive little dopamine input in rats. The human brain is also distinctive at the cellular level, with greater relative percentages of certain neuronal and glial cells in the cerebral cortex. For example, the relative proportion of GABAergic interneurons is ∼15 percent in rodent cerebral cortex, but in humans, 20 to 25 percent of all neurons in most cortical areas are GABAergic. In addition, molecular characterization has revealed subtypes of neurons in the human cerebral cortex that are not found in rodent cerebral cortex. Intralaminar and polarized astrocytes are found exclusively in humans, and human protoplasmic astrocytes are larger and have more processes than their rodent counterparts. Furthermore, the astrocyte to neuron ratio is fivefold greater in humans compared to rodents, leading to greater astrocytic coverage of neurons and synapses and thus possibly enhanced regulation of neurotransmission in human cerebral cortex. These findings of a greater contribution of astrocytes in human brain function suggest that astrocytes are critical for higher brain functions and may be vulnerable in human psychiatric disorders. Thus, the human brain exhibits differences in gross anatomy, cellular constituents, and molecular composition, features that distinguish it from phylogenetically lower species.

These types of species differences indicate that there are limits to the accuracy of generalizations made concerning human brain function when using studies in rodents or even nonhuman primates as the basis for the inference. Direct investigation of the organization of the human brain, however, is obviously limited and complicated by numerous factors.

As indicated earlier, the expansion of the human brain is associated with the appearance of additional regions of the cerebral cortex. For example, the entorhinal cortex of the medial temporal lobe in humans is sometimes considered to be a single cortical region, but the cytoarchitecture and chemoarchitecture of this cortex differ substantially along its rostral–caudal extent (see Fig. 1.2–3). It is tempting to identify these regions by their location relative to other structures, but sufficient interindividual variability exists in the human brain to make such a topologic definition unreliable. In the case of the entorhinal cortex, the location of its different subdivisions relative to adjacent structures, such as the amygdala and the hippocampus, varies across human brains. Therefore, in all studies, particularly studies using the human brain, areas of interest must be defined in a manner (e.g., using cyto-, chemo-, or myeloarchitectural features) that allows investigators to accurately identify the same region in all cases.

An additional limitation to the study of the human brain concerns the changes in morphology and biochemistry that can occur during the interval between the time of death and the freezing or fixation of brain specimens. In addition to the influence of the known postmortem interval, such changes may begin to occur during the agonal state preceding death. When comparing aspects of the organization of the human brain with that of other species, the researcher must try to account for changes that may have occurred in the human brain as a result of postmortem delay or agonal state. In the study of disease states, appropriate controls must be used because differences in neurotransmitter content or other characteristics among cases could be a result of factors other than the disease state, such as methods of tissue preparation. Studies of the human brain in vivo—using such imaging techniques as positron emission tomography (PET), magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), and diffusion tensor imaging (DTI)—circumvent many of these problems but are limited by insufficient resolution for the study of many aspects of human brain organization.

STRUCTURAL COMPONENTS

Major Brain Structures

In the early stages of human brain development, three primary vesicles can be identified in the neural tube: the *prosencephalon*, the *mesencephalon,* and the *rhombencephalon* (Fig. 1.2–6). Subsequently, the prosencephalon divides to become the *telencephalon* and the *diencephalon*. The telencephalon gives rise to the cerebral cortex, the hippocampal formation, the amygdala, and some components of the basal ganglia. The diencephalon becomes the thalamus, the hypothalamus, and several other related structures. The mesencephalon gives rise to the midbrain structures of the adult brain. The rhombencephalon divides into the *metencephalon* and the *myelencephalon*. The metencephalon gives rise to the pons and the cerebellum; the medulla is the derivative of the myelencephalon.

The cerebral cortex of each hemisphere is divided into four major regions: the *frontal, parietal, temporal*, and *occipital* lobes (see Fig. 1.2–5). The frontal lobe is located anterior to the central sulcus and consists of the primary motor, premotor, and prefrontal regions (Fig. 1.2–7). The prefrontal cortex can be divided into dorsolateral and ventrolateral regions, with each of these regions having different functional properties. For example, the dorsolateral prefrontal cortex (DLPFC) seems to be more involved in the manipulation of data during working memory tasks than does the ventrolateral prefrontal cortex, which seems to be more involved with pure maintenance of information during working memory. The primary somatosensory cortex is located in the anterior parietal lobe; in addition, other cortical regions related to complex visual and somatosensory functions are located in the posterior parietal lobe. The superior portion of the temporal lobe contains the primary auditory cortex and other auditory regions; the inferior portion contains regions devoted to complex visual functions. In addition, some regions within the superior temporal sulcus receive a convergence of input from the visual, somatosensory, and auditory sensory areas. The occipital lobe consists of the primary visual cortex and other visual association areas. The brains of humans and other anthropoid primates also contain a major area called the insula which is a cortical region located within the depths of the lateral sulcus (Figs. 1.2–8 and 1.2–9), covered dorsally by the frontal and parietal opercula and ventrally by the temporal operculum. The human insula is gyrencephalic (convoluted), unlike the insula in nonhuman primates, which is lissencephalic (smooth). The human insula has extensive connections with other cortical areas, the amygdala, and the thalamus.

Beneath the outer mantle of the cerebral cortex are many other major brain structures, such as the caudate nucleus, the putamen, and the globus pallidus (see Fig. 1.2–8). These structures are components of the basal ganglia, a system involved in the control of movement and certain cognitive processes. The hippocampus and the amygdala, components of the limbic system, are located deep in the medial temporal lobe (Figs. 1.2–9 to 1.2–11). In addition, the derivatives of the diencephalon, such as the thalamus and the hypothalamus, are prominent internal structures; the thalamus is a relatively large structure composed of numerous nuclei that have distinct patterns of connectivity with the cerebral cortex (see Figs. 1.2–9 to 1.2–11). In contrast, the hypothalamus is a much smaller structure involved in autonomic and endocrine functions.

White Matter Tracts

The cerebral hemispheres contain billions of myelinated axons or fibers, giving the white matter its characteristic color, which carry information to and from the cerebral cortex. These axons are bundled into white matter tracts that include projection, commissural, and associational fibers.

Projection Fibers. Two of the major projection fiber systems comprise fibers that originate in the cerebral cortex and project to subcortical targets (corticofugal) and fibers that originate outside of the telencephalon and project to the cerebral cortex (corticopetal). Examples of these are the corticothalamic and thalamocortical projections, respectively. These projection fibers travel through the *internal capsule*, a compact bundle of fibers that is structurally associated with the thalamus and lenticular nucleus (i.e., the putamen and globus pallidus considered as one structure). In each cerebral hemisphere, the internal capsule is bordered laterally by the lenticular nucleus and medially by the thalamus and head of the caudate (Fig. 1.2–12). Other fiber systems, such as the corticopontine, corticospinal, and corticobulbar tracts, descend from the cortex through the internal capsule and cerebral peduncle to reach their destinations in the pons, spinal cord, and brainstem. All the fibers traveling through the internal capsule form the *corona radiata* (see Fig. 1.2–8), a fan-like structure that sits just above the internal capsule.

The internal capsule has been divided into five regions, with the name and location of each region based on its relationship with the lenticular nucleus (see Fig. 1.2–12). In addition, each region of the internal capsule contains different fiber systems. The *anterior limb* lies between the lenticular nucleus and the head of the caudate and carries frontopontine fibers and fibers interconnecting the thalamus and the frontal cortex. The *posterior limb*, the largest component, is located between the lenticular nucleus and the thalamus and conveys corticospinal fibers. The *genu* is the intersection of the anterior and posterior limbs and carries corticobulbar fibers. The *retrolenticular limb* lies posterior or behind the lenticular nucleus, and fibers in this region of the internal capsule form the bulk of the *optic radiation*, the large group of fibers projecting from the lateral geniculate thalamic nucleus to the primary visual cortex in the occipital lobe. The *sublenticular limb* lies inferior to the lenticular nucleus and contains fibers of the *auditory radiation*, a collection of fibers connecting the medial geniculate thalamic nucleus with the primary auditory cortex in the temporal lobe.

Commissural Fibers. Commissural fibers interconnect areas in the two cerebral hemispheres with each other. The two main commissural fiber systems are the corpus callosum and the anterior commissure. The *corpus callosum* is the largest fiber bundle in the brain, containing roughly 300 million axons. Most of these axons interconnect cortical regions in one lobe with homotopic (i.e., similarly placed) regions in the opposite lobe. However, heterotopic connections (i.e., those that link dissimilar cortical regions) also are carried in the corpus callosum. Almost all cortical regions are connected via the corpus callosum, with the notable exceptions of the hand area of the motor and somatosensory cortices and all of the primary visual cortex except the portion representing areas adjacent to the vertical midline.

The corpus callosum consists of four parts (Fig. 1.2–13). The corpus callosum starts at the *rostrum* and then curves anteriorly and dorsally to form the *genu*. The *body* of the corpus callosum is the largest part and gives way to the *splenium*, the enlarged, rounded posterior end. Sometimes the narrow portion of the corpus callosum between the body and splenium is referred to as the *isthmus*. Axons carrying higher-order cognitive and sensory information from the prefrontal, temporal, and parietal cortices primarily travel through the genu and splenium, whereas visual, auditory, and somatosensory information is carried predominantly in the body and isthmus of the corpus callosum.

The anterior commissure is a compact bundle of fibers that is caudal to the corpus callosum and crosses the midline in front of the fornix (see Fig. 1.2–8). The anterior commissure interconnects areas in the two temporal lobes and fibers from the anterior olfactory nucleus. Smaller commissural fiber tracts include the posterior commissure, which connects caudal portions of the diencephalon, and the hippocampal commissure, which interconnects the two hippocampal formations.

Associational Fibers. Associational fibers connect cortical areas within a hemisphere and range in size from very short fibers that connect areas within the same lobe to longer fibers that connect areas within different lobes. *Short association fibers* connect adjacent gyri and are often called *U fibers* because they form a U connecting one gyrus to another gyrus (Fig. 1.2–14). There are five major tracts of *long association fibers* that connect distant cortical areas within the same hemisphere. The *superior longitudinal fasciculus* is located laterally within the hemisphere above the insula and connects frontal, parietal, and occipital cortices. The *arcuate fasciculus* interconnects the frontal and temporal lobes. The *uncinate fasciculus* is a curved fiber bundle that connects the orbital portion of the frontal lobe with the anterior region of the temporal lobe. As its name implies, the *inferior occipitofrontal fasciculus* connects the occipital and frontal lobe in a bundle of fibers that courses ventrally and laterally within the hemisphere. The *cingulum* lies within the white matter under the cingulate gyrus and connects this gyrus with the parahippocampal gyrus. The *inferior longitudinal fasciculus* connects the temporal and occipital lobes. These fiber bundles are not discrete, point-to-point pathways between cortical regions but are continuous pathways with fibers entering and leaving all along their course. Other associational fiber bundles include the *external capsule*, which is sandwiched between the claustrum and the putamen, and the *extreme capsule*, which lies between the claustrum and the insular cortex (see Fig. 1.2–8).

Disturbances in the connectivity within and between hemispheres have been implicated in the pathophysiology of schizophrenia. For example, MRI studies of individuals with schizophrenia have revealed lower white matter density in the corpus callosum, internal capsule, and anterior commissure. In addition, studies using DTI, which provides information on the organization and microstructure of tissue, have shown abnormalities in almost every major white matter tract, including the corpus callosum, internal capsule, cingulum bundle, uncinate fasciculus, and fornix, in patients with schizophrenia, as well as altered microstructure in the corpus callosum and uncinate fasciculus in patients with depression. Abnormalities in white matter tracts have also been reported in other neuropsychiatric disorders. For example, MRI studies have revealed a reduction in the cross-sectional area of the corpus callosum in individuals with Alzheimer disease as well as in children with autism.

Ventricular System

As the neural tube fuses during development, the cavity of the neural tube becomes the ventricular system of the brain. It is composed of two C-shaped *lateral ventricles* in the cerebral hemispheres that can be divided further into five parts: the anterior horn (which is located in the frontal lobe), the body of the ventricle, the inferior or temporal horn in the temporal lobe, the posterior or occipital horn in the occipital lobe, and the atrium (Fig. 1.2–15). The *foramina of Monro* (interventricular foramina) are the two apertures that connect the two lateral ventricles with the *third ventricle*, which is found on the midline of the diencephalon. The *cerebral aqueduct* connects the third ventricle with the *fourth ventricle* in the pons and the medulla.

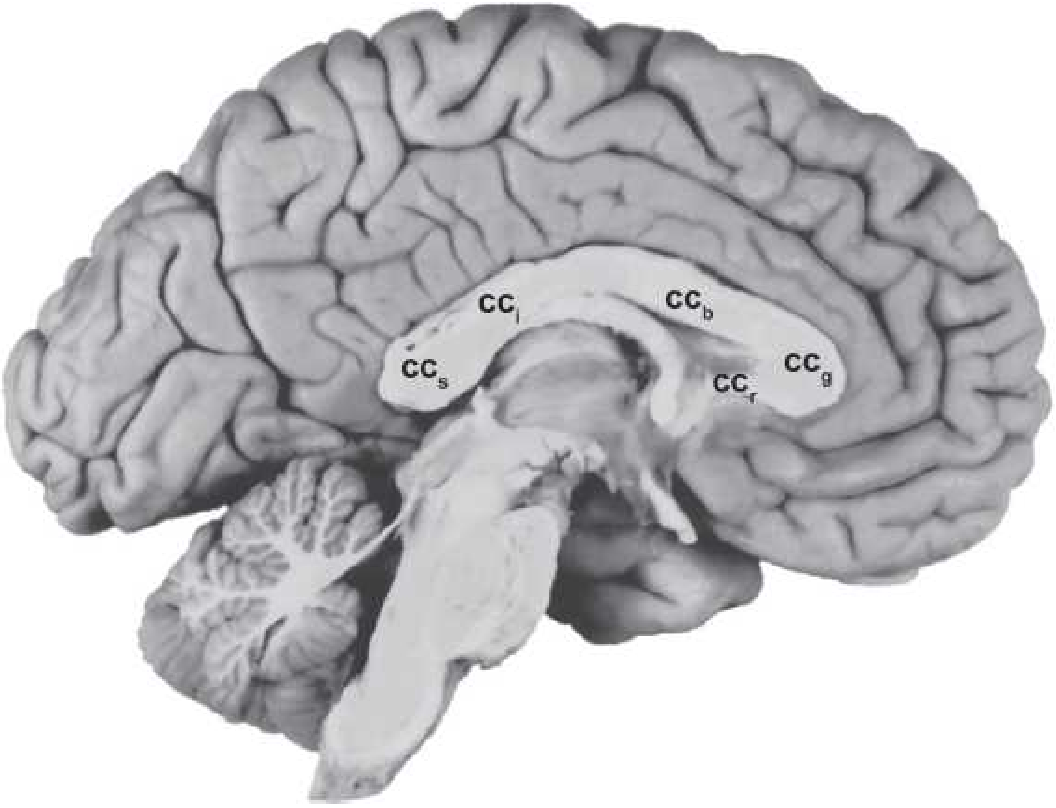

FIGURE 1.2–13. Photograph of the medial view of the right cerebral hemisphere of a human brain illustrating the different parts of the corpus callosum (cc). cc_r, rostrum; cc_g genu; cc_b, body; cc_i, isthmus; cc_s, splenium.

The ventricular system is filled with cerebrospinal fluid (CSF), a colorless liquid containing low concentrations of protein, glucose, and potassium and relatively high concentrations of sodium and chloride. Most (70 percent) of the CSF is produced at the choroid plexus located in the walls of the lateral ventricles and in the roof of the third and fourth ventricles. The *choroid plexus* is a complex of ependyma, pia, and capillaries that invaginate the ventricle. In contrast to other parts of the brain, the capillaries in the choroid plexus are fenestrated, which allows substances to pass out of the capillaries and through the pia mater. The ependymal or choroid epithelial cells, however, have tight junctions between cells to prevent the leakage of substances into the CSF; this provides what is sometimes referred to as the *blood–CSF barrier*. In other parts of the brain, the endothelial cells of the capillaries exhibit tight junctions that prevent the movement of substances from the blood to the brain; this is referred to as the *blood–brain barrier*.

The CSF is constantly produced and circulates through the lateral ventricles to the third ventricle and then to the fourth ventricle. The CSF then flows through the medial and lateral apertures to the cisterna magna and pontine cistern and, finally, travels over the cerebral hemispheres to be absorbed by the arachnoid villi and released into the superior sagittal sinus. Disruptions in the flow of the CSF usually cause some form of hydrocephalus; for example, if an intraventricular foramen is occluded, the associated lateral ventricle becomes enlarged, but the remaining components of the ventricular system remain normal.

Several functions are attributed to the CSF: it serves to cushion the brain against trauma, maintain and control the extracellular environment, and spread endocrine hormones. Because the CSF bathes the brain and is in direct communication with extracellular fluid, it is possible to measure certain compounds in the CSF as a correlate of the amount of that substance in the brain. For example, CSF levels of amyloid beta$_{1\text{-}42}$ and total tau are thought to be markers of altered amyloid metabolism and axonal damage, respectively. The concentration of amyloid beta$_{1\text{-}42}$ and total tau in samples of the CSF taken in a lumbar puncture have been used in studies examining the progression from mild cognitive impairment to Alzheimer disease. In addition, CSF measures of amyloid beta$_{1\text{-}42}$ and total tau are well-established predictive biomarkers of Alzheimer dementia in patients with mild cognitive impairment.

FUNCTIONAL BRAIN SYSTEMS

The relationships between the organizational principles and the structural components of the human brain are illustrated in three functional systems: the thalamocortical, basal ganglia, and limbic systems.

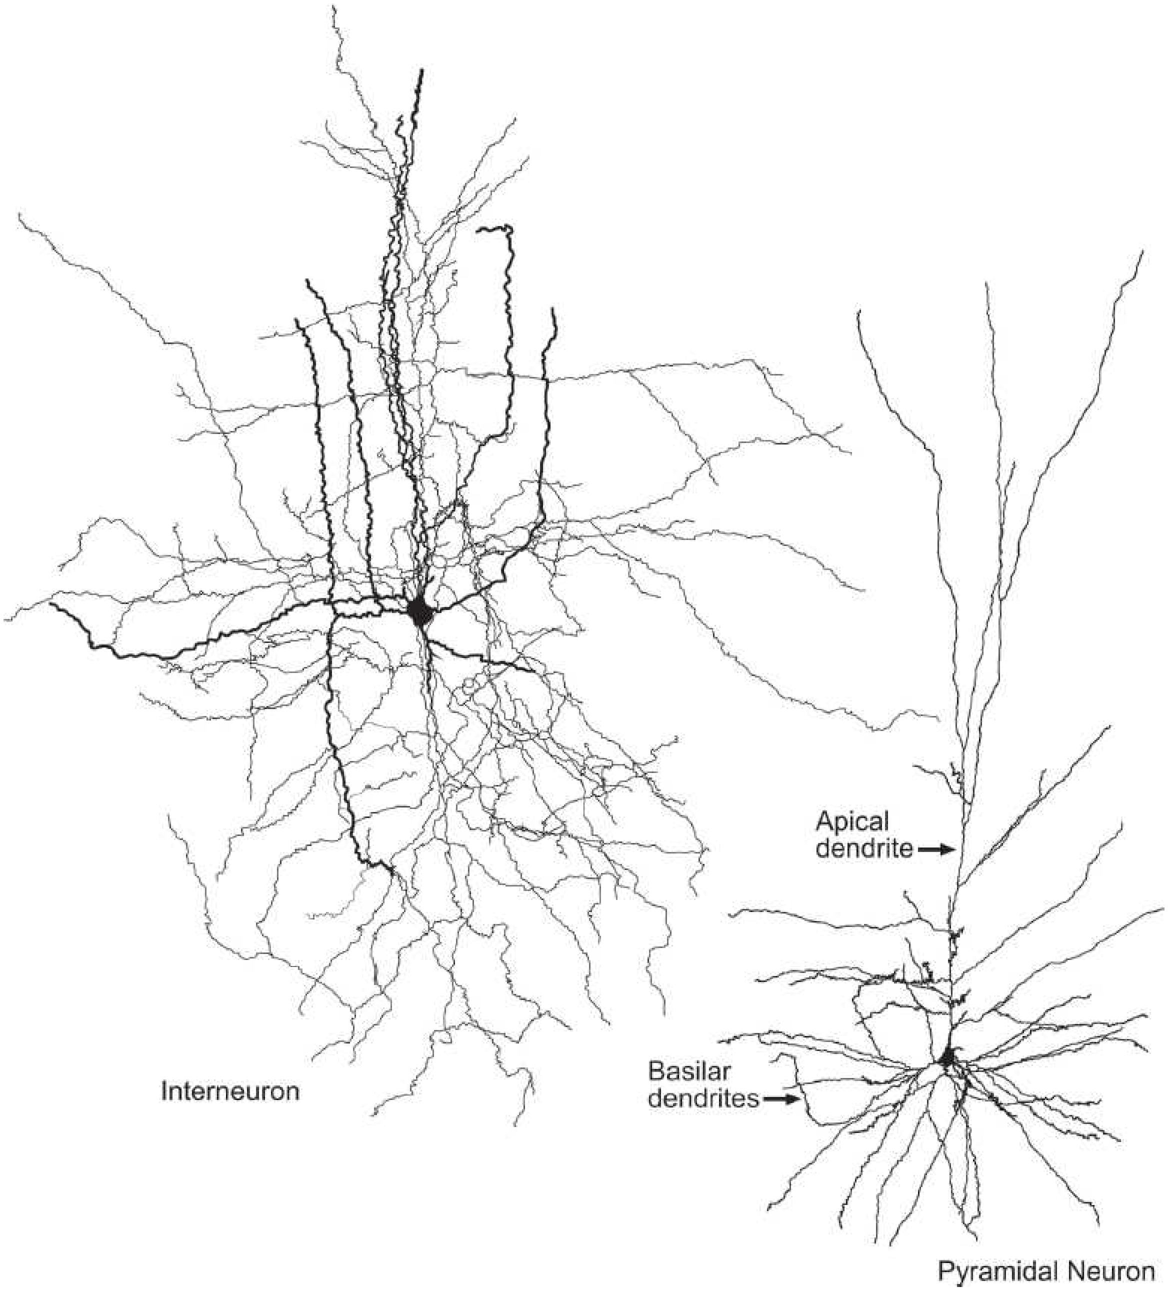

FIGURE 1.2–16. Drawings of an interneuron **(left)** and a pyramidal neuron **(right)**. Note the difference in the morphology of these two types of neurons. The soma of interneurons tends to be round or ovoid, whereas that of pyramidal neurons generally appears triangular from a two-dimensional perspective. Also, note the difference in the dendritic and axonal arbors between the two cells. The processes arising from the interneuron appear to branch in multiple directions, whereas the pyramidal neuron has prominent, well-defined apical and basilar dendrites. (Permission from: Neuromorpho.org; Ascoli GA, Donohue DE, Halavi M. NeuroMorpho.Org: a central resource for neuronal morphologies. *J Neurosci*. 2007;27(35):9247–9251(NM)-01861; Krimer LS, Zaitsev AV, Czarner G, et al. Cluster analysis-based physiological

classification and morphological properties of inhibitory neurons in layer 2–3 of monkey dorsolateral prefrontal cortex. *J Neurophysiol*. 2005;94(5): 3009–3022.)

Cerebral Cortex

The *cerebral cortex* is a laminated sheet of neurons, several millimeters thick, that covers the cerebral hemispheres. It consists of approximately 22 billion neurons communicating via approximately 165 trillion synapses. These neurons have approximately 12 million km of dendrites, and the cerebral cortex and subcortical regions are interconnected by approximately 100,000 km of axons. More than 90 percent of the total cortical area consists of the *neocortex*, which has a six-layered structure (at least at some point during development). The remainder of the cerebral cortex is referred to as the *allocortex* (cortical regions with other laminar structures) and consists of the *paleocortex* and the *archicortex*, regions that are restricted to the base of the telencephalon and the hippocampal formation, respectively.

Within the neocortex, the two major neuronal cell types are the pyramidal and stellate, or nonpyramidal, neurons (Fig. 1.2–16). *Pyramidal neurons*, which account for approximately 75 percent of all neocortical neurons, usually have a characteristically shaped cell body that gives rise to a single apical dendrite that ascends vertically toward the cortical surface. In addition, these neurons have an array of short dendrites that spread laterally from the base of the cell. The dendrites of pyramidal neurons are coated with short protrusions, called *dendritic spines*, which are the sites of most of the excitatory synapses to these neurons (Fig. 1.2–17). Most pyramidal cells are excitatory projection neurons that use glutamate as a neurotransmitter. Interestingly, in postmortem studies, subjects with schizophrenia appear to have fewer spines on the dendrites located at the base of pyramidal neurons in deep layer 3 of the DLPFC. This deficit in dendritic spines may be due to a genetic liability in the regulation of actin dynamics, leading to a loss of dendritic spines due to structural instability and/or excessive microglia-mediated pruning of spines. The presence of fewer spines, and presumably of the excitatory synapses they receive, results in less excitation of pyramidal neurons, eventually leading to less output of these pyramidal neurons and ultimately in lower indices of cortical activity.

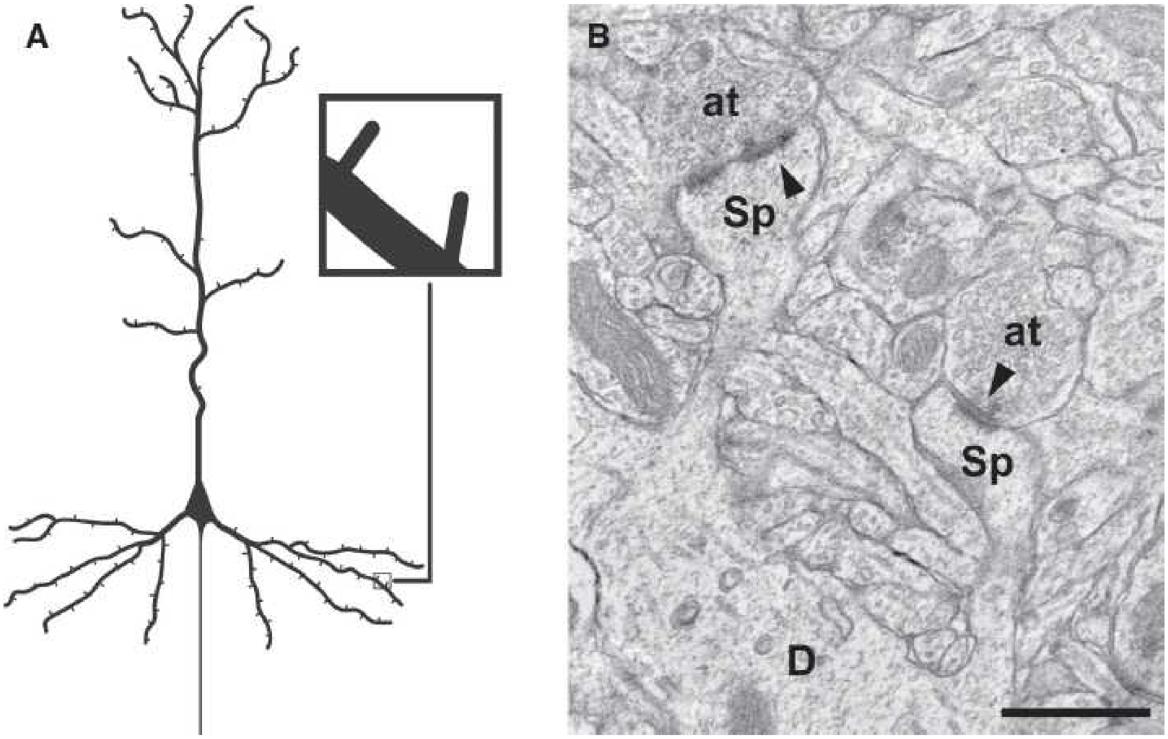

FIGURE 1.2–17. Dendritic spines in the cerebral cortex. **A:** Diagram of a cortical pyramidal neuron illustrating the location of dendritic spines. **B:** Electron micrograph from monkey prefrontal cortex showing two dendritic spines (*Sp*) emanating from a single dendrite (*D*), both of which receive an asymmetric synapse (*arrowhead*) from an axon terminal *(at)*. Calibration bar = 200 nm.

In contrast, *nonpyramidal cells* are generally small, local circuit neurons, many of which use the inhibitory neurotransmitter GABA (Figs. 1.2–16). Also known as *interneurons*, the axons of cortical GABA cells arborize within the gray matter, and most do not project out of the cortical region in which they reside. Multiple different subtypes of GABA neurons can be found in the cerebral cortex, and these can be distinguished biochemically, electrophysiologically, and morphologically. For example, subpopulations of GABA cells can be distinguished by the presence of certain neuropeptides or calcium-binding proteins. In addition, the organization of the axonal arbor and synaptic targets of the axon terminals differ greatly across these different subtypes. The chandelier class of GABA cells expresses the calcium-binding protein parvalbumin (PV) and has axon terminals that are arrayed as distinct vertical structures termed cartridges (Fig. 1.2–18). These axon terminals form inhibitory or symmetric synapses exclusively with the axon initial segments of pyramidal cells. PV-containing basket neurons form symmetric synapses onto the cell bodies and dendrites of pyramidal neurons. PV-containing neurons are predominantly located in layers 3 and 4. In contrast, the Martinotti class of GABA neurons contains the neuropeptide somatostatin and forms symmetric synapses onto the tuft dendrites of pyramidal neurons. Some double-bouquet GABA neurons have radially oriented axonal arbors, contain somatostatin and the calcium-binding protein calbindin, and form symmetric synapses onto the distal dendritic shafts and spines of pyramidal neurons. The neuropeptide cholecystokinin (CCK) is present in a separate population of basket cells which also express the brain cannabinoid receptor 1 (CB1). These CCK/CB1 basket cells predominantly synapse onto the dendritic shafts and cell bodies of pyramidal neurons. In contrast, calretinin-containing double-bouquet cells form symmetric synapses predominantly onto the dendritic shafts of other GABA neurons. Calretinin-containing Cajal–Retzius cells reside solely in layer 1 and target the tuft dendrites of pyramidal neurons.

A: Brightfield photomicrograph of chandelier neuron axon terminal *(arrow)* immunostained for the GABA transporter-type 1 (GAT-1). **B:** Brightfield photomicrograph of a pyramidal neuron (*P*) axon initial segment (the site of action potential generation) immunostained for the α_2 subunit of the GABA$_A$ receptor. **C:** Schematic diagram of the synaptic relationship between chandelier and pyramidal neurons illustrating the pre- and postsynaptic changes in schizophrenia. (A and B, reprinted from and C, adapted from Volk DW, Pierri JN, Fritschy JN, Auh S, Sampson AR, Lewis DA. Reciprocal alterations in pre- and postsynaptic inhibitory markers at chandelier cell inputs to pyramidal neurons in schizophrenia. *Cereb Cortex*. 2002;12:1063, by permission of Oxford University Press.)

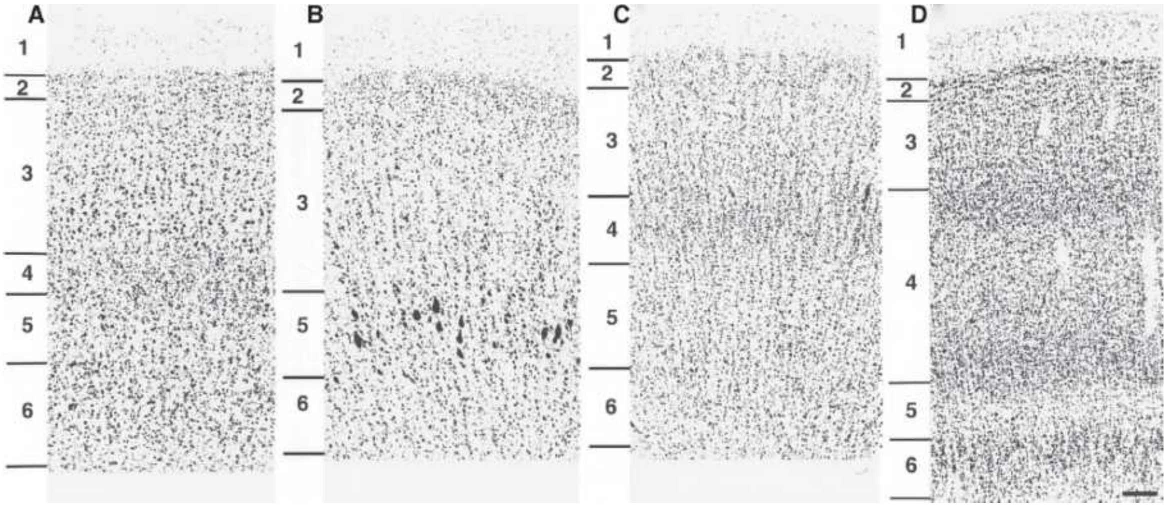

FIGURE 1.2–19. Nissl-stained sections of Brodmann area 46 (DLPFC) **(A)**, area 4 (primary motor cortex) **(B)**, area 41 (primary auditory cortex) **(C)**, and area 17 (primary visual cortex) **(D)** from a control human brain. Note the marked differences in the size and laminar organization of neurons across areas. The large neurons in panel B are Betz cells, which extend their axons to the spinal cord. Arabic numerals indicate the cortical layers. Calibration bar (200 μm) applies to **A–D**.

Many studies have revealed abnormalities in different populations of nonpyramidal neurons in a variety of neurologic and psychiatric disorders. For example, lower numbers of calretinin neurons and morphologic changes in the axonal arbors of PV neurons have been reported in epileptic tissue. In schizophrenia, basket cells express lower levels of PV and the 67 kilodalton form of the biosynthetic enzyme glutamic acid decarboxylase (GAD67). The axon terminals of chandelier neurons have reduced levels of the membrane GABA transporter-type 1 (GAT-1) and greater levels of $GABA_A$ α_2 receptors in postsynaptic pyramidal neurons (see Fig. 1.2–18C). In concert, these findings reflect dysfunctional prefrontal cortical circuitry, which may contribute to the cognitive symptoms observed in schizophrenia.

Neocortical neurons are distributed across six layers of the neocortex; these layers are distinguished by the relative size and packing density of their constituent neurons (Fig. 1.2–19). Each cortical layer tends to receive particular types of inputs and furnish characteristic projections. For example, afferents from thalamic relay nuclei terminate primarily in deep layer 3 and layer 4, and afferents from other cortical areas predominantly terminate in layers 1 to 3. In contrast, corticostriatal projections arise from layer 5 pyramidal cells, and corticothalamic projections originate mainly from layer 6 pyramidal neurons (Fig. 1.2–20). These laminar distinctions provide important clues for dissecting possible pathophysiologic mechanisms in psychiatric disorders. Reports of smaller somal size and lower spine density on deep layer 3 pyramidal neurons in the prefrontal cortex of individuals with schizophrenia suggest that these alterations may be associated with alterations in afferent projections from the medial dorsal thalamic nucleus, the primary thalamic projection nucleus to the prefrontal cortex.

In addition to the horizontal laminar structure, many aspects of cortical organization have a vertical or columnar characteristic. For example, the apical dendrites of pyramidal neurons and the axons of some local circuit neurons have a prominent vertical orientation, indicating that these neural elements may sample the input to or regulate the function of neurons in multiple layers respectively. Afferent inputs to the neocortex from other cortical regions also tend to be distributed across cortical layers in a columnar fashion. Finally, physiologic studies in the somatosensory and visual cortices have shown that neurons in a given column respond to stimuli with particular characteristics, whereas neurons in adjacent columns respond to stimuli with different features.

Although best studied in sensory cortices, this pattern of organization is also present in association cortices. More recent studies in monkeys using tract-tracing techniques have shown that clusters of prefrontal cortical neurons are organized into reciprocally connected, discrete modular stripes that appear to be the analog of columns identified in the visual cortex (see Fig. 1.2–4). It has been hypothesized that this organization may subserve prefrontal working memory and executive functions.

The neocortex can be divided into two general types of regions. Regions with a readily identifiable six-layer appearance are known as the *homotypical cortex* and are found in association regions of the frontal, temporal, and parietal lobes. In contrast, some regions of the neocortex do not have a six-layer appearance. These regions, referred to as the *heterotypical cortex*, include the primary motor cortex, which lacks a defined layer 4 (see Fig. 1.2–19B), and primary sensory regions, which exhibit an expanded layer 5 (see Fig. 1.2–19D). The neocortex can be divided further into discrete areas, each area having a distinctive architecture, a certain set of connections, and a role in particular brain functions. Most subdivisions of the human neocortex have been based on cytoarchitectural features; that is, subdivisions differ in size, packing density, and arrangement of neurons across layers (see Fig. 1.2–19). The most widely used system is that of Korbinian Brodmann (Fig. 1.2–21), who divided the cortex of each hemisphere into 44 numbered areas. Some of these numbered regions correspond closely to functionally distinct areas, such as area 4 (primary motor cortex in the precentral gyrus) and area 17 (primary visual cortex in the occipital lobe). In contrast, other Brodmann areas appear to encompass several cortical zones that differ in their functional attributes. Although Brodmann's brain map has been used extensively in postmortem studies of psychiatric disorders, many of the distinctions among regions are subtle, and the locations of the boundaries between regions vary across individuals.

FIGURE 1.2–20. Schematic diagram of the laminar origins of efferent projections from the cerebral cortex. These data are mainly derived from the study of monkeys via tract-tracing studies. Parentheses indicate projections that may not arise from the identified layer in all species or in all cortical areas. Note that afferents from the thalamus project mainly to the lower half of layers 3 and 4, whereas cortical afferents terminate in layers 1–3. (Adapted from Jones EG. Laminar distribution of cortical efferent cells. In: Peters A, Jones EG, eds. Cerebral cortex. *Volume 1: Cellular Components of the Cerebral Cortex*. Plenum Press; 1984:535, reproduced with permission of SNCSC.)

Although a given cortical area may receive other inputs, it is heavily innervated by projections from particular thalamic nuclei and from certain other cortical regions either in the same hemisphere (*associational fibers*) or the opposite hemisphere (*commissural fibers*). The patterns of connectivity make it possible to classify cortical regions into different types. *Primary sensory areas* are dominated by inputs from specific thalamic relay nuclei and are characterized by a topographic representation of visual space, the body surface, or the range of audible frequencies on the cortical surface of the primary visual, primary somatosensory, and primary auditory cortices, respectively. These regions project to nearby *unimodal association regions*, which are also devoted to processing information from a particular sensory modality. Output from these regions converges in *multimodal association areas*, such as the prefrontal cortex or the temporoparietal cortical regions. Neurons in these regions respond to complex stimuli and are thought to be mediators of higher cognitive functions. Finally, these regions influence the activity of the *motor areas* of the cerebral cortex that control behavioral responses.

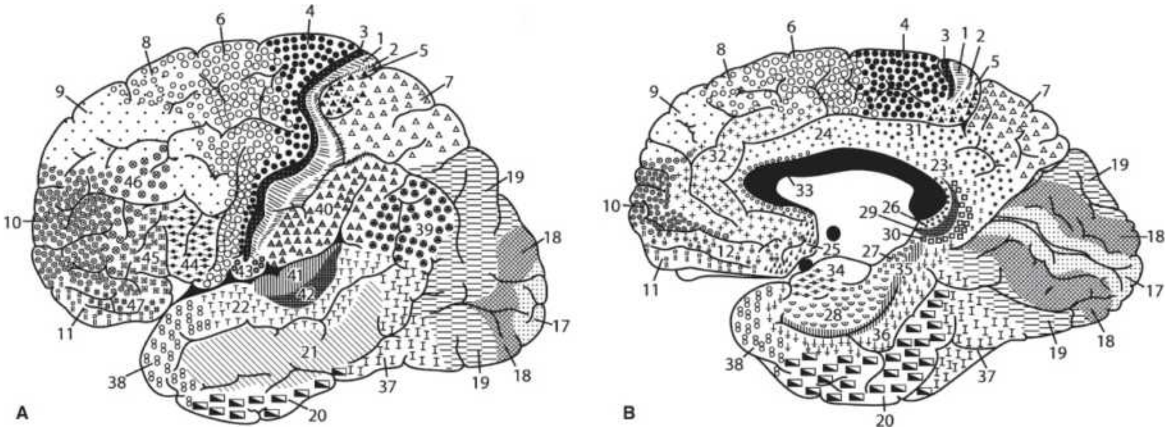

FIGURE 1.2–21. Drawing of the lateral view **(A)** and medial view **(B)** of the cytoarchitectonic subdivisions of the human brain as determined by Brodmann.

Although this classification scheme of cortical regions is accurate in many respects, it fails to account for some of the known complexities of cortical information processing. For example, somatosensory input from the thalamus projects to several distinct topographically organized maps in the cerebral cortex. In addition, information flow within the cortex is not confined to the serial processing route implied in the classification scheme but also involves parallel processing streams, such as sensory input from the thalamus to the primary and the association areas.

Although this discussion has not distinguished between the cerebral hemispheres, certain brain functions, such as language, are localized to one hemisphere. The structural bases for the lateralization of function have not been determined, but some anatomical differences between the cerebral hemispheres have been observed. For example, a portion of the superior temporal cortex, called the *planum temporale*, is generally larger in the left hemisphere than in the right hemisphere. That cortical area, which is located close to the primary auditory cortex and includes the region known as *Wernicke area* (see Fig. 1.2–5), seems to be involved in receptive language functions that are localized to the left hemisphere. In addition, Brodmann area 44 in the left inferior frontal cortex (Broca area) (see Fig. 1.2–5) contains larger pyramidal neurons than the homotopic region of the right hemisphere, a difference that may contribute to the specialization of Broca area for motor speech function. A lesion in Broca area causes broken speech, whereas a lesion in Wernicke area causes wordy speech that does not make sense.

Functional Circuitry

CORTICOCORTICAL CONNECTIONS. Corticocortical connections comprise the majority of connections within the cerebral cortex and can be divided into three basic categories: (1) intrinsic—connections within one cortical area, (2) associational—connections between cortical areas within the same hemisphere, and (3) callosal—connections between cortical areas in different hemispheres. Intrinsic connections are formed by the axon collaterals of pyramidal neurons, whereas associational and callosal connections are formed by the principal axons of pyramidal neurons.

Corticocortical connections are responsible for the coordinated activity of large groups of neurons distributed within and across cortical areas. The synchronization of this activity appears to be involved in the majority of perceptual and cognitive functions ascribed to the cerebral cortex.

The synchronous neural activity or oscillations of these connected groups of neurons generates characteristic patterns of electrical activity that can be recorded with an electroencephalogram (EEG). The greater the number of neurons oscillating together at a particular frequency, the greater the amplitude of the EEG signal above noise. These oscillations are grouped into different frequency bands such as theta (4 to 8 Hz), alpha (8 to 12 Hz), and gamma (30 to 80 Hz). Oscillatory activity in all frequency bands arises from networks of inhibitory, GABAergic neurons whose output modulates the activity of pyramidal neurons.

High-frequency oscillations have been suggested as a possible mechanism for the integration of distributed neuronal networks involved in a variety of mental processes such as perception, attention, and cognition. Gamma-band oscillations in the DLPFC are thought to be a key neural substrate for cognition. Moreover, the synaptic connections between the PV basket subclass of GABA neurons and pyramidal neurons within the supragranular layers of the DLPFC appear to generate this oscillatory activity. Interestingly, individuals with schizophrenia exhibit lower power of prefrontal gamma oscillations when performing cognitive tasks, perhaps a consequence of the abnormalities in the GABAergic system, including PV neurons, observed in postmortem DLPFC from individuals with schizophrenia.

NETWORKS OF CORTICOCORTICAL CIRCUITRY. The study of corticocortical connections had once only been possible in animals with the use of tract-tracing methods. Although improvements in these methods have refined and deepened our knowledge of the projections between different cortical areas, the connections revealed by this methodology can only be inferred to be the same in humans. Over the last 20 years, neuroimaging studies have vastly expanded our knowledge of corticocortical connectivity in humans. However, it is important to note that most of these neuroimaging studies have identified functional connectivity (i.e., brain areas that are coactivated during a specific task) and not physical connections between regions. Evidence of direct anatomical corticocortical connections in the human brain is sparse, although newer imaging techniques such as DTI do provide some structural detail. Large-scale cortical networks linking distributed areas that subserve particular functions, such as attention or memory, have long been suggested and are now more readily studied with the aforementioned neuroimaging techniques. Numerous networks have been described, but three particular networks have received the greatest focus.

Table 1.2–2.
Functional Networks in Cerebral Cortex

Network	Brain Areas Involved	Function
Central executive	Dorsolateral prefrontal cortex Lateral posterior parietal cortex	Attention Working memory Decision making
Salience	Anterior cingulate cortex Ventromedial prefrontal cortex Insula	Detection of relevant incoming stimuli
Default	Medial prefrontal cortex Posterior cingulate cortex Medial posterior parietal cortex	Internal cognition Theory of mind

The *central executive network* includes the DLPFC (see Fig. 1.2–7) and multiple areas of lateral posterior parietal cortex (see Fig. 1.2–5) and is involved in certain cognitive functions such as attention, working memory, and decision making (Table 1.2–2). The *salience network*, comprised of the anterior cingulate cortex (see Fig. 1.2–5), the ventromedial prefrontal cortex (see Fig. 1.2–7), and the insula (see Figs. 1.2–8 and 1.2–9), responds to the degree of salience of incoming cognitive, homeostatic, or emotional information (Table 1.2–2). The involvement of the insula in the salience network is understandable given its physical location as well as its function. The insula is primarily associated with interoception, the representation, and integration of the physiologic status of the organs and tissues of the body. However, recent studies indicate that the insula has more extensive functions, including bodily awareness, self-recognition, emotional awareness, and the integration of interoceptive information and emotions.

Perhaps the most intriguing network that has been described is the *default mode network*, which is formed by the medial prefrontal cortex (Fig. 1.2–5), the posterior cingulate cortex (Fig. 1.2–5), and the medial areas of the posterior parietal cortex (Fig. 1.2–5). The brain regions of the default mode network are active when a person is at rest and not engaged in an externally cued task, suggesting that this network is involved in internal modes of cognition, including recall of personal experiences, envisioning the future, and theory of mind (see Table 1.2–2).

Recent studies suggest that these three networks interact, with the salience network acting as a switch between the task-positive central executive network and the task-negative default mode network. The frontoinsular region of the salience network appears to play a key role in switching between the default mode and central executive networks. Interestingly, the human-specific von Economo class of neurons is found exclusively in the frontoinsular cortex, and it has been suggested that these neurons are responsible for the switching capability of the salience network.

Given that these networks are involved in the processing of cognitive and emotional information, it is not surprising that their dysfunction has been implicated in a variety of neuropsychiatric disorders. For example, individuals with depression have abnormally high functional connectivity within the default mode network and reduced connectivity among regions involved in the central executive network. In schizophrenia, the functional connectivity across the default mode, central executive, and salience networks is less organized. In particular, salience network dysfunction, perhaps driven by lower gray matter in the insula and/or anterior cingulate cortex, results in an imbalance between the default mode and central executive networks. This breakdown in network connectivity may lead to a disruption in the capability to distinguish between the external world and internal thoughts and feelings, manifested as psychotic symptoms such as delusions and hallucinations.

THE CLAUSTRUM. The *claustrum*, a telencephalic structure derived from the lateral pallium, consists of a thin strip of gray matter that is situated between the insular cortex and extreme capsule, the external capsule or the putamen (see Figs. 1.2–8 and 1.2–9). It extends caudally from the level of the very rostrum of the corpus callosum to the beginning of the pulvinar nucleus of the thalamus. Because of its small size and cloistered location, the claustrum has not been extensively studied. However, studies in nonhuman primates have shown that it has widespread connections across the brain. It is most extensively connected with the cerebral cortex, and these connections are topographic, with dedicated claustrum regions for specific cortical areas. In particular, sensory cortical regions are heavily interconnected with the claustrum, with regions of the claustrum identified by sensory modality (e.g., visual claustrum). This widespread connectivity has led some researchers to liken the claustrum to a salience detector, while others describe it as an area that binds together information from a variety of sources into a conscious experience. Interestingly, the claustrum contains the highest expression of serotonin 2A receptors in the brain. Activation of serotonin 2A receptors by psychedelic substances affects consciousness, cognition, and perception, providing a rationale for the current interest in the use of psychedelic substances as treatments for psychiatric disorders, although the location of the receptors that mediate the effects of psychedelic drugs remains an active research question.

Thalamus

The largest portion of the diencephalon consists of the *thalamus*, a group of nuclei located medial to the basal ganglia that serves as the major synaptic relay station for information reaching the cerebral cortex. Anatomically, the thalamic nuclei can be divided into six groups: anterior, medial, lateral, reticular, intralaminar, and midline nuclei (Fig. 1.2–22). A thin Y-shaped sheet of myelinated fibers, the *internal medullary lamina*, delimits the anterior, medial, and lateral groups of nuclei. In the human thalamus, the anterior and medial groups each contain a single large nucleus, the *anterior* and *medial dorsal nuclei*. The lateral group of nuclei can be subdivided further into dorsal and ventral tiers. The dorsal tier is composed of the *lateral dorsal*, the *lateral posterior*, and the *pulvinar nucleus*; the ventral tier consists of the *ventral anterior*, the *ventral lateral*, the *ventral posterior lateral*, and the *ventral posterior medial nuclei*. The lateral group of nuclei is covered by the *external medullary lamina*, another sheet of myelinated fibers. Interposed between these fibers and the internal capsule is a thin group of neurons forming the *reticular nucleus* of the thalamus. Also considered part of the lateral group, the lateral geniculate nucleus and the medial geniculate nucleus are located posterior to the ventral tier nuclei and inferior to the pulvinar nucleus, protruding posteriorly alongside the midbrain. The *intralaminar nuclei*, the largest of which is the *central median nucleus*, are located within the internal medullary lamina. The final group of thalamic nuclei, the *midline nuclei*, covers portions of the medial surface of the thalamus. The midline nuclei of each hemisphere may fuse to form the interthalamic adhesion, which is variably present.

FIGURE 1.2–22. Expanded view of the dorsal thalamus illustrating the organization of thalamic nuclei. (Reprinted from Haines DE. *Fundamental Neuroscience for Basic and Clinical Applications*. 3rd ed. Churchill Livingstone; 2006:236.)

Thalamic nuclei also can be classified into several groups based on the pattern and information content of their connections (Table 1.2–3). *Relay nuclei* project to and receive input from specific regions of the cerebral cortex. These reciprocal connections apparently allow the cerebral cortex to modulate the thalamic input it receives. *Specific relay nuclei* process input either from a single sensory modality or from a distinct part of the motor system. For example, the lateral geniculate nucleus receives visual input from the optic tract and projects to the primary visual area of the occipital cortex. As summarized in Figure 1.2–23, neurons of the thalamic relay nuclei furnish topographically organized projections to specific regions of the cerebral cortex, although some cortical regions receive input from more than one nucleus.

In contrast, *association relay nuclei* receive highly processed input from more than one source and project to larger areas of the association cortex. For example, the medial dorsal thalamic nucleus receives input from the hypothalamus and the amygdala and is reciprocally interconnected with the prefrontal cortex and certain premotor and temporal cortical regions (Fig. 1.2–24). In contrast to relay nuclei, *diffuse-projection nuclei* receive input from diverse sources and project to widespread areas of the cerebral cortex and to the thalamus. The divergent nature of the cortical connections of these nuclei indicates that they may be involved in regulating the level of cortical excitability and arousal. Finally, the reticular nucleus is unique in that it contains inhibitory neurons that receive input from collaterals of the axons that reciprocally connect other thalamic nuclei and the cerebral cortex. Each portion of the reticular nucleus then projects to the thalamic nucleus from which it receives input. The pattern of connectivity indicates that the reticular nucleus samples cortical afferent and efferent activity and then uses that information to regulate thalamic function.

The classification of thalamic nuclei into different categories has been refined over the last 20 years to reflect our greater understanding of thalamic circuitry. Although classification into different nuclei is useful, the focus has shifted to the type of inputs to the various nuclei. For example, thalamic afferents can be defined as either drivers or modulators. Drivers convey information from the senses and periphery that are then relayed to the cerebral cortex. These inputs determine the nature of the thalamic relay. For example, the lateral geniculate nucleus is a visual relay because it transmits retinal input to the primary visual cortex. The driver inputs for association and diffuse-projection nuclei are more difficult to determine, but these inputs most likely arise from layer 5 pyramidal neurons in the cerebral cortex. Modulators include all other inputs to the thalamus, such as monoaminergic and cholinergic projections from brainstem nuclei and the feedback projections from layer 6 pyramidal neurons in the cerebral cortex. Thalamic circuits can then be distinguished based on the source of driver inputs. First-order relays have drivers that arise from ascending pathways and transmit information that has not yet been processed in the cortex. In contrast, higher-order relays have drivers that arise from layer 5 pyramidal neurons, allowing for the transmission of information from one cortical area to another via the thalamus. Thus, it is possible that a given thalamic nucleus contains both first-order and higher-order relays. Interestingly, over half of the circuits in the thalamic nuclei of primates are considered to be higher order, suggesting a complex role of the thalamus in corticothalamocortical function.

Functional Circuitry. The connections between the thalamus, the cortex, and certain related brain structures constitute three types of thalamocortical systems, each with different patterns of functional circuitry. These three systems—sensory, motor, and association systems—are described separately here but are heavily interconnected.

Table 1.2–3.
Connections of Thalamic Nuclei[a]

Specific Relay Nuclei

Nucleus	Afferents	Efferents	Function
Anterior	Mammillary body of hypothalamus Hippocampal formation	Cingulate cortex, parahippocampal gyrus	Expression of emotions Learning, memory
Ventral Anterior	Globus pallidus Substantia nigra	Premotor cortex Frontal eye fields	Control of limb movement Control of eye, face, and head movements
Ventral lateral	Dentate nucleus of cerebellum	Motor, premotor cortices	Control of head and limb movement
Ventral posterior lateral	Medial lemniscal and spinothalamic pathways	Somatosensory cortex	Processes pain, temperature, touch sensation, pressure and joint movement
Ventral posterior medial	Sensory nuclei of trigeminal nerve	Somatosensory cortex	Processes pain, temperature, touch sensation, pressure, and proprioception
Medial geniculate	Inferior colliculus	Auditory cortex	Hearing
Lateral geniculate	Optic tract	Visual cortex	Vision

Association Relay Nuclei

Nucleus	Afferents	Efferents	Function
Lateral dorsal	Pretectal area	Cingulate cortex, retrosplenial cortex, subiculum	Expression of emotions

Lateral posterior	Superior colliculus Pretectal area	Parietal cortex Precuneus	Sensory integration
Pulvinar	Superior colliculus Cerebellum	Temporal, parietal, occipital cortices	Integration of visual, auditory and somatosensory information
Medial dorsal	Amygdala, hypothalamus, brainstem	Prefrontal cortex	Expression of emotions, integration of sensory information
Diffuse-Projection Nuclei			
Nucleus	**Afferents**	**Efferents**	**Function**
Midline	Reticular formation, hypothalamus, striatum, hippocampus	Striatum, hippocampus, limbic cortex	Modulation of cortical excitability
Intralaminar	Reticular formation, spinothalamic tract, globus pallidus	Basal ganglia, cerebral cortex	Control of cortical activity
Reticular	Cerebral cortex Other thalamic nuclei	Other thalamic nuclei	Integration and control of thalamic activity

[a] This table does not include the cortical inputs to each thalamic nucleus.

THALAMOCORTICAL SENSORY SYSTEMS. Several general principles govern the organization of the thalamocortical sensory systems. First, sensory receptors transduce certain stimuli in the external environment to neural impulses. The impulses ascend, often through intermediate nuclei in the spinal cord and the medulla, and ultimately synapse in specific relay nuclei of the thalamus.

Second, projections from peripheral sensory receptors to the thalamus and the cortex exhibit topography. That is, a particular portion of the external world is mapped onto a particular region of the brain. For example, in the somatosensory system, axons carrying information regarding a distinct part of the body synapse in a discrete part of the ventral posterior nucleus of the thalamus. Specifically, the ventral posterior medial nucleus receives inputs regarding the head, and the ventral posterior lateral nucleus receives inputs regarding the remainder of the body. The nuclei project topographically to the primary somatosensory cortex, where several representations of the contralateral half of the body can be found. These representations are distorted; regions heavily innervated by sensory receptors, such as the fingers, are disproportionately represented in the primary somatosensory cortex.

Third, in some cases, sensory inputs travel to the thalamus in a segregated manner according to the submodality of the information conveyed. The inputs are processed in a parallel fashion; particular pathways may be devoted exclusively to processing a submodality. For example, in the somatosensory system (Fig. 1.2–25), most fibers carrying tactile and proprioceptive information travel in the medial lemniscus, whereas fibers carrying pain and temperature information travel in the spinothalamic tract; both pathways terminate in the ventral posterior thalamic nuclei. Although some tactile information is carried in the spinothalamic tract, the submodalities of pain and temperature are largely segregated from tactile and proprioceptive inputs as they ascend to the thalamus.

Finally, sensory pathways exhibit convergence. That is, primary sensory areas process sensory information and project to unimodal association areas. Subsequently, the unimodal areas project to and converge in multimodal associational areas. Convergence in sensory pathways is illustrated in the somatosensory system. The primary somatosensory cortex, located in the anterior parietal lobe, has been divided into four regions on the basis of cytoarchitecture. Each of the cytoarchitectonic regions—numbered 1, 2, 3a, and 3b by Brodmann—contains a topographical representation of the body. The regions are heavily interconnected, and all project to the next level of somatosensory processing in area S-II (Brodmann areas 40 and 43). This type of projection, from one level of processing to a more advanced level, is termed a *feedforward* projection. The reciprocal connection, from the more advanced processing level back to the simpler level, is called a *feedback* projection. Both projections have distinct patterns of laminar termination: feedforward projections originate in cortical layers 2 and 3 and terminate in layer 4; feedback projections originate primarily in layers 5 and 6 and terminate outside layer 4. Further processing of somatosensory information occurs in higher-order somatosensory areas, such as area 7b of the posterior parietal cortex, which receives feedforward projections from S-II. Lesions of the posterior parietal cortex reflect the complexity of the information processed there; after a person has sustained a posterior parietal lesion, the ability to understand the significance of sensory stimuli is impaired, and extreme cases result in contralateral sensory neglect and inattention.

THALAMOCORTICAL MOTOR SYSTEMS. The thalamocortical motor systems exhibit some unique organizational principles but also share many of the features present in the sensory systems. First, in contrast to sensory systems, which primarily ascend from sensory receptors to cortical association areas, motor systems descend from association and motor regions of the cortex to the brainstem and the spinal cord. The corticospinal tract originates in the large Betz cells of layer 5 in the premotor and primary motor cortices (see Fig. 1.2–19B) of the frontal lobe and terminates in the spinal cord to influence motor behavior.

Second, motor systems exhibit strong topography at the thalamic and cortical levels. The corticospinal tract is organized so that a topographic representation of the contralateral half of the body is evident in the primary motor and premotor cortices. The representation of the body is disproportionate, with large regions of the motor cortex devoted to areas of the body involved in fine movement, such as the face and the hands.

Finally, projections from several sensory association regions converge in the motor regions of the frontal cortex. The premotor cortex receives a convergence of afferents from higher-order somatosensory and visual areas of the posterior parietal cortex, whereas afferents from the primary somatosensory cortex converge on the primary motor cortex. In addition to cortical input, the primary motor cortex receives afferents from the ventral lateral nucleus of the thalamus; this nucleus receives afferents predominantly from the cerebellum. The premotor cortex receives input from the ventral anterior thalamic nucleus, which receives much of its input from the globus pallidus.

THALAMOCORTICAL ASSOCIATION SYSTEMS. The multimodal association areas of the cortex are organized according to several general principles. First, association regions receive a convergence of input from a variety of sources, including unimodal and multimodal association regions of the cortex, association nuclei of the thalamus, and other structures. The prefrontal cortex receives afferents from higher-order sensory cortices of the parietal and temporal lobes, the contralateral prefrontal cortex, the cingulate cortex of the limbic system, the medial dorsal thalamic nucleus (an association relay nucleus), and portions of the amygdala. The medial dorsal thalamic nucleus receives highly processed inputs from many sources, including some regions, such as the amygdala, hippocampus, and hypothalamus, that project directly to the prefrontal cortex. These redundant (direct and indirect) projections may serve to attach additional significance to certain inputs received by the prefrontal cortex. The significance of these inputs may also be influenced by their temporal and spatial coincidence with modulatory inputs from brainstem nuclei that use the monoamine neurotransmitters dopamine, norepinephrine, or serotonin. These monoamine systems project broadly to the cerebral cortex, although with substantial regional differences in density (Fig. 1.2–26).

(Adapted from Hendelman WJ. *Student's Atlas of Neuroanatomy*. WB Saunders; 1994:199. Copyright © 1994 Elsevier.)

The second way that the projections are organized is according to topography. The projections that terminate in multimodal association regions exhibit a topographic organization. Different cytoarchitectonic regions of the medial dorsal thalamic nucleus project to discrete regions of the prefrontal cortex. In addition, some cortical afferents received by the prefrontal cortex are topographically organized; certain regions of the prefrontal cortex predominantly receive highly processed information from one sensory modality.

The patterns of connectivity are clearly related to some of the functional characteristics attributed to the prefrontal cortex. For example, in monkeys, lesions of the DLPFC consistently produce impairments in a monkey’s ability to perform spatial working memory tasks. These tasks require that monkeys maintain a spatial representation of the location of an object during a delay period in which the object is out of sight; the DLPFC appears to play a key role in maintaining the spatial representation of the object. This property requires the DLPFC to receive information regarding the location of objects in space, and in fact, such information is conveyed to the DLPFC via projections from association regions of the parietal cortex. Although the DLPFC is necessary for the performance of working memory tasks in monkeys, it is not sufficient for the performance of such tasks. For example, lesions of the medial dorsal thalamic nucleus in monkeys result in similar impairments in the performance of spatial working memory tasks.

Knowledge of the integration of afferent inputs into the neural circuitry of certain prefrontal regions may also be important for understanding the nature of prefrontal cortical dysfunction in schizophrenia. Individuals with schizophrenia perform poorly on tasks that are known to be mediated by the prefrontal cortex. These findings have been correlated with other measures to suggest, albeit indirectly, that the dopamine projections to the DLPFC are impaired in schizophrenia. Studies in nonhuman primates have shown that performance of delayed-response tasks that require working memory, the same type of behaviors that are impaired in subjects with schizophrenia, requires an appropriate level of dopamine input to the DLPFC.

During visuospatial delayed-response tasks, the DLPFC guides decisions about how to sample and process complex visual information, and it does this through circuitry involving the frontal eye fields, the mediodorsal thalamic nucleus, and the superior colliculus. The frontal eye fields are located in the frontal cortex, situated between the more anterior prefrontal cortex and the more caudal motor cortex, and control saccadic eye movements, which are an integral component of visuospatial delayed-response activity. Interestingly, the mediodorsal thalamic nucleus has recently been described as containing both first-order and higher-order relays, both of which appear to be involved in visuospatial delayed-response tasks. First-order brainstem afferents from the superior colliculus send eye movement–related information to the mediodorsal thalamic nucleus, which then transmits this information to the frontal eye fields. In addition to direct corticocortical connections between the DLPFC and the frontal eye fields, information from the frontal eye fields concerning the executed saccadic eye movement is transmitted to the prefrontal cortex via higher-order relays in the mediodorsal thalamic nucleus. This transthalamic circuitry suggests that the mediodorsal thalamic nucleus plays a significant role in contributing to the control of behavior executed by the DLPFC.

CEREBELLOTHALAMOCORTICAL SYSTEMS. The cerebellum traditionally has been considered to be involved solely with motor control, regulating posture, gait, and voluntary movements. More recent studies indicate, however, that the cerebellum may also play an important role in the mediation of certain cognitive abilities through inputs to portions of the thalamus that project to association regions of the cerebral cortex.

The cerebellum is located in the posterior cranial fossa, inferior to the occipital lobes (see Figs. 1.2–5 and 1.2–11). The external surface of the cerebellum, the cerebellar cortex, is composed of small folds, termed *folia*, separated by sulci. Viewed from the dorsal surface, the cerebellum contains a raised central portion, called the *vermis*, and lateral portions, called the *cerebellar hemispheres* (see Fig. 1.2–11). Located within the cerebellum are the deep cerebellar nuclei, which are arranged as follows: the fastigial nucleus is located next to the midline; the globose and emboliform nuclei are slightly more lateral; and the largest nucleus, the dentate, occupies the most lateral position (see Fig. 1.2–11). Generally, the cerebellar cortex processes the inputs to the cerebellum, and the deep nuclei process the outputs. Although many portions of the cerebellum are interconnected with brain regions that regulate motor actions, the circuitry of the cerebellum involved in cognitive functions may be of greatest interest from the standpoint of psychiatric illness. For example, the lateral cerebellar cortex and the dentate nucleus are markedly expanded in the primate brain. It has been suggested that these changes are associated with an increase in the size of cortical areas (especially the prefrontal regions) influenced by cerebellar output and an expanded role of the cerebellum in cognitive functions. More recent studies in nonhuman primates have shown that the DLPFC receives inputs from two ipsilateral thalamic nuclei (medial dorsal and ventral lateral), which receive inputs from the contralateral cerebellar dentate nucleus. The cells of the dentate nucleus involved in these connections are distinct from the cells that influence the motor and premotor regions of the cerebral cortex. Interestingly, functional imaging studies in individuals with schizophrenia have revealed abnormal patterns of activation in the cerebellum, thalamus, and prefrontal cortex, suggesting that dysfunction of this circuitry might be associated with the disturbances in cognitive processes exhibited by these individuals.

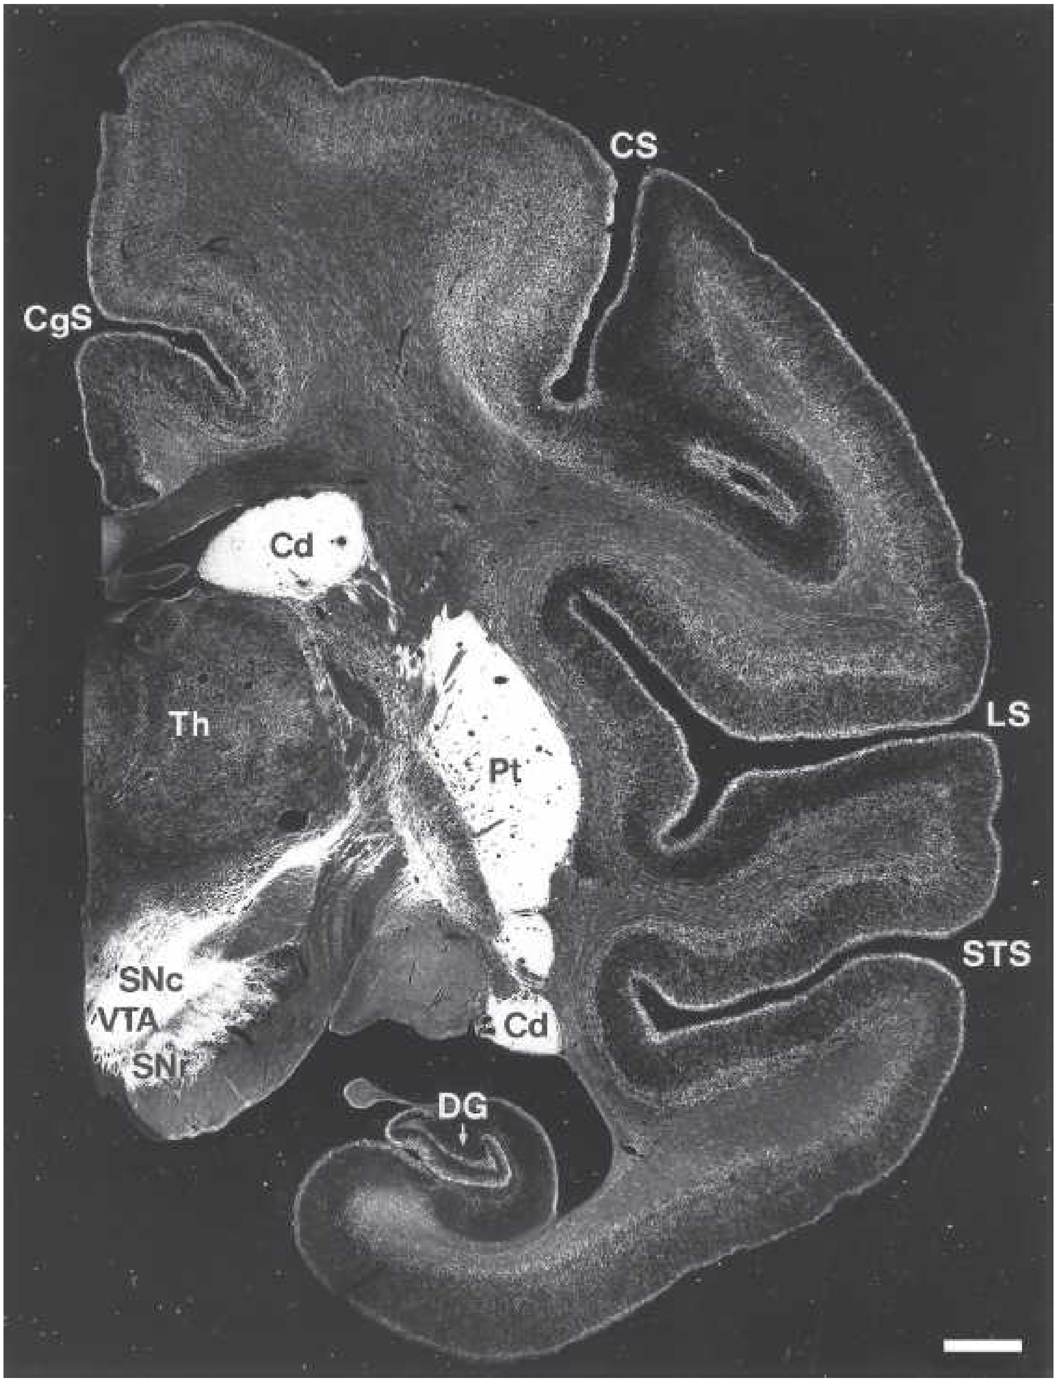

FIGURE 1.2–26. Darkfield photomicrograph of a coronal section through a hemisphere of a macaque monkey immunolabeled for the dopamine transporter. This image illustrates the differential distribution of dopamine-containing axons in different regions of the brain. The brighter the image, the greater the quantity of dopamine-containing structures. Dopamine-rich areas such as the caudate (*Cd*), putamen (*Pt*), ventral tegmental area (*VTA*), and the substantia nigra (*SNc* and *SNr*) appear white, whereas dopamine innervation of the cortex and thalamus, although clearly seen, is less dense and varies by the specific cortical and thalamic region. Dopamine transporter immunoreactivity in monkey cerebral cortex: Regional, laminar and ultrastructural localization. *J Comp Neurol*. 2001;432(1):119. Used with permission.)

Basal Ganglia System

The basal ganglia are a collection of nuclei that have been grouped together on the basis of their interconnections. These nuclei play an important role in regulating movement and in certain disorders of movement (dyskinesias), which include jerky movements (chorea), writhing movements (athetosis), and rhythmic movements (tremors). In addition, more recent studies have shown that certain components of the basal ganglia play an important role in many cognitive functions.

Major Structures. The basal ganglia are generally considered to include the *caudate nucleus*, the *putamen*, the *globus pallidus* (referred to as the *pallidum*), the *subthalamic nucleus*, and the *substantia nigra* (Fig. 1.2–27). The term *striatum* refers to the caudate nucleus and the putamen together; the term *corpus striatum* refers to the caudate nucleus, the putamen, and the globus pallidus; and the term *lentiform nucleus* refers to the putamen and the globus pallidus together.

Although these nuclei are generally agreed to comprise the basal ganglia, some controversy exists concerning whether other nuclei should be included in the definition of the basal ganglia. Some investigators believe that additional regions of the brain have anatomic connections that are similar to other components of the basal ganglia and should, therefore, be included in the term. These additional regions are usually termed the *ventral striatum* and the *ventral pallidum*. The ventral striatum includes the nucleus accumbens (Fig. 1.2–28), which is the region where the putamen and the head of the caudate nucleus fuse, and the olfactory tubercle. The ventral pallidum is a region that receives afferents from the ventral striatum and includes, but is not limited to, a group of neurons termed the *substantia innominata* (see Fig. 1.2–8). This section focuses on the structures generally accepted as belonging to the basal ganglia but also discusses additional structures when relevant to the functional anatomy of the system.

CAUDATE NUCLEUS. The caudate nucleus is a C-shaped structure that is divided into three general regions. The anterior portion of the structure is referred to as the *head*, the posterior region is the *tail*, and the intervening region is the *body* (see Fig. 1.2–27). The caudate nucleus is associated with the contour of the lateral ventricles: the head lies against the frontal horn of the lateral ventricle, and the tail lies against the temporal horn (see Figs. 1.2–8 to 1.2–10). The head of the caudate nucleus is continuous with the putamen; the tail terminates in the amygdala of the temporal lobe.

PUTAMEN. The putamen lies in the brain medial to the insula and is bounded laterally by the fibers of the external capsule and medially by the globus pallidus (see Figs. 1.2–8 and 1.2–9). As noted earlier, the putamen is continuous with the head of the caudate nucleus (see Fig. 1.2–27). Although bridges of neurons between the caudate nucleus and the putamen show the continuity of the nuclei, the two structures are separated by fibers of the anterior limb of the internal capsule (see Fig. 1.2–28).

GLOBUS PALLIDUS. In contrast to the caudate nucleus and the putamen, which are telencephalic in origin, the globus pallidus is derived from the diencephalon. The globus pallidus constitutes the inner component of the lentiform nucleus (see Fig. 1.2–27, bottom panel); with the putamen, it forms a cone-like structure, with its tip directed medially (see Figs. 1.2–8 and 1.2–9). The posterior limb of the internal capsule bounds the globus pallidus medially and separates it from the thalamus; the putamen borders the globus pallidus laterally. In humans, the medial medullary lamina divides the globus pallidus into external (lateral) and internal (medial) segments (see Fig. 1.2–28).

SUBTHALAMIC NUCLEUS. The subthalamic nucleus (of Luys) is also derived from the diencephalon. The large-celled nucleus lies dorsomedial to the posterior limb of the internal capsule and dorsal to the substantia nigra (see Figs. 1.2–9 and 1.2–27). Discrete lesions of the subthalamic nucleus in humans lead to hemiballism, a syndrome characterized by violent, forceful choreiform movements that occur on the side contralateral to the lesion.

SUBSTANTIA NIGRA. The substantia nigra is present in the midbrain between the tegmentum and the basis pedunculi and is mesencephalic in origin (see Fig. 1.2–9). The substantia nigra consists of two components: a dorsal cell-rich portion referred to as the *pars compacta* and a ventral cell–sparse portion denoted the *pars reticulata*. Most of the neurons in the pars compacta of the substantia nigra in humans are pigmented because of the presence of neuromelanin; these cells contain the neurotransmitter dopamine (see Fig. 1.2–26). The dendrites of the pars compacta neurons frequently extend into the pars reticulata, where they receive synapses from the neurons of the pars reticulata that use the inhibitory neurotransmitter GABA.

In rodents, the dopamine-containing neurons of the substantia nigra (A9 region) have been distinguished from the neurons located in the ventral tegmental area (A10 region) (Fig. 1.2–29) and the retrorubral field (A8 region), but more recent studies in monkeys and humans suggest that dopamine neurons can be more meaningfully organized at a functional level into dorsal and ventral tiers (Fig. 1.2–29). The dorsal tier is formed by a medially–laterally oriented band of neurons that includes the dopamine-containing cells that are (1) located in the medial ventral mesencephalon, (2) scattered dorsal to the dense cell clusters in the substantia nigra, and (3) distributed lateral and caudal to the red nucleus. The ventral tier comprises the dopamine neurons that are densely packed in the substantia nigra and the cell columns that penetrate into the substantia nigra pars reticulata. Dorsal tier dopamine neurons express relatively low levels of mRNA for the dopamine transporter and the dopamine type 2 receptor (D_2), contain the calcium-binding protein calbindin, and send axonal projections to the regions of the striatum that are dominated by input from limbic-related structures and association regions of the cerebral cortex. In contrast, ventral-tier neurons contain high levels of mRNA for the dopamine transporter and the D_2 dopamine receptor, typically lack calbindin, and send axonal projections to the sensorimotor regions of the striatum. Each of these features may contribute to the greater vulnerability of ventral tier neurons to the pathology of Parkinson disease, whereas dorsal tier neurons may be more likely to be involved in the pathophysiology of schizophrenia.

Internal Organization. The caudate nucleus and the putamen are frequently referred to together as the striatum because of their common characteristics. In rodents, these nuclei are a continuous structure, and, in all mammals, they are composed of histologically identical cells. Most neurons in the striatum are medium-sized cells (10 to 20 μm in diameter) that possess spines on their dendrites; these so-called *medium spiny neurons* are known to send their axons out of the striatum. In addition to medium spiny neurons, medium-sized cells without spines (medium aspiny neurons) are present, as are large cells with and without spines (large spiny neurons and large aspiny neurons). With the exception of the medium and large spiny cells, most other striatal neurons are local circuit neurons.

Immunohistochemical and receptor-binding studies have shown a discontinuity in the distribution of certain neurotransmitter-related substances that form the functional circuitry of the basal ganglia. For example, in the striatum, zones that contain a low density of acetylcholinesterase (AChE) enzymatic activity are surrounded by regions rich in AChE activity. The AChE-rich regions are referred to as the *matrix*, and the AChE-poor zones are termed either *striosomes* in primates or *patches* in rodents. Several neuropeptide systems also follow this organization. For example, the distributions of enkephalin, substance P, and somatostatin immunoreactivity are organized in a similar manner as the AChE-rich and the AChE-poor areas in the striatum. In addition, in rodents, certain subtypes of dopamine receptors are present predominantly in one compartment. Furthermore, the distribution of some afferent systems terminating in the striatum follows the striosome-matrix organization. For example, afferents from the thalamus terminate preferentially in the matrix rather than in the striosome.

Functional Circuitry. Projections into, within, and out of the basal ganglia are topographically organized and maintain this topography throughout the processing circuits of the basal ganglia. The existence of such patterns of connectivity has resulted in the hypothesis that parallel independent circuits in the basal ganglia process information from different regions of the brain and mediate separate complex functions. For example, and as illustrated in Figure 1.2–29, there is an inverse dorsal–ventral topographic organization to the projection from the dorsal and ventral dopamine neurons to the striatum. Dorsally and medially located dopamine neurons project to the ventral and medial parts of the striatum, whereas ventrally and laterally located dopamine neurons project to dorsal and lateral parts of the striatum. Another prominent input to the striatum comes from the cerebral cortex, and this projection has a topographic organization related to that of the striatonigrostriatal pathway. Orbital and medial prefrontal cortices project to the ventral striatum, the DLPFC projects to the central striatum, and premotor and motor cortices project to the dorsolateral striatum. These topographies create limbic, associative, and motor pathways within the corticostriatal and striatonigrostriatal projections.

INPUTS TO THE BASAL GANGLIA. The striatum is the major recipient of the inputs to the basal ganglia. Three major afferent systems are known to terminate in the striatum: the corticostriatal, nigrostriatal, and thalamostriatal afferents (Fig. 1.2–30). The corticostriatal projection originates from all regions of the neocortex, arising primarily from the pyramidal cells of layers 5 and 6, which use the excitatory neurotransmitter glutamate. A topography governing corticostriatal projections has been found in monkeys. Afferents from the sensorimotor cortex terminate predominantly in the putamen; association regions of the cortex terminate preferentially in the caudate nucleus. The prefrontal regions, in particular, provide a heavy input to the head of the caudate nucleus. In addition, afferents from the limbic cortical areas, the hippocampus, and the amygdala terminate in the ventral striatum. The second major class of afferents uses the neurotransmitter dopamine. In Figure 1.2–30, these projections are shown arising from the substantia nigra pars compacta, but, as noted earlier (see Fig. 1.2–29), different portions of the striatum receive input from the dorsal-tier or ventral-tier dopamine-containing neurons of the ventral mesencephalon. Electron microscopy studies have shown that many of the synapses formed by dopamine axon terminals on medium spiny neuron dendrites are immediately adjacent to the synapses provided by corticostriatal axons, suggesting that dopamine may play an important role in modulating the excitatory influence of cortical projections on striatal neurons. The third afferent system originates in the thalamus. The thalamic nuclei providing the projections are the intralaminar nuclei, particularly the central median nucleus.

FIGURE 1.2–30. Diagram of the inputs to the basal ganglia system. Three major afferent systems have been identified: the corticostriatal, thalamostriatal, and nigrostriatal pathways.

Disruption of the input pathways of the basal ganglia has been associated with some movement disorders, such as Parkinson disease, which is characterized by muscular rigidity, fine tremor, shuffling gait, and bradykinesia. The most consistent neuropathologic feature of Parkinson disease is degeneration of the dopamine neurons in the substantia nigra pars compacta, accompanied by a loss of dopamine terminals in the striatum. The compound levodopa, a precursor in the biosynthesis of dopamine, is used as a treatment for Parkinson disease because of its ability to augment the release of dopamine from the remaining terminals. Conversely, the administration of typical antipsychotic agents in the treatment of schizophrenia is frequently associated with parkinsonian features and other motor system abnormalities; the fact that these agents are D_2 dopamine-receptor antagonists is thought to explain their movement-related side effects.

INTERNAL PROCESSING. The major processing pathways within the basal ganglia are summarized in Figure 1.2–31. As noted earlier, the striatum receives a major projection from the cerebral cortex. Within the striatum, the subclass of medium spiny neurons that contain the neuropeptide substance P sends inhibitory projections to the internal segment of the globus pallidus in what is termed the *direct pathway*. In contrast, the subpopulation of medium spiny neurons that contain the neuropeptide enkephalin provides inhibitory projections to the external segment of the globus pallidus, which sends inhibitory afferents to the internal segment of the globus pallidus in what is termed the *indirect pathway*. The globus pallidus external segment also projects to the pars reticulata of the substantia nigra. The topography found in the afferent projections to the striatum appears to be maintained in that processing pathway. For example, the sensorimotor territories of the striatum project most heavily to the ventral portion of the globus pallidus, whereas association territories project to the dorsal regions of the globus pallidus.

The external segment of the globus pallidus also gives rise to an inhibitory projection that terminates in the subthalamic nucleus. In contrast, neurons in the subthalamic nucleus provide excitatory projections that terminate in both segments of the globus pallidus and in the pars reticulata. Although most connections within the basal ganglia are unidirectional, a reciprocal projection is found between the external segment of the globus pallidus and the subthalamic nucleus. The intrinsic circuitry of the basal ganglia is disrupted by a severe loss of neurons in the striatum in Huntington disease. This autosomal dominant disorder is characterized by progressive chorea and dementia. The excessive number of trinucleotide repeats in the causal gene leads to the selective degeneration of striatal cells via the accumulation of the mutant huntingtin protein within the cytoplasm and nucleus of these neurons.

FIGURE 1.2–31. Diagram of the intrinsic circuitry of the basal ganglia. Cortical neurons project to the striatum. Substance P (SP)–containing striatal neurons send an inhibitory projection directly to the internal segment of the globus

pallidus (GPi), whereas neurons containing enkephalin provide an inhibitory projection to GABA neurons in the external segment of the globus pallidus (GPe), which project to the GPi. The subthalamic nucleus (STN) receives a projection from the GPe and projects back to both segments. The STN and GPe then project to the substantia nigra pars reticulata (SNr), which projects to the thalamus. Finally, the thalamus projects back to the cerebral cortex, completing the loop.

OUTPUT OF THE BASAL GANGLIA. The internal segment of the globus pallidus is the source of much of the output of the basal ganglia (Fig. 1.2–32). This segment of the globus pallidus provides a projection to the ventral lateral and ventral anterior nuclei of the thalamus and to the intralaminar thalamic nuclei, particularly the central median nucleus. The pars reticulata of the substantia nigra also provides a projection to the ventral anterior and ventral lateral thalamic nuclei. These portions of the ventral lateral and ventral anterior thalamic nuclei project to the premotor and prefrontal cortices. As a result of the projections of the premotor and prefrontal cortices to the primary motor cortex, the basal ganglia are able to influence the output of the primary motor cortex indirectly. In addition, the cortical output of the basal ganglia exhibits marked convergence; although the striatum receives afferents from all regions of the neocortex, the eventual output of the globus pallidus and pars reticulata is largely conveyed through the thalamus to a much smaller portion of the neocortex—the premotor and prefrontal regions.

The functional consequences of the neural circuitry of the basal ganglia can also be considered in the context of some of the neurotransmitters used (see Figs. 1.2–31 and 1.2–32). Because the afferents from the cortex are thought to use glutamate, which is an excitatory neurotransmitter, cortical afferents presumably excite the structures of the basal ganglia in which they terminate. Many of the processing pathways within the basal ganglia use the inhibitory neurotransmitter GABA. Finally, the output pathways of the basal ganglia—the globus pallidus and the substantia nigra pars reticulata—use GABA as well. Excitation from cortical afferents eventually disinhibits the target structures of the basal ganglia because of the back-to-back inhibitory pathways of the basal ganglia.

Historically, motor systems have been divided into pyramidal (corticospinal), and extrapyramidal (basal ganglia) components; the names of these systems derive from the presence of the former in the pyramids, bilateral white matter structures which characterize the ventral surface of the medulla in the brainstem. This division into pyramidal and extrapyramidal is supported by clinical findings that lesions of each system result in distinct motor syndromes. For example, lesions of the extrapyramidal system result in involuntary movements, changes in muscle tone, and slowness of movement; lesions of the pyramidal system result in spasticity and paralysis. Because of these findings, the pyramidal and extrapyramidal systems were thought to control voluntary and involuntary movement independently. However, this division is no longer accurate for several reasons. First, other structures of the brain outside the traditional pyramidal and extrapyramidal systems, such as the cerebellum, are involved in the control of movement. Second, the pyramidal and extrapyramidal systems are not independent; the neural circuits of these systems are interconnected. For example, the basal ganglia influence motor behavior through certain regions of the cerebral cortex, which then directly (through the corticospinal tract) or indirectly (through specific brainstem nuclei) produce motor activity.

Finally, although the basal ganglia are important in the control of movement, this neural system also seems to be involved in other functions of the brain. More recent studies of the connections of the basal ganglia in nonhuman primates also support a role for these structures in cognitive functions. The DLPFC has been shown to receive inputs from portions of the thalamus that are the targets of projections from specific locations within the internal segment of the globus pallidus, providing evidence for a distinct pallidothalamocortical pathway. In addition to linking association regions of the cerebral cortex, such as the prefrontal and posterior parietal areas, with the control of motor activity in the primary motor cortex, some of the output of the basal ganglia seems to be directed back to regions of the prefrontal cortex. These findings suggest that “closed” loops are present between the prefrontal cortex and basal ganglia, which presumably have a cognitive rather than a motor function.

The basal ganglia are interconnected with the cerebral cortex and thalamus, forming five corticostriatalthalamocortical loops. These five parallel loops are depicted as closed, but recent studies suggest that they should be considered at least partially open due to some overlap among them. These loops can be categorized into Motor, Cognitive, or Limbic groups (Fig. 1.2–33). All five of these loops start in an area of the frontal cortex, make their way through specific input and output nuclei of the basal ganglia, and pass through a specific thalamic nucleus before returning to the cortical area of origin (Fig. 1.2–33). Each of these loops constitutes an integrated network mediating specific functions. The dorsolateral prefrontal loop contains structures known to be dysfunctional in schizophrenia, namely the DLPFC, the substantia nigra pars reticulata, and the mediodorsal thalamic nucleus. Given the role of the anterior cingulate cortex in affect regulation, the limbic loop is also likely affected in schizophrenia, as well as major depressive disorder. The ventral striatum's role in reward circuitry also implicates the limbic loop in the pathophysiology of major depressive disorder and addiction. Many regions within the lateral orbitofrontal loop appear to be dysfunctional in obsessive–compulsive disorder.

Limbic System

The concept of the limbic system as a neural substrate for emotional experience and expression has a rich but controversial history. More than 100 years ago, Paul Broca applied the term *limbic* (from the Latin *limbus*, meaning “border”) to the curved rim of the cortex, including the cingulate and the parahippocampal gyri, located at the junction of the diencephalon and the cerebral hemispheres (Fig. 1.2–34). In 1937, James Papez postulated, primarily on the basis of anatomic data, that these cortical regions were linked to the hippocampus, mammillary body, and anterior thalamus in a circuit that mediated emotional behavior (Fig. 1.2–35). This concept was supported by the work of Heinrich Klüver and Paul Bucy, who showed that temporal lobe lesions, which disrupt components of the circuit, alter affective responses in nonhuman primates. In 1952, Paul MacLean coined the term *limbic system* to describe Broca limbic lobe and related subcortical nuclei as the neural substrate for emotion. However, over the last 40 years, it has become clear that some limbic structures (e.g., the hippocampus) are also involved in other complex brain processes, such as memory. In addition, expanding knowledge of the connectivity of traditional limbic structures has made it increasingly difficult to define the boundaries of the limbic system. Despite these limitations, the concept of a limbic system may still be a useful way to describe the circuitry that relates certain telencephalic structures and their cognitive processes with the hypothalamus and its output pathways that control autonomic, somatic, and endocrine functions.

Major Structures. As noted above, no unanimity exists on the brain structures that constitute the limbic system. This section includes the brain regions that are most commonly listed as components of the limbic system: the cingulate and parahippocampal gyri (limbic cortex), the hippocampal formation, the amygdala, the septal area, the hypothalamus, and related thalamic and cortical areas.

LIMBIC CORTEX. The limbic cortex is composed of two general regions, the cingulate gyrus and the parahippocampal gyrus (see Fig. 1.2–34). The *cingulate gyrus*, a C-shaped stretch of cortex that lies dorsal to and follows the corpus callosum, includes several cortical regions that are defined by their relationship to the corpus callosum (Fig. 1.2–36). For example, *the subgenual anterior cingulate* lies ventral to the corpus callosum, extending from the anterior boundary of the genu to the rostrum (Fig. 1.2–36). The subgenual anterior cingulate is composed of Brodmann area 25 and subcallosal portions of Brodmann areas 32 and 24. The subgenual anterior cingulate is connected to other structures of the limbic system, such as the amygdala and hypothalamus, brain regions also often associated with depression. Recent imaging studies reveal that the subgenual anterior cingulate is overactive in people with depression and that a variety of treatments, such as antidepressants, electroconvulsive therapy, and repetitive transcranial magnetic stimulation, result in a decrease in activity in this area. Moreover, in preliminary studies of patients with treatment-resistant depression, deep brain stimulation (DBS) of the subgenual anterior cingulate and the underlying white matter has proven effective in the alleviation of symptoms. It’s important to note that the response documented after DBS stimulation likely results from not only direct activation of the subgenual anterior cingulate but also the activation of brain regions directly connected to it, including the amygdala, hypothalamus, and hippocampus. These areas are connected to the subgenual anterior cingulate via the callosum bundle, the unicate fasciculus, and the subcortical fascicle, and stimulation of these white matter tracts is necessary for the antidepressant response to DBS. Moreover, transsynaptic activation of areas not directly connected to the subgenual anterior cingulate, such as the DLPFC and the insula, might also play a role in the antidepressant effect of DBS.

The habenula, although technically part of the epithalamus, has significant connections within the limbic system and is divided into medial and lateral subdivisions. The lateral habenula serves as a hub connecting limbic, basal ganglia, and brainstem circuits. These links, specifically those involving projections from the lateral habenula to serotonergic neurons of the raphe nuclei and dopaminergic cells of the ventral tegmental area, suggest that the lateral habenula may be involved in mood regulation and disorders, such as depression. Preliminary studies targeting the lateral habenula for DBS have been successful and opened the door to further study of this brain region in the pathophysiology and treatment of depression.

As illustrated in Figure 1.2–36, the cingulate gyrus is extensive, and as it travels posteriorly, it becomes continuous (via the cingulum bundle of fibers in the white matter) with the *parahippocampal gyrus*, located in the medial temporal lobe, which contains several distinct cytoarchitectonic regions. One of the most important of these regions is the *entorhinal cortex*, which not only funnels highly processed cortical information to the hippocampal formation but also is a major output pathway from the hippocampal formation.

HIPPOCAMPAL FORMATION. The hippocampal formation comprises three distinct zones—the dentate gyrus, the hippocampus, and the subicular complex—and is located in the floor of the temporal horn of the lateral ventricle (see Fig. 1.2–10). These zones are composed of adjacent strips of cortical tissue that run in a rostral–caudal direction but fold over each other mediolaterally in a spiral fashion, resulting in a C-shaped appearance. The *dentate gyrus* comprises three layers: an outer, acellular molecular layer, which faces the subarachnoid space of the hippocampal fissure; a middle layer composed of granule cells; and an inner polymorphic layer (Fig. 1.2–37). The granule cells extend their dendritic trees into the molecular layer and give rise to axons that form the mossy fiber projection to the hippocampus.

The *hippocampus* is also a trilaminate structure composed of molecular and polymorphic layers and a middle layer that contains pyramidal neurons. On the basis of differences in the cytoarchitecture and connectivity, the hippocampus can be divided into three distinct fields, which have been labeled CA3, CA2, and CA1 (see Fig. 1.2–37) (*CA* is derived from the term *cornu ammonis* after the Egyptian deity Ammon, who was depicted with ram’s horns, which some early investigators thought described the shape of the hippocampus). Some disagreement exists regarding the so-called CA4 region. This terminology has been applied to the portion of the hippocampus adjacent to CA3 and within the “C” created by the granule cell layer of the dentate gyrus. Connectional studies have revealed, however, that this area is more closely related to the dentate gyrus and should be referred to more appropriately as the hilar region or hilus of the dentate gyrus (see Fig. 1.2–37). The white matter adjacent to the polymorphic layer of the hippocampus is known as the *alveus*. The axons in this structure contribute to the fimbria, which, at the caudal end of the hippocampus, becomes the crus of the *fornix*. These bilateral structures converge to form the body of the fornix, which travels anteriorly and then turns inferiorly to form the columns of the fornix, which pass through the hypothalamus into the mammillary bodies (Fig. 1.2–38).

The *subicular complex* is generally considered to have five components—the presubiculum, the parasubiculum, the prosubiculum, the postsubiculum, and the subiculum—that together serve as transition regions between the hippocampus and the parahippocampal gyrus.

The components of the hippocampal formation have a distinct pattern of intrinsic connectivity that is largely unidirectional and provides for a specific flow of information. The major input to the hippocampal formation arises from neurons in layers 2 and 3 of the entorhinal cortex that project through the *perforant path* (that is, through the subiculum and the hippocampus) to the outer two-thirds of the molecular layer of the dentate gyrus where they synapse on the dendrites of granule cells. The mossy fiber axons of the granule cells provide a projection to the pyramidal neurons of the CA3 field of the hippocampus. Axon collaterals from CA3 pyramidal neurons project within CA3, and the primary axons of these CA3 neurons, the so-called Schäffer collaterals, project to the CA1 field of the hippocampus. This region projects to the subicular complex, which provides output to the entorhinal cortex, completing the circuit.

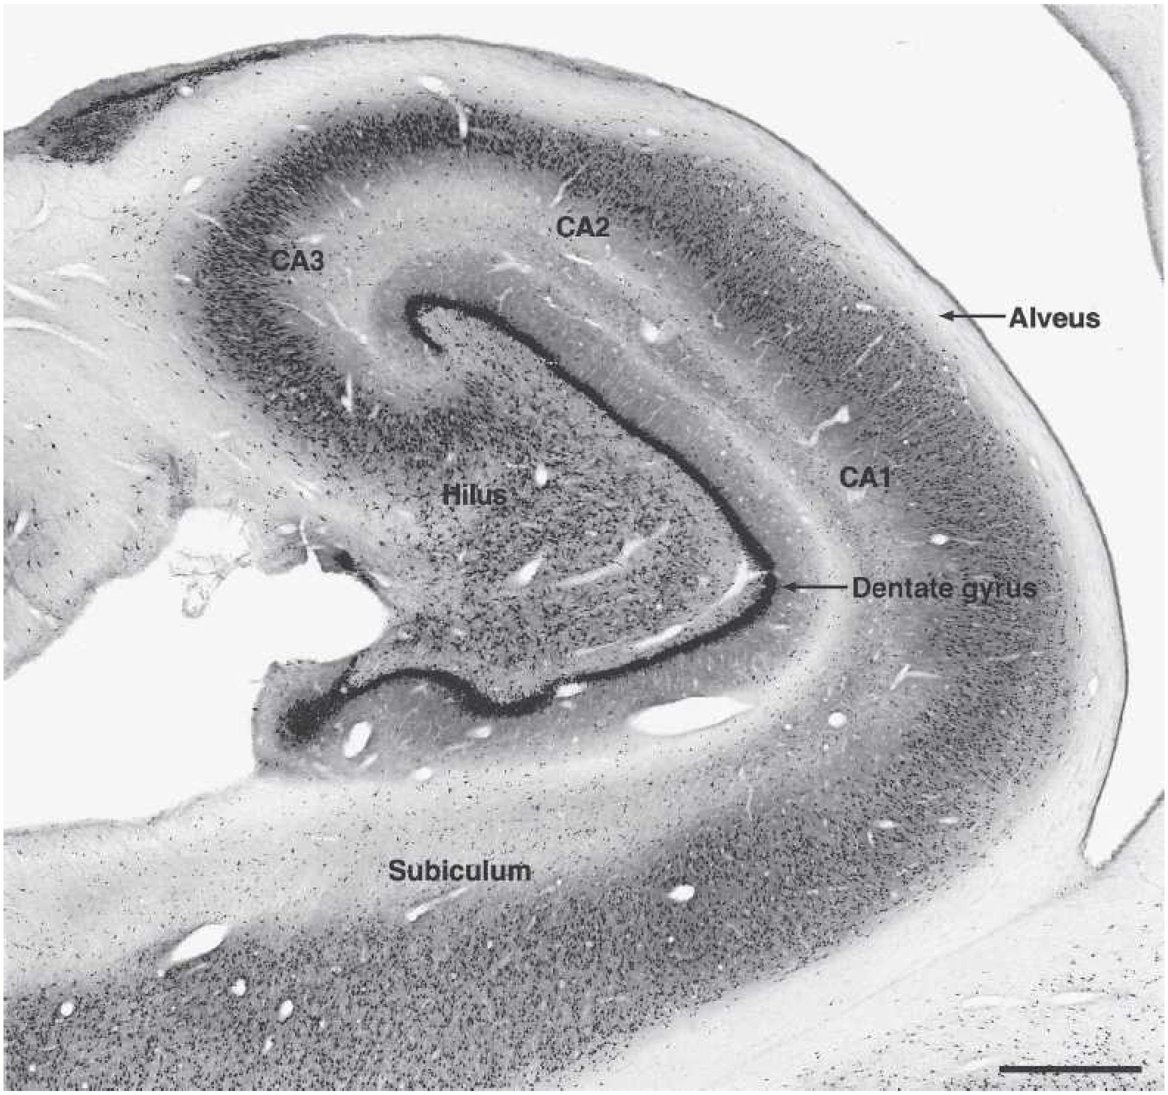

FIGURE 1.2–37. Photomicrograph of neurons immunoreactive for neuron-specific nuclear protein in the human hippocampal formation. The immunostaining illustrates the major components of the hippocampal formation. Scale bar = 1 mm.

AMYGDALA. Located in the medial temporal lobe just anterior to the hippocampal formation are a group of nuclei referred to as the *amygdala* (see Fig. 1.2–9). These nuclei form several distinct clusters: the basolateral complex, the centromedial amygdaloid group, and the olfactory group, which includes the cortical amygdaloid nuclei. These nuclei are usually delineated using cytoarchitectural features revealed by Nissl stains. However, the chemoarchitecture of cannabinoid CB_1 receptor–containing axons also clearly demarcates these nuclei (Fig. 1.2–39). CB_1 receptor immunoreactivity is found within the basolateral nuclei, the largest of the three groups, whereas the central and medial nuclei are devoid of CB_1 receptor labeling. The *basolateral complex* differs from the remaining amygdaloid nuclei in many respects. Although the basolateral complex is not a laminated structure, its connectivity and some other anatomic characteristics are more similar to cortical regions than to the remaining amygdaloid nuclei. For example, the basolateral nuclei are directly and reciprocally connected with the temporal, insular, and prefrontal cortices. In addition, similar to some cortical regions, the basolateral complex shares bidirectional connections with the medial dorsal thalamic nucleus and receives projections from the midline and intralaminar thalamic nuclei. Finally, neurons of the basolateral complex with a pyramidal-like morphology that use excitatory amino acids as neurotransmitters furnish projections to the striatum. On the basis of these anatomic characteristics, one may hypothesize that the basolateral complex actually functions similar to a multimodal cortical region.

In contrast, the *centromedial amygdala* appears to be part of a larger structure that is continuous through the sublenticular substantia innominata with the bed nucleus of the stria terminalis. This larger structure, which has been termed the *extended amygdala*, consists of two major subdivisions. The central subdivision of the extended amygdala includes the central amygdaloid nucleus and the lateral portion of the bed nucleus of the stria terminalis. This subdivision is reciprocally connected with brainstem viscerosensory and visceromotor regions and with the lateral hypothalamus. In addition, it receives afferents from cortical limbic regions and the basolateral amygdaloid complex. In contrast, the medial subdivision of the extended amygdala, composed of the medial amygdaloid nucleus and its extension into the medial part of the bed nucleus of the stria terminalis, is distinguished by reciprocal connections with the medial or endocrine portions of the hypothalamus.

SEPTAL AREA. The *septal area* is a gray matter structure located immediately above the anterior commissure (Fig. 1.2–40). The septal nuclei are reciprocally connected with the hippocampus, the amygdala, and the hypothalamus and project to numerous structures in the brainstem. The septum and the hippocampus have extensive reciprocal connections, forming the septohippocampal pathway, a neurobiologic circuit for the regulation of anxiety.

HYPOTHALAMUS. The hypothalamus, a small structure within the diencephalon, is a crucial component of the neural circuitry regulating not only emotions but also autonomic, endocrine, and some somatic functions. In addition to its relationships with other components of the limbic system, it is interconnected with various visceral and somatic nuclei of the brainstem and the spinal cord and provides an output that regulates the function of the pituitary gland. On its inferior surface, the hypothalamus is bounded rostrally by the optic chiasm and caudally by the posterior edge of the mammillary bodies. The area of the hypothalamus between these two structures, called the *tuber cinereum*, gives rise to the median eminence, which is continuous with the infundibular stalk and then the posterior lobe of the pituitary gland (Fig. 1.2–41). On the basis of these features, the hypothalamus is subdivided from anterior to posterior into three zones: the supraoptic region, the infundibular region, and the mammillary region. (In addition, the preoptic area, a telencephalic structure located immediately anterior to the supraoptic region, is usually considered part of the hypothalamus.) These three zones also are divided on each side into medial and lateral areas by the fornix as it travels through the body of the hypothalamus to the mammillary bodies. As shown in Table 1.2–4, the six parts of the hypothalamus contain different nuclei.

These different nuclei mediate the diverse functions of the hypothalamus. The *suprachiasmatic nucleus* receives direct and indirect projections from the retina and is important in the regulation of diurnal rhythms. The *supraoptic* and *paraventricular nuclei* contain large cells (magnocellular neurons) that send oxytocin-containing and vasopressin-containing fibers to the posterior neural lobe of the pituitary. In addition, some neurons of the paraventricular nucleus project to the median eminence, where they release neuropeptides, such as corticotropin-releasing factor, into the portal blood system. These neuropeptides control the synthesis and release of anterior pituitary hormones. The paraventricular nucleus also gives rise to descending projections that regulate the sympathetic and parasympathetic autonomic areas of the medulla and the spinal cord.

Within the medial tuberal region of the hypothalamus, the *ventromedial* and *arcuate nuclei* also participate in the regulation of the anterior pituitary function. In addition, the ventromedial nucleus may play an important role in reproductive and ingestive behavior. The medial posterior section of the hypothalamus contains the *posterior nucleus* and the *mammillary bodies*. Within the mammillary bodies, the lateral and medial mammillary nuclei receive hippocampal input through the fornix (see Fig. 1.2–38) and project to the anterior nuclei of the thalamus. The posterior nucleus shares reciprocal connections with the extended amygdala. This nucleus appears to be relatively more developed in primates than in rodents, suggesting that it plays an important but still-to-be-clarified role in the human brain.

The lateral portions of the hypothalamus contain a low density of neurons scattered among longitudinally running fibers of the medial forebrain bundle. This region is interconnected with multiple regions of the forebrain, the brainstem, and the spinal cord. The lateral hypothalamic area also contains a population of neurons that express the orexin neuropeptides, orexin A and orexin B (also known as hypocretin A and hypocretin B), which seem to be involved in sleep and wakefulness. The approximately 70,000 orexin-producing neurons in the human brain project throughout the brain, with the exception of the cerebellum (Fig. 1.2–42). Orexin neurons project to most of the monoaminergic (i.e., substantia nigra, locus coeruleus, dorsal raphe) and cholinergic (i.e., medial septum, pedunculopontine, laterodorsal tegmental) nuclei. Orexin neurons also have widespread projections throughout the cerebral cortex.

Areas containing high densities of orexin axons include the paraventricular thalamic nucleus, the arcuate nucleus of the hypothalamus, the locus coeruleus, and the dorsal raphe nucleus. The projections of orexin neurons to neuronal systems involved in sleep and wakefulness (i.e., locus coeruleus, raphe nuclei, and laterodorsal/pedunculopontine tegmental nuclei) suggest that orexin neurons participate in these functions. Numerous studies in animals and humans show that an orexin deficiency is the main cause of narcolepsy. For example, mice that lack the orexin gene exhibit physiologic symptoms similar to human narcolepsy, and postmortem examination of the brains of narcolepsy patients have revealed an 85 to 95 percent reduction in the number of orexin-immunoreactive neurons.

Functional Circuitry. The major structures of the limbic system are interconnected with each other and with other components of the nervous system in various ways. Several major output pathways of the limbic system are clearly defined. In one pathway (Fig. 1.2–43), highly processed sensory information from the cingulate, the orbital and temporal cortices, and the amygdala is transmitted to the entorhinal cortex of the parahippocampal gyrus and then to the hippocampal formation. After traversing the intrinsic circuitry of the hippocampal formation, information is projected through the fornix either to the anterior thalamus, which projects to the limbic cortex, or to the septal area and the hypothalamus. These latter two regions provide feedback to the hippocampal formation through the fornix. In addition, the mammillary bodies of the hypothalamus project to the anterior thalamus. Finally, the hypothalamus and the septal area project to the brainstem and the spinal cord.

Another major pathway within the limbic system centers on output from the amygdala (Fig. 1.2–44). Highly processed sensory information, primarily from the association regions of the prefrontal and temporal cortices, projects to the amygdala. Output from the amygdala is conducted through two main pathways (see Fig. 1.2–40). A dorsal route, the *stria terminalis*, accompanies the caudate nucleus in an arch around the temporal lobe and contains axons that project primarily to the septal area and the hypothalamus. The second major output route, the *ventral amygdalofugal pathway*, passes below the lenticular nucleus and contains fibers that terminate in many regions, including the septal area, the hypothalamus, and the medial dorsal thalamic nucleus. As mentioned earlier, the medial dorsal thalamic nucleus projects heavily to prefrontal and some temporal cortical regions, suggesting that this pathway may be important for the integration of emotional and homeostatic information into cognitive circuits.

Both of these pathways reveal how the limbic system is able to integrate the highly processed sensory and cognitive information content of the cerebral cortical circuitry with the hypothalamic pathways that control autonomic and endocrine systems. In addition, the limbic system interacts with components of the basal ganglia system (Fig. 1.2–45). For example, the ventral amygdalofugal pathway also projects to the nucleus accumbens (ventral striatum), the area where the head of the caudate nucleus fuses with the putamen (see Figs. 1.2–27 and 1.2–28). This region sends efferents to the ventral pallidum, an extension of the globus pallidus, which, in turn, projects to the medial dorsal thalamic nucleus. This pathway illustrates that the functions of the basal ganglia extend beyond the regulation of motor activities and shows the necessity of considering the function or dysfunction of particular brain regions in the context of all aspects of their circuitry.

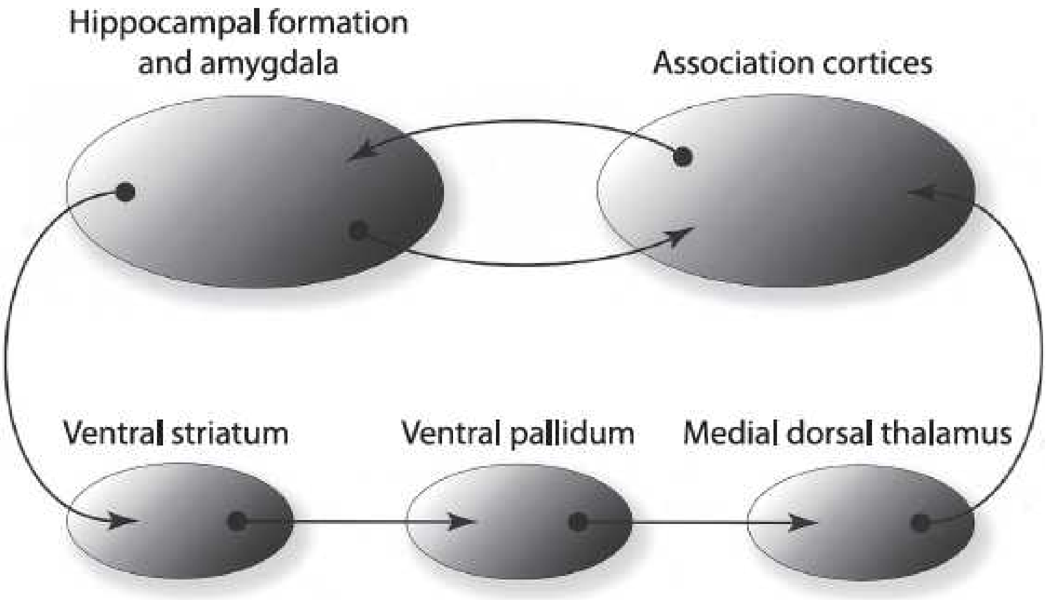

FIGURE 1.2–45. Functional neural circuitry of the limbic system. This drawing illustrates the interaction between the limbic system and certain components of the basal ganglia. (Adapted from Nolte J. *The Human Brain: An Introduction to Its Functional Anatomy*. 3rd ed. Mosby; 1993:412.)

THE BRAINSTEM. As noted earlier, the brainstem is divided into three subdivisions, ranging from rostral to caudal, the *midbrain*, *pons*, and *medulla* (Fig. 1.2–46). The brainstem is a multi-faceted structure and generally has been regarded as dealing with autonomic functions and sensory processing. The reticular nuclei of the brainstem together comprise the reticular formation, which includes all the neurons that are interspersed among the more compact and named nuclei of the brainstem. Numerous studies have revealed that several of the nuclei embedded within the brainstem play an important role in emotional and cognitive functions that are often disrupted in psychiatric illnesses.

Sensory nuclei are located at all three levels of the brainstem, and their associated pathways course from the spinal cord through the brainstem to higher levels, specifically the thalamus and cerebral cortex. The basic sensory representations in the brainstem share a common pathway to the insular cortex and adjacent frontal opercula areas, thus creating the interoceptive pathway. Interoception is an individual’s ability to detect, integrate, and interpret signals from the body, and it is tightly associated with the concept of self. Recent studies have reported reduced interoceptive accuracy in subjects with schizophrenia and increased interoceptive sensibility in subjects with obsessive–compulsive disorder.

The Midbrain. Within the midbrain, the substantia nigra and ventral tegmental area (see Figs. 1.2–26, 1.2–46, and 1.2–47) are of significant relevance to psychiatric disorders, as the neurons in these areas are the major producers of dopamine. The connections and their implications for psychiatric disorders are outlined in the previous section (Basal Ganglia/Major Structures/Substantia nigra).

Other notable nuclei within the midbrain include the *periaqueductal gray* (see Fig. 1.2–46), an area that has historically been associated with the regulation of emotions and experience of pain. The periaqueductal gray surrounds the cerebral aqueduct (see Fig. 1.2–47) and is comprised of four columns that are oriented rostral to caudal; the dorsomedial periaqueductal gray, the dorsolateral periaqueductal gray, the lateral periaqueductal gray and the ventrolateral periaqueductal gray (see Fig. 1.2–47). The two dorsal and two ventral columns are often combined to form dorsal periaqueductal gray and ventral periaqueductal gray, respectively. The dorsal periaqueductal gray is innervated by the amygdala, the ventromedial hypothalamus, the medial prefrontal cortex, and all sensory systems. The dorsal periaqueductal gray innervates the sympathetic nervous system and is thought to facilitate the fight/flight and other active coping responses associated with increased autonomic activation. The ventral periaqueductal gray is targeted by the anterior insula and dorsomedial prefrontal cortices and innervates the parasympathetic nervous system. The ventral periaqueductal gray is thought to mediate passive coping mechanisms.

FIGURE 1.2–46. Schematic drawing of a midsagittal section of the brain stem indicating the positions of various nuclei implicated in psychiatric disorders. (Adapted from Carpenter MB, Sutin *J. Human Neuroanatomy*. 8th ed. Williams & Wilkins; 1983.)

The periaqueductal gray is often considered a gateway between the spinal cord and brainstem, transmitting sensory and pain sensations, and has been implicated in a variety of disorders, including panic disorder and chronic pain. Recent studies suggest that unchecked amygdala input to the periaqueductal gray (due to a reduction in prefrontal cortical input to the amygdala) results in inappropriate activation of the periaqueductal gray, possibly contributing to the symptoms of posttraumatic stress disorder.

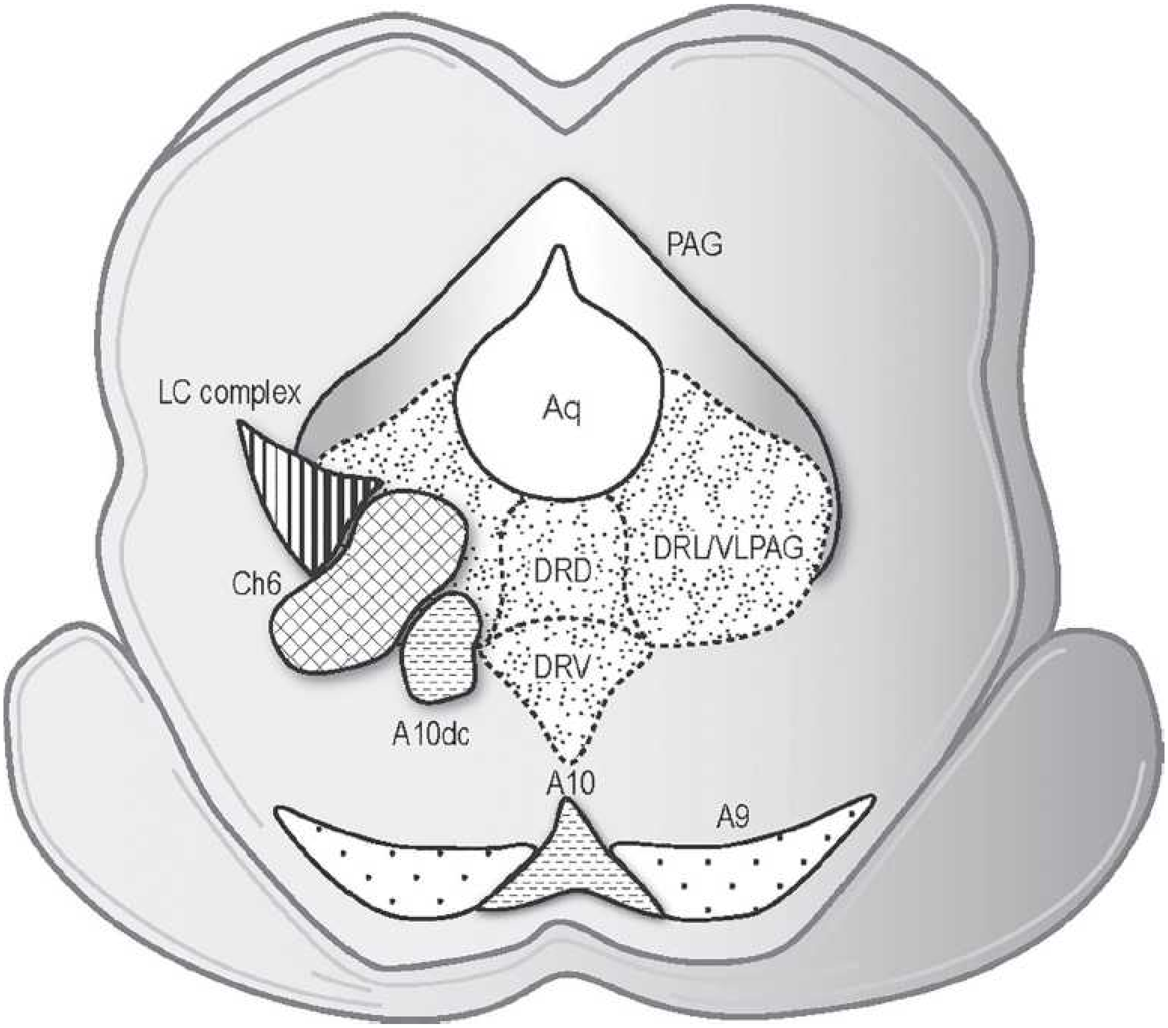

FIGURE 1.2–47. Schematic drawing of the monoaminergic and cholinergic nuclei in a coronal section through the brainstem. In order to include as many relevant nuclei, this section represents nuclei present in both the midbrain and pons. As described in the text, the dorsal raphe nucleus has several subdivisions, all of which can be related to the periaqueductal gray (PAG) and the cerebral aqueduct (Aq). The *raphe nuclei*, which span the length of the brainstem, from the midbrain to the medulla (see Fig. 1.2–46), are the primary source of serotonergic projections within the brain. Seven distinct raphe nuclei within the human brain can be distinguished based on their location within the brainstem. The nuclei can also be divided into a dorsal group and a caudal group, based primarily on their efferent projections. The dorsal group contains the nucleus linearis, the dorsal raphe nucleus, and the medial raphe nucleus.

The nucleus linearis is located along the midline between the two red nuclei, dorsal to the interpeduncular nucleus, and ending at the level of the decussation of the superior cerebellar peduncle. This nucleus is the most rostral raphe nucleus that synthesizes serotonin, although it also contains a variety of chemical-specific cells, including dopaminergic neurons.

At rostral levels, the dorsal raphe is located along the midline, ventral to the periaqueductal gray, and bordered laterally by the oculomotor nucleus and the medial longitudinal fasciculus, and caudally it remains ventral to the periaqueductal gray with the trochlear nucleus and medial longitudinal fasciculus serving as lateral borders. The dorsal raphe can be further subdivided into subnuclei, including the dorsal raphe, which contains the largest population of serotonergic neurons in the human brain, the lateral dorsal raphe, and the ventral dorsal raphe (see Fig. 1.2–47).

The median raphe is situated along the midline and ventral to the dorsal raphe. At some levels, the two nuclei are adjacent to each other. The median raphe extends from the decussation of the superior cerebellar peduncle to the level of the trigeminal motor nucleus and ends in the pons below the medial longitudinal fasciculus.

Numerous studies have revealed that serotonergic neurons within the dorsal raphe and median raphe send projections to the cerebral cortex and other forebrain structures, such as the thalamus, basal ganglia, amygdala, and hippocampus. The projections to the cerebral cortex of these two nuclei are parallel, dense projections and can be distinguished by the morphology of the fibers and their laminar arborization pattern. Briefly, axons from dorsal raphe neurons have small varicosities and are widely distributed in the cerebral cortex and hippocampus, whereas axons from the median raphe have large varicosities and are distributed mainly in the hippocampus and provide a more modest innervation of the cerebral cortex.

The dorsal and median raphe nuclei and their axonal projections are important targets for the treatment of many psychiatric conditions in which mood is affected, as indicated by the effectiveness of selective serotonin reuptake inhibitors.

The Pons. The predominant source of noradrenergic projections arises from the locus coeruleus nucleus, which is embedded within the tegmentum of the brainstem. The locus coeruleus nucleus is situated in the floor of the fourth ventricle and upper dorsolateral pons. Named for the blue pigmentation of the neurons within this nucleus (Latin, *caeruleus* for blue), this small cluster of neurons has widespread projections throughout the cerebral cortex. Although there are other noradrenergic nuclei within the brain, the locus coeruleus nucleus is the major source of projections to the cerebral cortex and thalamus.

Norepinephrine has a widespread and multifunctional impact on brain functioning and can be considered a hormone (both within the CNS and the body) as well as a neurotransmitter. Noradrenergic neurotransmission in the cerebral cortex has strongly been associated with anxiety disorders, including panic disorder and generalized anxiety disorders. However, given the widespread distribution of norepinephrine axons across all areas of the cerebral cortex, it is likely that the noradrenergic neurons of the locus coeruleus nucleus play a role in many psychiatric disorders.

The pedunculopontine and lateral dorsal tegmental nuclei are the primary sources of cholinergic projections to the thalamus as well as to other brainstem areas, including the ventral tegmental area. Most cholinergic projections to the cerebral cortex arise from the basal forebrain, and this circuitry has been the most studied in psychiatric disorders.

The Medulla. Anatomically, the medulla is characterized by the pyramids, white matter tracts that carry information from the precentral, postcentral, and premotor cortices to the spinal cord, forming the corticospinal tract. Medullar nuclei that may play a role in psychiatric disorders include the A2/C2 nuclei and two raphe nuclei; the nucleus raphe obscuris and pallidus. The A2/C2 nuclei are comprised of adrenergic and cholinergic neurons, which send their respective projections to other brainstem areas as well as the thalamus.

IMPLICATIONS FOR BIOLOGICALLY BASED DIAGNOSTIC SYSTEMS

The integrity of the neuroanatomic features described in this chapter can be assessed in individuals with psychiatric disorders at different levels of resolution. Disease-associated changes in neuron number, neuron size, or connections among neurons may be reflected in gross structural alterations detected by in vivo imaging techniques. It remains unclear, however, if the resolution afforded by these imaging techniques would be able to discriminate among different disease processes in a manner that could inform clinical diagnosis. For example, a disease-related difference in the volume of a given brain region could be due to fewer neurons, smaller neurons, or fewer neuronal connections; the same abnormality evident by structural imaging could represent very different underlying disease processes. Although postmortem studies provide the level of resolution needed to distinguish among such possibilities, the diagnostic value of findings from these investigations (as is the case for imaging studies) requires the capacity to distinguish among the following five "C's": (1) *cause*, an upstream factor related to the disease pathogenesis; (2) *consequence*, a deleterious effect of a cause; (3) *compensation*, the brain's response to either a cause or a consequence that helps restore homeostasis; (4) *comorbidity*, a product of factors frequently associated with, but not a part of, the disease process; or (5) *confound*, an artifact of the approach used to obtain the measure of interest. The future incorporation of anatomic data into a diagnostic schema for psychiatric disorders will depend on the ability to make measurements at the appropriate level of resolution and to determine which "C" category a given observation represents.

1.3 Functional Genomics of Human Brain Development

Kartik Pattabiraman, M.D., Ph.D., Sirisha Pochareddy, PH.D., John C. Silbereis, PH.D., John N. Constantino, M.D., and Nenad Sestan, M.D., PH.D.

The human central nervous system (CNS) comprises approximately 86 billion neurons connected by hundreds of thousands of kilometers of myelinated axons and several hundred trillion to well over a quadrillion synapses, along with a roughly equal number of glial cells. Reflecting this complexity, building the human CNS requires the precise regulation of molecular and cellular processes. Through this regulation, intrinsic processes encoded in the human genome and extrinsic modulators from the environment converge in development to shape the circuitry, anatomical features, synaptic interactions, and cellular processes that carry out neural function. The greater size and complexity of the human brain are, of course, foundational to the expanded intellectual, cognitive, and emotional capacities of humans. As a result of its size and complexity, the human brain as a whole, but most especially the association areas of the cerebral neocortex, takes relatively more time than the brains of other mammals to develop, and humans have a particularly long gestational time, as well as childhood and adolescence (Fig. 1.3–1). This prolonged developmental course and period of dependency allows, more so than in other species, environmental factors to shape the development of cognitive, emotional, and social capabilities and capacities. Indicative of the biologic challenge of precisely regulating diverse molecular and cellular processes over a protracted period of time and across myriad cell types and regions, the CNS exhibits regionally and temporally distinct patterns of vulnerability to various diseases and insults (see Fig. 1.3–1).

Thus, the many neurodevelopmental processes that enable human brain complexity seem to have required an evolutionary trade-off that rendered it especially susceptible to certain disorders.

Recent technologic advances and increased focus on human neurodevelopment have enabled a more comprehensive characterization of the human CNS and its development in both health and disease. In particular, "-omic"-level characterizations of the transcriptional (e.g., gene expression properties), gene regulatory, and epigenetic processes of the developing human CNS across developmental periods and brain regions combined with comparative studies in non-human primates and rodents have generated new insights into the molecular landscapes that define human CNS development and their dysfunction in disease. Furthermore, the genomic revolution has considerably advanced knowledge about the genetic variations that confer risk for various neurologic and psychiatric disorders, confirming that psychiatric disease is, by and large, genetically complex and etiologically diverse.

This chapter details the current understanding of the transcriptional and regulatory architecture of the developing human neocortex and other regions of the CNS. It further provides examples of how a broad dysfunction of these processes likely underlies neurodevelopmental and psychiatric disease. Emphasis will be given to studies of the neocortex because of its importance in higher-order cognition, emotional regulation, complex behaviors, and the pathobiology of many neurodevelopmental and psychiatric disorders. Another chapter of this book, titled "Neurodevelopment and Neurogenesis," describes the basic principles of the organization and development of the CNS, and it is recommended as companion reading.

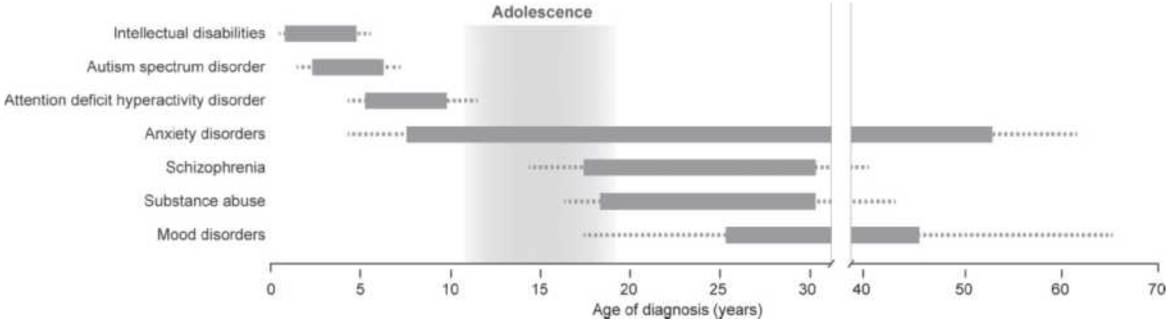

FIGURE 1.3–1. Psychiatric and neurodevelopmental disorders have discrete ages of onset. An illustration detailing the ages of onset of major psychiatric and neurodevelopmental disorders. The bars indicate the age range that each disorder commonly affects, with less frequent ages of diagnosis denoted as *dotted lines*. Note that the age of diagnosis is highly variable between brain disorders. Many psychiatric disorders emerge in adolescence and early adulthood, while neurodevelopmental disorders emerge earlier. This variability is indicative of dysregulation of tightly regulated developmental processes. (Based in part on data from Kessler RC, Amminger GP, Aguilar-Gaxiola S, et al. Age of onset of mental disorders: a review of recent literature. *Curr Opin Psychiatry*. 2007;20:359–364; Silbereis J, Pochareddy S, Zhu Y, Li M, Sestan N. The cellular and molecular landscapes of the developing human central nervous system. *Neuron*. 2016;89:248–268.)

THE TRANSCRIPTIONAL LANDSCAPE OF THE DEVELOPING HUMAN CNS

At the root of the cell and molecular processes governing human brain development is the immensely complex genome (see section “Organization of the Human Nuclear Genome”). Transcription refers to the conversion of genetic information encoded in DNA to mRNA; mRNA is then translated into the proteins that ultimately carry out the common and unique functions of specific cell types. Therefore, the selection of genes for transcription and the determination of gene expression levels are largely responsible for establishing the molecular and physiologic properties of distinct cell types and brain regions. Transcription is therefore tightly governed by a diverse array of regulatory mechanisms. The development of high-throughput technologies (see section “High-Throughput Techniques to Study Molecular Landscapes”) has greatly advanced the ability to explore the transcriptome in the developing human CNS in order to understand the diverse cell and molecular phenotypes that underlie CNS function and disease processes.

Organization of the Human Nuclear Genome

The human nuclear genome comprises approximately 6.2 (in males) or 6.4 (in females) billion base pairs distributed across 46 chromosomes and provides the blueprint for building the body and its function. Current GENCODE estimates (/www.gencodegenes.org/stats/current.html; version 39) predict 61,533 genes. Of these, 19,982 are protein-coding genes, 26,378 are noncoding RNA (long and short) genes and the remaining are pseudogenes. Furthermore, recent studies have found that greater than 90% of human protein-coding genes have splice variants, with the human brain showing the greatest splicing complexity. A significant part of the remaining genome is believed to be *cis*-regulatory elements (CREs), the DNA sequences that regulate transcription. According to some estimates, the human nuclear genome harbors approximately 400,000 putative enhancers and 70,000 promoters. Access to CREs by transcription factors and other components of the transcriptional machinery is regulated by epigenetic modification of both DNA and chromatin. Most notably, methylation of DNA generally represses gene expression by blocking DNA binding, while acetylation of histones promotes transcription by opening up the chromatin to make DNA more accessible. This highlights both the complexity of the human genome and the challenges in elucidating the molecular mechanisms underlying complex processes like neurodevelopment.

High-Throughput Techniques to Study Molecular Landscapes

Several major techniques have been applied over the past decade to study the human genome and its functions at a global scale. Many of these techniques rely on either hybridization or deep sequencing to identify and quantify the molecular species (RNA, DNA) tested. Some of the popular high-throughput techniques applied to investigate gene expression and its regulation at a genome-wide scale are discussed below:

Exon arrays—A microarray platform to quantify RNA expression at the exon level through hybridization to sequences of exons for known genes.

RNA-seq—Next-generation sequencing of RNA to identify and quantify the various RNA species, including coding and noncoding RNAs in a given sample. Allows unbiased detection of transcripts, thus leading to the identification of novel transcripts. This technique can be performed both at the tissue and single-cell levels. Single-cell level analysis has been especially important in studying the brain, given the numerous transcriptomically and functionally distinct cell types.

ATAC-seq—Assay for Transposase-Accessible Chromatin (ATAC) followed by next-generation sequencing identifies regions of genomic DNA that are defined as “open” chromatin, which are regions that can be bound by transcriptional machinery. Allows for unbiased detection of putative active CREs and gene promoters. This technique can be performed at the tissue and single-cell level.

ChIP-seq—Chromatin immunoprecipitation (ChIP) followed by next-generation sequencing identifies regions of genomic DNA at which a particular protein of interest is interacting. Typically, DNA interacting with the protein of interest (e.g., transcription factor or histone mark) is precipitated along with the protein by using an antibody specific to the protein of interest. The precipitated DNA is then sequenced to identify the genomic sequences. This technique has been applied to identify genomic regions enriched for certain histone modifications or bound by specific transcription factors.

Methylation arrays—Microarrays that quantify DNA methylation levels at an array of regulatory sites by selective hybridization of methylated DNA that utilizes a reaction with bisulfate that marks methylated but not unmethylated DNA by converting methylated cytosine to uracil.

WGBS—Whole genome bisulfite sequencing is a sequencing-based approach to determine DNA methylation levels on a genome-wide scale.

Spatial–Temporal Transcriptional Dynamics of Human Brain Development

A number of recent genome-wide profiling studies of the developmental transcriptome (see Silbereis et al. for a comprehensive review) have produced comprehensive datasets describing coding and noncoding RNAs across multiple time points and regions of the human brain. These analyses have shed new light on the transcriptional architecture of brain regions and neocortical areas, neurodevelopmental processes, and the underlying biology of complex neurodevelopmental disorders. This work indicates that most protein-coding genes (at least 86% according to Kang et al., 2011) and a growing number of noncoding genes (see section

"Organization of the Human Nuclear Genome") are involved in building the human CNS at some point in development. Of the protein-coding genes expressed in the brain, about 90% were either differentially expressed or spliced across brain regions and/or time. Such differences in the transcriptional architecture of brain regions and neocortical areas reflect their distinct ontologies, cellular compositions, biologic processes, and developmental timing (Fig. 1.3–2).

Another common finding of these studies is that transcriptomes differ more prominently across time and space than they do between sexes, ethnicities, or individuals, despite the underlying genetic differences. In particular, the majority of the temporal variance occurs during two phases: an early fetal transition (postconception weeks 6 to 10) and a late fetal transition between midfetal development and infancy. In contrast, expression changes over several decades of adulthood are relatively minute (Fig. 1.3–2A). When compared with dorsal pallial structures (amygdala, hippocampus, and neocortex), the cerebellum is the most transcriptionally distinctive region in the developing and adult brain, followed by the thalamus and striatum (Fig. 1.3–2B). Transcriptional differences in primordial areas of the developing neocortex are less robust than those between the neocortex and the other analyzed brain regions. A majority of these spatially enriched genes are also temporally dynamic; notably, some are transiently enriched during a specific time window, including protracted epochs of postnatal development such as late childhood and adolescence. Single-cell transcriptomic and epigenetic analyses in fetal tissues have similarly identified complex dynamic expression across individual neuronal and nonneuronal populations, including differential maturation rates. These findings reveal that regional transcriptomes are developmentally regulated and may reflect cellular and functional differences.

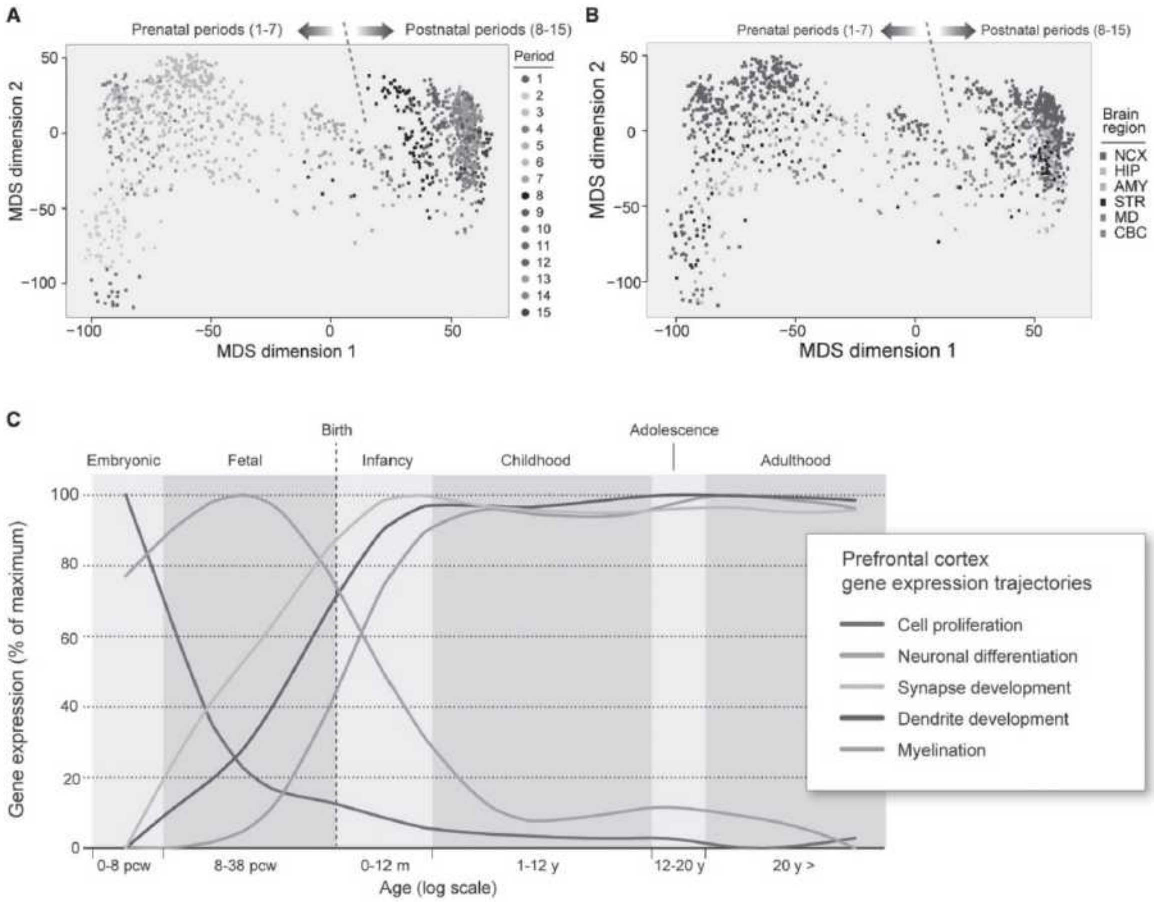

FIGURE 1.3–2. Global spatiotemporal dynamics of the human brain transcriptome. **A:** This panel shows a multidimensional scaling (MDS) plot that describes gene expression differences between developmental periods. MDS is statistical/graphical technique that reduces the complexity of data by plotting individual data points apart from one another at distances corresponding to the degree to which they are different. In the plot, each dot represents a sample and is colored according to period as defined by Kang et al., 2011; the *dotted line* indicates birth. Note that the most pronounced differences (approximately two-thirds) occur during prenatal development (periods 1 to 7). By contrast, over four decades of adulthood (periods 13 to 15), less than 1% of genes are differentially expressed. **B:** Here the same MDS plot as in (**A**) is shown except that the new data points are colored by brain region. Note that the most prominent transcriptional differences between regions are between cerebellar cortex (CBC) and forebrain regions. NCX, neocortex; HIP, hippocampus; AMY, amygdala; STR, striatum; MD, mediodorsal nucleus of thalamus. **C:** A line graph illustrating the developmental trajectory of expression of genes important for major neurodevelopmental processes demonstrating how gene expression profiles are linked to the cellular processes that take place at different periods of development. The y-axis represents the percentage of gene expression relative to maximum and the x-axis corresponds to age. (See eBook for color images.)

Transcriptional studies have also demonstrated correlations between gene expression dynamics and the morphologic and functional development of brain regions and consequently shed light on the timing of developmental processes and the onset of specific biologic functions (Fig. 1.3–2C). For example, gene coexpression network analyses have revealed that the developmental brain transcriptome is segregated into distinct modules or clusters of genes with highly correlated expression. The expression trajectories of such modules often exhibit dynamic patterns across development, indicating that they play roles in distinct and dynamic developmental processes. For example, in a study by Kang et al., 2011, the two largest modules were composed of genes that are coregulated across brain regions and time, indicating that many transcriptional processes are shared and coordinated across different regions as the brain develops. Many modules could be defined by functional ontologies, as they were highly enriched for genes important for specific biologic processes.

Looking broadly at the expression levels of genes implicated in major developmental processes by functional ontology analysis sheds light on the molecular dynamics of human brain maturation and the timing of key neurodevelopmental events across areas. For instance, in the prefrontal cortex, genes promoting cell proliferation are most highly expressed embryonically, and expression declines markedly during the fetal period; genes associated with neuronal differentiation peak in the fetal period and are downregulated in infancy; and genes important for myelination rise markedly during perinatal development, plateauing around 1 year of age (Fig. 1.3–2C). Taken together, transcriptomic analyses of human brain development across the spatial, temporal, and cellular dimensions have provided novel insights into normal neurodevelopmental processes and the interpretation of disease-associated mutations and underlying neuropathology, as discussed later in this chapter.

Transcriptional Organization of the Fetal Neocortex

These gene expression differences play essential roles in establishing the complex anatomical, circuit, and functional organization of the CNS, as can be exemplified in the development of the cerebral neocortex. At least two types of spatial information must be encoded in nascent projection neurons of the cortical plate (CP). First, their position in the radial direction, corresponding to their laminar position, with distinct cell types, synaptic connectivities, and functions within each lamina or layer; and second, their position in the tangential plane, corresponding to their particular cortical region/area identity. The human cerebral neocortex exhibits the basic organizing principle common to all mammals; however, there are human-enriched and defining features that are largely responsible for differences in cognition, emotion, behavior, and manifestations of disease.

Most of the neurons of the cortex are generated from the late embryonic period to the late fetal period, as is detailed in depth in chapter Neurodevelopment and Neurogenesis. During this period, the neocortical wall becomes segregated into laminar zones, each composed of characteristic cell compositions carrying out discrete neurodevelopmental processes. These lamina exhibits highly distinct gene expression patterns that define their biologic roles. For instance, in early and midfetal development genes associated with proliferation and stem cell identity are enriched in the ventricular and subventricular zones (VZ and SVZ), which are germinal lamina overlying the ventricles. In contrast, the CP, which is the primordium for the cerebral cortex, is characterized by high expression of genes promoting neuronal differentiation and synaptogenesis. Recent single-cell level studies are beginning to reveal greater heterogeneity in both progenitors and neurons in the VZ, SVZ, and CP, including the outer subventricular zone (OSVZ), which is greatly expanded in the human cerebral cortex.

The CP will ultimately form the mature neocortex, which is a six-layered structure with the upper layers (e.g., through 4) sending intracerebral projections and the lower layers 5 and 6 sending projections to the sub cerebrum, brain stem, spinal cord, and other cortical areas, as well as, in the case of layer 6, reciprocal connections to the thalamus. Each of these layers is also characterized by distinct gene expression patterns, which are important for conveying the unique projection identities, synaptic receptivities, and functional properties within them. Defining these layers requires the establishment of spatially restricted gene expression patterns through transcriptional regulation, which shall be described later in this chapter.

Transcriptional Patterns Define Neocortical Regions and Areas in Development

While the neocortex has a highly specialized laminar organization, its organization into functionally discrete regions and areas along the tangential dimension is arguably far more complex, especially in humans. Work in mice shows this is governed by graded expression of transcription factors during early embryonic development, followed by extrinsic signaling from thalamic axonal inputs. Studies of the human transcriptome have revealed substantial regional/areal gene expression differences in the developing human neocortex (Fig. 1.3–3). Indeed, each region/area exhibits discrete temporally specified transcriptional properties that are likely reflective of underlying biologic processes involved in the patterning and specialization of neural circuits encompassing particular regions and areas (Fig. 1.3–3A). Interestingly, these regional/areal transcriptional profiles were largely symmetric between hemispheres at the population level from fetal development through adulthood. This is surprising given the functionally distinct roles and different developmental trajectories of the left and right hemispheres, which arise in the late midfetal period and become more prominent during early postnatal periods. These findings, therefore, suggest that transcriptional neocortical left-right asymmetry may be too subtle for detection by tissue-level transcriptomic methods or that nontranscriptional mechanisms, such as neural activity, play more critical roles.

Interareal transcriptional differences were found to be most robust during midfetal development (postconception weeks 15 to 24), a crucial period for specification and the initial assembly of neocortical neural circuits (Fig. 1.3–3B,C). During these periods, there were prominent and specific transcriptional signatures associated with prospective prefrontal and perisylvian areas, which are involved in some of the most distinctly human aspects of cognition and behavior. In addition, prefrontal/frontal-enriched gradients of expression along the anteroposterior axis of the CP, as well as gradients with enrichment in temporal, occipital, occipitotemporal, perisylvian, and ventromedial areas, were observed. Recent transcriptomic analysis of the human midfetal cortex identified a novel enrichment of genes associated with retinoic acid signaling in the frontal lobe established by a prefrontal cortex-enriched rostrocaudal gradient of retinoic acid. Disruption of the gradient of retinoic acid in the developing mouse cortex led to disruption of prefrontal cortex specification and connectivity.

Strong early and midfetal interareal transcriptional differences and gradients diminish perinatally and increase again after adolescence (Fig. 1.3–3B,C). By contrast, in late fetal periods and early postnatal development, more general molecular programs governing glial development, synaptogenesis, synaptic plasticity, and dendritic maturation can predominate. The progressive increase in regional differences that emerge in adolescence could be reflective of variations in the maturational trajectories between certain neocortical areas (e.g., associative vs. primary areas) and may be important for late cognitive, emotional, and socio-behavioral development.

Taken together, these findings indicate that, similar to other species (Brain Initiative Cell Census Network, 2021), the generation and differentiation of neocortical cell types and their assembly into functional neural circuits in humans are achieved through precise regulation of spatiotemporal gene expression. Psychiatric disorders and neurodevelopmental disorders are associated with both selective dysfunctions of specific brain regions and neocortical areas and abnormal functional and anatomical connectivity between them. It is, therefore, likely that distinct etiologies of psychiatric disorders can be defined by abnormal gene expression at specific times and places in the developing brain.

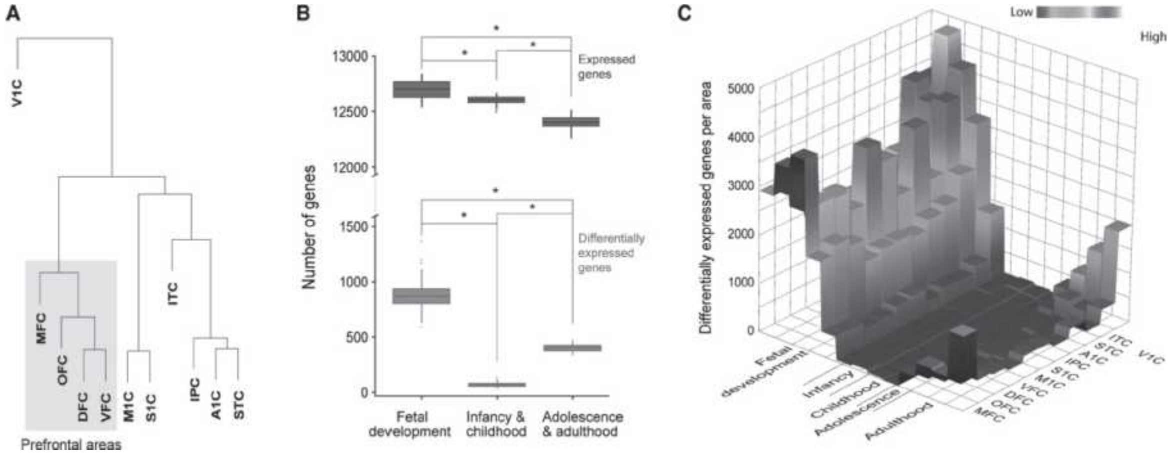

FIGURE 1.3–3. Transcriptional differences among human neocortical areas are temporally regulated. **A:** Illustration of the relative transcriptional differences between brain areas in an unsupervised hierarchical clustering chart that arranges the 11 neocortical regions/areas profiled by Pletikos et al., 2014, based on the similarity of the transcriptome of each area from early fetal development throughout adulthood. OFC, orbital prefrontal cortex; DFC, dorsal prefrontal cortex; VFC, ventral prefrontal cortex; MFC, medial prefrontal cortex; M1C, primary motor cortex; S1C, primary somatosensory cortex; IPC, posterior inferior parietal cortex; A1C, primary auditory cortex; STC, superior temporal cortex; ITC, inferior temporal cortex; V1C, primary visual cortex. **B:** Boxplots showing the number of expressed (*dark gray*, top panel) and differentially expressed (*light gray*, bottom panel) genes among neocortical areas across fetal development (periods 3 to 7), infancy (periods 8 and 9), childhood (periods 10 and 11), adolescence (period 12), and adulthood (periods 13 to 15). Note that the total number of genes expressed decreases over development. However, the number of differentially expressed genes observed over development exhibits a temporal hourglass pattern with the most substantial differential expression occurring in fetal development, a marked decline in infancy and childhood, and an increase in adolescence through adulthood. **C:** A three-dimensional Manhattan plot showing the number (post hoc Tukey test) of genes with differential expression between any two neocortical areas, demonstrating that the hourglass pattern of interareal differential expression persists in all neocortical areas, but is most prominent in MFC and V1C. Differential expression corresponds to the y-axis, the x-axis delineates developmental periods, and the z-axis delineates brain region. (Reprinted from Pletikos M, Sousa AM, Sedmak G, et al. Temporal specification and bilaterality of human neocortical topographic gene expression. *Neuron* 2014;81(2):321–332. doi: 10.1016/j.neuron.2013.11.018 Copyright © 2014, with permission from Elsevier.)

THE REGULATORY LANDSCAPE OF THE DEVELOPING HUMAN CNS

The spatiotemporal patterns of gene expression discussed above are established by elaborate regulatory mechanisms that govern each step of transcription. The current understanding of the general properties of transcriptional regulation of the developing human CNS is discussed below.

Regulation of Gene Transcription

A gene is transcribed when core transcriptional machinery, including RNA polymerase and other proteins, is recruited to the gene's proximal core promoter, a minimal region of contiguous DNA sequence that is sufficient to accurately initiate a basal level of gene expression. But the tissue specificity, timing, and level of a gene's expression are greatly controlled by distal DNA sequences like enhancers (sequences that increase expression), silencers (sequences that repress expression), and insulators (sequences that act as barriers), which along with core promoters are referred to as "cis-regulatory elements" (CREs) for their ability to mediate transcriptional activity in cis (i.e., proximal regions of the genome). Enhancers are believed to activate transcription by recruiting important accessory proteins to the promoter. They have binding sites for multiple transacting regulatory proteins, primarily transcription factors, and can function on their target promoters from locations as remote as another chromosome. Bound transcription factors recruit other transcription factors or chromatin-modifying enzymes and interact with mediator complexes. One model of activation proposes that enhancer-bound transcription factors, along with mediator complex proteins, loop the intervening DNA and bring enhancers and core promoters in close proximity, leading to the activation of gene expression. Like enhancers, silencers or repressors recruit proteins, but these proteins inhibit transcription. Silencer proteins act by inhibiting transcription initiation or elongation or by sequestering activator proteins or altering chromatin state. Insulators also bind proteins, and these DNA–protein complexes act as barriers in the genome, blocking the action of an enhancer/silencer on its noncognate promoter or preventing the spread of heterochromatin.

cis-Regulation of Transcription in Neocortical Development

Comparative genomic studies, which assess sequence conservation across different organisms, have shown that many of the regulatory networks involved in neurodevelopment are highly conserved across mammals. For instance, the regulation of *FEZF2*, a gene that is necessary for corticospinal (CS) tract development and that has remarkably similar neocortical expression patterns between mouse and human, are highly similar in these species. Studies of *Fezf2* regulation in mouse neocortical development exemplify key concepts that describe developmental regulatory networks. A conserved enhancer (E4), which lies downstream of the Fezf2 transcription start site, was identified to regulate *Fezf2* expression in the developing neocortical plate and is essential for the specification of the CS tract (see Fig. 1.3–4A). *Fezf2* expression is highly enriched in the layer projection neurons of the cerebral cortex that give rise to the CS tract. This pattern suggests that the expression has to be activated in L5 and inhibited in L6 and other layers of the cortex. The gene regulatory network that accomplishes this selective expression has recently been defined (see Fig. 1.3–4A) and provides a model of spatial control of gene expression. Two related transcription factors of the SOX family, SOX4 and SOX11, were shown to be essential for FEZF2 expression by binding and activating the E4 enhancer in the cortex. SOX5, another member of the SOX family of transcription factors, also binds E4 but represses FEZF2 expression (see Fig. 1.3–4A). It was observed that SOX4 and SOX11 functionally compete with SOX5 to determine if *Fezf2* transcription is activated or repressed. The spatiotemporal dynamics of neocortical FEZF2 expression are further controlled by TBR1, another transcription factor expressed in L6 neurons. TBR1 binds to a different enhancer in a highly conserved region downstream of the *Fezf2* transcription start site and represses the expression of FEZF2 in L6. This process is indicative of a common principle of gene regulatory networks in which competitive binding of transcriptional activators and repressors in key regulatory elements form gradients that determine the areas and levels of gene expression.

FIGURE 1.3–4. **A.** Deletion of the conserved E4 enhancer which regulates transcription factor, FEZF2, leads to loss of the corticospinal tract (*white arrow*) in mouse (top). Expression of FEZF2 is restricted to layer 6 of the cortex (Fezf2 On), where the corticospinal tract originates, through the complex interplay the transcription factors SOX4, SOX5, SOX11, and TBR1. **B.** A 15 base pair deletion in the promoter of the gene GPR56 was observed

in patients with perisylvian polymicrogyria. In these patients, this mutation likely led to malformations of the perisylvian neocortex important for language among other functions. (Adapted with permission from Bae BI, Tietjen I, Atabay KD, et al. Evolutionarily dynamic alternative splicing of GPR56 regulates regional cerebral cortical patterning. *Science* 2014; 343(6172):764–768. doi:10.1126/science.1244392.) **C.** CBLN2 expression is expanded into deep layers (L) 5 and 6 in the human prefrontal cortex (PFC) compared to mouse (right). This layer specific expansion CBLN2 is likely due to hominini-specific deletion, which contains repressive SOX5 bindings sites, in the otherwise conserved CBLN2 PFC enhancer (middle). Targeted replacement of the mouse Cbln2 enhancer with the human CBLN2 enhancer led to a stable increase in dendritic spines in pyramidal neurons in PFC, which is well-defined specialization of the human PFC. (Adapted from Shibata M, Pattabiraman K, Muchnik SK, Kaur N, Morozov YM, Cheng X, Waxman SG, Sestan N. Hominini-specific regulation of CBLN2 increases prefrontal synaptogenesis. *Nature* 2021;598:489–494. doi: 10.1038/s41586-021-03952-y.)

Recent studies have also identified human and primate-specific aspects of gene regulatory networks, which are likely essential for the unique properties of the human and primate cortex and possibly advanced human cognition. For example, the synaptic organizer, CBLN2, shows species-specific expression differences in the developing prefrontal cortex. In the midfetal human prefrontal cortex, *CBLN2* is expressed in all layers of the CP, while *Cbln2* expression is restricted to the upper layer of the mouse prefrontal cortex at developmental stages equivalent to human midfetal development. This difference in expression is due to a hominini (human, chimpanzee, and bonobo)-specific deletions in a prefrontal cortex enhancer of CBLN2 (Fig. 1.3–4C). These deleted regions contain binding sites for the repressive transcription factor, SOX5, leading to the de-repression of CBLN2 expression in the human midfetal prefrontal cortex. In situ genetic humanization of the mouse CBLN2 enhancer led to the human-like expression of CBLN2 and increased dendritic spines on PFC pyramidal neurons. Of note, there is a disproportionately higher number of spines on pyramidal neurons in the human PFC compared to the PFC of other analyzed primates.

Transcriptional Regulation of Human Neurodevelopment

Although studies of individual CREs in model organisms have provided great advances in the current understanding of neurodevelopment, it is also highly evident that a comprehensive understanding of gene regulation in human neurodevelopment requires a catalog of all CREs that are active in humans. Based on the conservation of genomic sequence during evolution, many putative CREs have been identified, a large number of which are proposed to regulate the expression of genes enriched in the human brain. Conversely, DNA sequences with dramatically increased substitution rates in the human lineage compared to other organisms have also been used to predict CREs in humans.

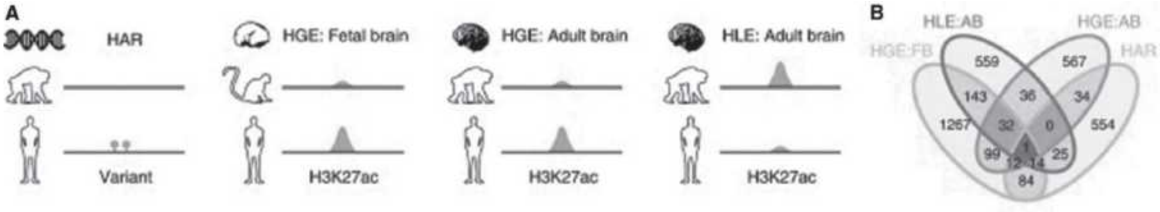

FIGURE 1.3–5. **A.** Schematic of human evolved elements. Human accelerated regions (HAR) are defined as regions with accelerated sequence change in human compared to other primates. Human hypermethylated regions are defined as regions with increased DNA methylation in human compared to other primates. Human-gained elements (HGEs) are defined as genomic regions with gained regulatory activity, defined by H3K27ac levels, in humans compared to other primates. Human lost elements (HLEs) are defined as regulatory regions lost in humans. **B.** Genes associated with human-evolved elements are enriched in outer radial glia and endothelial cells in the fetal brain (FB) and astrocytes in adult brain (AB). (Reproduced from Won H, Huang J, Opland CK, et al. Human evolved regulatory elements modulate genes involved in cortical expansion and neurodevelopmental disease susceptibility. *Nat Commun* 2019;10(1):2396. doi: 10.1038/s41467-019-10248-3. License: https://creativecommons.org/licenses/by/4.0/)

Similar to studying the transcriptome, the development of high-throughput technologies (see section "High-Throughput Techniques to Study Molecular Landscapes") has greatly improved the ability to detect CREs in the human brain. Traditionally, chromatin accessibility and nucleosome depletion and, more recently, enrichment for specific posttranslational histone modifications have been considered to be among the defining characteristics of CREs. High-throughput assay for transposase accessible chromatin (ATAC) and ChIP assays followed by deep sequencing (ChIP-seq) has been applied in postmortem human brain tissue. Visel et al. determined the genome-wide occupancy of the enhancer-associated proteins p300/CBP in the human fetal neocortex to identify active enhancers. By mapping enrichment of two enhancer-enriched posttranslational modifications of histones, histone 3 lysine 4 monomethylation (H3K4me1) and histone 3 lysine 27 acetylation (H3K27ac), enhancers active in different brain regions and at different time points were deciphered. For example, Won et al. identified evolutionarily dynamic regions in humans, including human accelerated regions, human-gained enhancers, and human lost enhancers (Fig. 1.3–5A). They annotate those regions to potential target genes and found that human-evolved regions are enriched for genes expressed in adult cortical oligodendrocytes and fetal outer radial glial cells (Fig. 1.3–5B). Combined with human cortical region-specific ATAC-seq studies, these studies have identified enhancers that have been gained in humans and putative enhancers specific to cortical regions. In addition, coregulated enhancers that form cell-type and context-specific networks have been identified. Many of these enhancer networks are correlated with modules of coexpressed genes that function in neuronal proliferation, migration, and cortical-map organization. Thus, the regulatory networks that govern spatial-temporal gene expression in the developing human CNS are beginning to be elucidated; however, this information has yet to be fully placed into a functional context.

EPIGENETIC REGULATION OF HUMAN BRAIN DEVELOPMENT

Epigenetics refers to the chemical modification of DNA, chromatin structure, and RNA that can modulate gene expression without changing the DNA sequence. Epigenetic states are dynamic over neurodevelopment and influenced by both the genome and the environment. Therefore, epigenetic regulation is a mechanism by which susceptibility to psychiatric disorders can emerge. The two most commonly studied epigenetic mechanisms are DNA methylation, which generally represses gene expression by inhibiting transcription factors from binding DNA, and posttranslational histone modifications, which alter the chromatic structure to make it either more or less accessible to transcriptional machinery.

DNA methylation of cytosine, primarily at CpG nucleotides, which are enriched in gene promoters, plays a key role in neural development and function and can be profiled at hundreds of thousands to millions of CpGs in the human genome in an unbiased manner. A widespread methylome reconfiguration during fetal to young adult development has been observed in multiple studies. Global DNA methylation in the human prefrontal cortex was shown to be greatly reconfigured during fetal-to-postnatal development. These changes were more rapid during fetal development and slowed down after birth and with aging. Many of these methylation changes correlate significantly with the changing cellular composition of the human cortex during development, highlighting the important role of DNA methylation in human neurodevelopment.

In addition to methylation CpGs, accumulation of non-CpG methylation (mCH) during the early postnatal developmental period that coincides with the primary phase of synaptogenesis has recently been discovered in the human brain. This accumulation exhibits cell-type specificity, with abundant mCH in neurons and insignificant levels in glial cells. CH methylation has increased over the course of human brain evolution, contributing to human-specific downregulation of genes and coexpression modules. The effects of CH hypermethylation are particularly pronounced in neuronal subtypes and active in early human postnatal development; disruption of developmental processes mediated by CH methylation may therefore contribute to vulnerability to neuropsychiatric disorders, and understanding them may lend new insights into the derivation of targeted treatments for those conditions. For both CpG and mCH methylation, a strong correlation with the expression of adjacent genes has been observed.

Another key epigenetic mechanism for establishing cellular diversity and regulating the timing of neurodevelopment is the posttranslational modification of histones. Methylation (mono-, di-, and tri-) and acetylation are the most extensively studied modifications, although many more have been observed. Studies have generated chromatin state maps in a limited number of postmortem human brains by applying ChIP coupled with next-generation sequencing (ChIP-seq). Cheung et al. profiled histone 3 lysine 4 trimethylation (H3K4me3) across development in neuronal and nonneuronal cells of the human prefrontal cortex of 11 individuals ranging in age from 0.5 to 69 postnatal years. A key finding of their study was significant remodeling during postnatal development and aging of prefrontal cerebral cortical neurons. Both methylation and *demethylation* of DNA are required for neuronal differentiation and function in all mammalian species; it has been observed that high levels of 5-hydroxymethylcytosine (5hmC) accumulate in mammalian neurons after birth when the cells are no longer dividing. Our knowledge of the role of

5hmC in terminal differentiation or as an intermediate in active DNA demethylation is still evolving; recently, Stoyanova et al. demonstrated in an animal model system that neurons do not mature properly if 5hmC is not produced continuously following the first week of life. Their data highlighted the role of Tet proteins, which convert 5mC into 5hmC, in preparing methylation marks for removal and demonstrating that active removal of these marks is essential for neuronal differentiation. Taken together, these data confirm that epigenetic mechanisms play a key role in establishing the regional and temporal landscape of gene expression and contribute to human brain evolution.

TRANSCRIPTIONAL AND EPIGENETIC DYSREGULATION IN NEURODEVELOPMENTAL AND PSYCHIATRIC DISORDERS

Increasingly, it is becoming understood that many neuropsychiatric conditions are rooted in genetic and environmental perturbations of early neurodevelopment. Over the last few years, genetics research has made significant strides in identifying genetic risk factors for psychiatric disorders. Most psychiatric disorders are highly complex, with multiple genes contributing to disease risk. There is very strong evidence that the genetic factors involved in psychiatric disease comprise both common and rare variants (SNPs) and submicroscopic variations in chromosomal structure (i.e., CNVs). For example, in schizophrenia and bipolar disorder, gene discovery has centered on the linkage between these disorders with common SNPs, while in ASD, highly penetrant rare and de novo single nucleotide variants are capable of engendering severe syndromes, usually associated with intellectual disability. When a neuropsychiatric condition is manifest by a single causative gene, as in many neural developmental disorders (e.g., fragile X syndrome [FXS]), there is broad dysregulation of neurodevelopmental processes that ultimately lead to disease phenotypes independent of the mutated gene’s direct biologic roles. The polygenicity of common psychiatric disorders makes identifying the molecular mechanisms underlying the pathobiology of psychiatric diseases difficult. Further complicating the ability to understand the genetic bases of disease is that, in addition to the above-mentioned germline mutations, somatic mutations—de novo mutations occurring postfertilization and often in specific cell and tissue types—can contribute to psychiatric and neurodevelopmental disorders.

Genetics and complex polygenic risk architecture do not completely explain susceptibility to many psychiatric diseases. Indeed, for many disorders, the possibility of two identical twins developing the disease is lower than the genetic risk, indicating that environmental factors influence disease susceptibility. For example, environmental factors such as obstetric complications have been reported to increase the risk of developing schizophrenia. Aversive stimuli from the environment have broad effects on the cellular processes in the developing brain, ranging from altered gene expression levels to dysregulated neural activity, which then interacts with neural development to convey increased susceptibility to psychiatric problems. Moreover, adverse events in development can lead to epigenetic changes that might have permanent effects on gene expression; in neuropsychiatric disease states, *stochastic influences*—random events that minimally affect the course of typical development—may have amplified effects on severity and variation in outcome. This is a specific example of genetic variation accentuating sensitivity to variation in the environment in a manner that induces highly variable rather than highly predictable responses.

Despite this etiologic complexity, the neurodevelopmental disruptions underlying psychiatric diseases converge on distinct and presumably definable cell and molecular processes, brain circuits, and epochs of development. Resolving these processes conveys a better understanding of the underlying pathology and may lead to more targeted therapeutic strategies. As described in several examples below, increasingly comprehensive studies of the cell and molecular biology of neurotypical human neurodevelopment can be integrated with studies of psychiatric disease, genetics, and pathology to interrogate disease mechanisms and identify the time and place where disrupted molecular processes are likely to act.

Fragile X Syndrome: Single Gene Mutations Can Have Broad Downstream Consequences

FXS is the leading inherited cause of intellectual disability and is often accompanied by autistic-like features, aggression, attention deficits, and delays in speech and language development. FXS is caused by the loss of function of the FMR1 gene, which encodes an RNA-binding protein

(FMRP) involved in mRNA localization, stability, and translation. Therefore, loss of FMRP function has broad downstream consequences on gene expression and translation. For example, in a recent study, FMRP was shown to interact with the human neuronal nitric oxide synthase 1 (NOS1) *gene* through both conserved and species-dependent processes. *In the cerebral cortex,* NOS1 protein expression is restricted to layer 5 (L5) subcerebrally projecting pyramidal neurons and exhibits expression in alternating minicolumns in the frontoparietal operculum. In humans, FMRP interacts with sequences in the NOS1-coding region and leads to increased NOS1 protein expression. Concordantly, neocortical NOS1 protein levels are dramatically reduced in the developing FXS human neocortex, where NOS1 and FMRP are transiently coexpressed during synaptogenesis in subpopulations of pyramidal neurons in regions involved in speech, language, and complex social behaviors.

Down Syndrome and ASD: Polygenic Disruptions Converging on Specific Developmental Processes

Down syndrome (DS) provides an interesting neurodevelopmental disorder for studying the biologic consequences of polygenic, complex disorders, as the source of polygenic disruption (trisomy 21) is well established. Studies have indicated that trisomy 21 causes genome-wide disruption of gene expression. Among these, a characterization of the DS developmental brain transcriptome found that approximately 5% of genes on all chromosomes were dysregulated at some point in development, with a roughly equal number of up- and downregulated genes, with the exception of 18% of Chr21 genes, all of which were upregulated (Fig. 1.3–6). Gene coexpression analysis revealed gene networks that were implicated in processes previously associated with DS (e.g., synaptic function and neuronal specification) and aberrations in genes for particular cellular and molecular processes that had not been well established in DS, such as altered expression of genes associated with myelination and oligodendrocyte development. Subsequent analysis of postmortem human DS brain specimens revealed prominent hypomyelination, disorganization of myelinated fibers, and slower conductance through myelinated fiber tracts as features of DS neuropathology.

FIGURE 1.3–6. Genome-wide dysregulation in Down syndrome (DS) leads to impaired oligodendrocyte development. Schematic of a study by Olmos-Serrano et al. showing how developmental transcriptome characterizations of

DS (trisomy 21, DS) have provided insight into how polygenic gene disruptions lead to far broader impacts on gene expression and ultimately cell and molecular function. In this study, global gene expression was characterized from midfetal development to adulthood in several brain regions of individuals with DS (first panel). It was determined that approximately 20% of genes of chromosome 21 genes were misexpressed at some point in development, while 3% to 8% of the genes on all other chromosomes were misexpressed. Thus, in total, far more nonchromosome 21 genes are misexpressed in DS (second panel). Network analysis of coexpressed genes revealed a module that was highly enriched in myelination genes. Subsequent analysis of gene networks enriched in genes highly expressed in either oligodendrocyte precursors or mature oligodendrocytes revealed substantial dysregulation of developmental gene expression dynamics in the oligodendrocyte lineage: progenitor genes were more highly expressed and mature genes were expressed at lower levels (third panel). Analysis of myelinated fiber tracts in the prefrontal cortex revealed hypomyelination and disorganization of myelinated axons in DS (fourth panel). This study suggests that trisomy of chromosome 21 leads to genome-wide disruptions in developmental gene regulation, which were particularly prominent in oligodendrocytes and resulted in impaired oligodendrocyte maturation and hypomyelination (fifth panel). (Modified from Olmos-Serrano JL, Kang HJ, Tyler WA, et al. Down syndrome developmental brain transcriptome reveals defective oligodendrocyte differentiation and myelination. *Neuron* 2016;89(6):1208–1222. Copyright © 2016, with permission from Elsevier. doi: 10.1016/j.neuron.2016.01.042.)

Similarly, to interrogate ASD and schizophrenia pathogenesis, recent studies have used computational approaches to integrate data on risk variants from GWAS and whole exome sequencing with spatiotemporal brain transcriptome data. For instance, by building coexpression networks of genes previously associated with ASD, researchers have identified modules of highly related genes and determined the time in development and cell types in the brain where these gene networks are enriched. Intriguingly, it was found that ASD-risk genes were highly enriched in cortical projection neurons in the frontal lobe during midfetal development (Fig. 1.3–7). Of note, genes associated with schizophrenia showed a similar enrichment. These data indicate that, in ASD and schizophrenia, development may be particularly disrupted in cortical projection neurons when they are in the process of terminal migration and beginning to elaborate dendrites and early axonal projections. Moreover, functional and anatomical imaging studies have revealed that brain circuits composed of these neurons are abnormal in both ASD and schizophrenia.

Noncoding Mutations in Neurodevelopmental Disorders

The majority of disease-associated sequence variants occur in noncoding regions of the genome. While the consequences of these mutations are difficult to study, many likely have developmental effects and represent risk factors for psychiatric disease. This is particularly the case for variants that lie within regulatory regions, such as enhancers and promoters. An illustrative example is a recently described study of perisylvian polymicrogyria that results from a deletion immediately upstream of one of 17 transcriptional start sites (TSSs) of *GPR56*, a G-coupled protein receptor encoding gene that is important for stem cell proliferation and cerebral cortical development. In five affected individuals, a 15-base pair deletion was detected in a region of the GPR56 core promoter that is essential for driving expression in perisylvian regions of the brain during prenatal development. This deletion likely impaired the expression of GPR56, specifically in the perisylvian cortex during neurogenesis, and led to reduced progenitor cell proliferation and microgyrification, specifically in the perisylvian cortex (Fig. 1.3–4B). While this example is extreme, it demonstrates how differences in noncoding sequences, particularly in regulatory elements, can convey different disease susceptibilities and neurodevelopmental phenotypes.

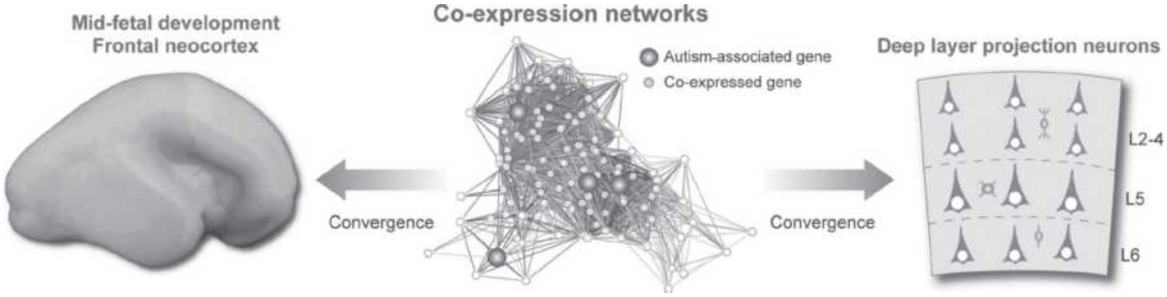

FIGURE 1.3–7. Dysregulation of autism spectrum disorder (ASD)-implicated genes converge on gene networks enriched in midfetal cortical projection neurons. This figure illustrates how a coexpression network analysis of ASD-associated genes with a spatiotemporal human transcriptome database inferred a convergence of autism-associated genes in frontal neocortex and deep layer projection neurons, suggesting that abnormalities in this cell type may play a role in ASD pathogenesis. ASD-associated genes identified in genome-wide sequencing studies were used as seed genes to build coexpression networks (middle panel). The networks of genes highly interconnected with ASD-associated genes were found to be enriched for genes highly expressed in the frontal cerebral cortex (left panel) and deep layer projection neurons (right panel). (Modified from Willsey AJ, Sanders SJ, Li M, et al. Coexpression networks implicate human midfetal deep cortical projection neurons in the pathogenesis of autism. *Cell* 155(5):997–1007. Copyright © 2013, with permission from Elsevier. doi: 10.1016/j.cell.2013.10.020.)

Somatic Mutations: Regionally Discrete Gene Mutations and Patterns of Gene Misexpression

Although somatic mutations in the brain cannot be readily detected using standard genomic screening techniques, recent advances in deep next-generation sequencing and single-cell sequencing have enabled the detection of somatic mutations in specific cells and tissues and advanced the current understanding of their contribution to disease etiology. This work has broad implications, from uncovering new disease mechanisms to providing new insights into neurotypical development. For example, these studies have demonstrated that certain neurodevelopmental diseases may be caused by *de novo* somatic mutations in neural progenitors that then expand clonally to produce aberrations in specific neural cell types and brain regions that can lead to brain malformations and more subtle phenotypes, as recently suggested by postmortem studies of schizophrenia.

Epigenetic Dysregulation in Schizophrenia

Dysregulation of epigenetic mechanisms can lead to transcriptome changes observed in disease states. While understanding the role of epigenetic modifications in psychiatric diseases remains in its nascent phase, recent systematic reviews have identified a moderate association between changes in various epigenetic modifications, including DNA methylation, histone modifications, and noncoding miRNAs, and schizophrenia and other psychotic disorders.

Initial studies analyzed the role of DNA methylation changes in promoters of individual candidate genes. In schizophrenia, several lines of evidence suggest that reelin gene (*RELN*) expression, which encodes an extracellular matrix protein that plays critical roles in the developing and adult brain, is downregulated due to hypermethylation of its promoter. A similar observation linked the promoter of the glutamic acid decarboxylase 67 (GAD1) gene, a gene encoding an enzyme that is required for the synthesis of GABA, with schizophrenia. In addition, decreased enrichment of H3K4me3 and an excess of H3K27me3, a repressive mark, have also been observed in the GAD1 promoter. Highlighting the potential importance of GAD1 dysregulation in schizophrenia are the well-established findings that GAD1 and GABA are not only expressed at lower levels in schizophrenia but also that mutations in GAD1 have been implicated in childhood-onset schizophrenia and that GAD autoantibody syndrome typically presents as schizophrenia.

Additionally, mutations and structural variations in genes involved in histone modifications, known as chromatin modifiers, have been associated with various neurodevelopmental disorders and schizophrenia. For example, loss of functions variants of the gene, SETD1A, which is part of a protein complex that mediates histone methylation, confer a large increase in risk for schizophrenia. Mouse lines carrying a heterozygous loss-of-function mutation in SETD1A show deficits in cortical connectivity and working memory. Furthermore, genes putatively regulated by SETD1A in the mouse brain were enriched for neurodevelopmental genes enriched in the developing cortex. While these monogenic forms of schizophrenia are likely to be rare, integrated analyses of schizophrenia-associated genetic variations do suggest a greater contribution of chromatin regulators to the neurobiology of schizophrenia.

More recently, studies have explored possible roles of epigenetic mechanisms of psychiatric disease at a genome-wide scale. For example, upon integrating the DNA methylation differences observed during normal brain development and risk loci associated with schizophrenia in a genome-wide association study, Jaffe et al. observed that global CpG methylation is different between neurotypical prenatal and postnatal samples. CpG sites that were hypermethylated prenatally were enriched for schizophrenia risk loci. However, a significant enrichment for risk was not observed at the age of onset of illness (around 25 years). A direct comparison of the DNA methylation profiles between the control and schizophrenia adult prefrontal cortex identified approximately 2,100 CpG loci that were differentially methylated. Although these loci were not enriched in schizophrenia risk alleles, they again exhibited pre- and postnatal changes in the neurotypical cortex.

FUTURE DIRECTIONS

Neuropsychiatric disorders owe in part to broad dysregulation of the genome over the course of development. Transcriptome data suggest that, in complex psychiatric and neurodevelopmental disorders, disruptions in many genes can converge on particular cell types and biologic processes to produce disease phenotypes. Thus, selective dysfunction of spatially and temporally regulated gene expression may account for differences in the age of onset and affected neural circuits in neurologic and psychiatric disorders (see Fig. 1.3–1). However, a great deal of work must be undertaken to further elucidate the mechanisms of diseases, determine how genetic and somatic variations cause diseases and develop more rational therapeutic strategies.

It is important to clarify that the changes in the transcriptome may reflect the cause or the *consequence* of a disorder. This is most notable for postmortem brain samples from adult patients with ASD and schizophrenia, which are associated with *in utero* disruptions of brain development. One way to infer the direction of causation is to compare genetic correlations between disease pairings with their corresponding transcriptome overlap, and this approach has confirmed that major components of gene-expression patterns in neuropsychiatric disorders reflect biologic processes coupled with underlying genetic variation. Another approach is to focus on mutations in noncoding regions of genes, which comprise most disease-associated variants. Specifically, characterizing the spatiotemporal activity of relevant CREs and identifying their associated gene can directly link disease-associated variants to transcriptomic changes. Modern experimental approaches such as Massively Parallel Reporter Assay (MPRA) and computational approaches such as quantitative trait locus (QTL) mapping are currently being utilized to further characterize and associate CREs with specific genes.

Multidimensional genomic data, including more comprehensive transcriptomic, epigenomic, and regulatory maps of the developing human brain, will greatly advance the current understanding of the pathophysiology of complex diseases such as psychiatric disorders. These datasets may one day reveal genetic and molecular phenotypes of diseases and disease subtypes that might be useful for diagnosis and more targeted treatment paradigms. In addition to generating genomic and transcriptomic data, integrative analyses with pathologic, neuroimaging, behavioral, and clinical studies will be critical for a full understanding of psychiatric conditions.

1.4 Neural Development and Neurogenesis

EMANUEL DICICCO-BLOOM, M.D., AND COURTNEY R. MCDERMOTT, B.A.

NEURAL DEVELOPMENT AND NEUROGENESIS

An understanding of molecular and cellular mechanisms mediating nervous system development is critical in psychiatry as we know well that abnormalities of developmental processes contribute to many brain disorders. While a developmental basis may not be surprising in early childhood disorders, such as autism, fragile X mental retardation, and Rett syndrome, even mature diseases including schizophrenia and depression reflect ontogenetic factors. For example, there are reductions in forebrain region volumes, neuron and glial cell numbers that may be apparent at the time of diagnosis, although with maturation additional changes occur in neuronal cell density, neuropil, and myelination. Similarly, in autism, early brain growth may be increased, while abnormalities of cellular organization are observed that reflect fetal disturbances in developmental cell proliferation and migration. When there is abnormal regulation of early brain development, we lay down a foundation of altered neuron populations that may differ in cell types, numbers, and positions, or may elaborate abnormal connections, with consequences for interacting glial populations. With progressive postnatal development, the maturing brain systems call upon component neurons to achieve increasing levels of complex information processing, which may be deficient should initial conditions be disturbed. New neural properties emerge during maturation as neuron populations elaborate additional functional networks based upon and modified by ongoing experience. Given the brain's dynamic character, developmental abnormalities in neural populations and systems, caused by genetic as well as environmental factors, will likely manifest at diverse times in a person's life.

OVERVIEW OF NERVOUS SYSTEM MORPHOLOGIC DEVELOPMENT

In considering brain development, several overarching principles may serve to guide our understanding. First, different brain regions and neuron populations are generated at distinct times of development, which in turn provide distinct *windows of susceptibility* to genetic and environmental insults. Second, the sequence of cellular processes that comprise ontogeny predicts that abnormalities in early events necessarily lead to differences in subsequent stages, though such abnormalities may not be accessible to our clinical tools. For example, a deficit in the number of early-born neurons will likely lead to later reductions in axonal processes and ensheathing white matter, though only the latter may be detectable on brain imaging using MRI or DTI of the mature brain. Third, it is clear that specific molecular signals, such as extracellular growth factors and cognate receptors or transcription factors, regulate multiple developmental stages of the cell, and play roles in cell proliferation, survival promotion, neuron migration, process outgrowth, and the momentary synaptic modifications (plasticity) underlying learning and memory. Finally, higher functioning mammals possess a higher capacity for neurogenesis, including stem cell proliferation as well as prolonged maturation of neural precursors that may serve for continued growth, learning and memory, and disease vulnerability. This chapter considers these principles as it examines cellular and molecular systems regulating development, and discusses implications for psychiatric disease.

The Neural Plate and Neurulation

The nervous system of the human embryo first appears between 2 and 1/2 and 4 weeks of gestation. During development, emergence of new cell types, including neurons, results from interactions between neighboring layers of cells. On gestational day 13, the embryo consists of a sheet of cells. Following gastrulation (days 14 and 15), which forms a two-cell–layered embryo consisting of ectoderm and endoderm, the neural plate region is delineated on day 16 by the underlying mesoderm. The mesoderm forms by cells entering a midline cleft in the ectoderm called the primitive streak and it induces overlying ectoderm to become neural plate. Induction involves release of soluble growth factors from one group of cells, which in turn bind receptors on neighboring cells, eliciting changes in nuclear transcription factors which control downstream gene expression. In some cases, cell–cell contact-mediated mechanisms are involved. In the gene patterning section below, the important roles of soluble growth factors and transcription factor expression will be described.

The neural plate, whose induction is complete by 18 days, is a sheet of columnar epithelium, and is surrounded by ectodermal epithelium. After formation, the edges of the neural plate elevate, forming the neural ridges. Subsequently, changes in intracellular cytoskeleton and cell–extracellular matrix attachment cause the ridges to merge in the midline and fuse, a process termed neurulation, forming the neural tube, with a central cavity presaging the ventricular system (Fig. 1.4–1). Fusion begins in the cervical region at the hindbrain level (medulla and pons) and continues rostrally and caudally. Neurulation occurs at 3 to 4 weeks of gestation, and its failure results in anencephaly rostrally and spina bifida caudally. The risk of developing neurulation defects are increased following exposure to retinoic acid in dermatologic preparations and anticonvulsants, especially valproic acid (VPA), as well as diets deficient in folic acid.

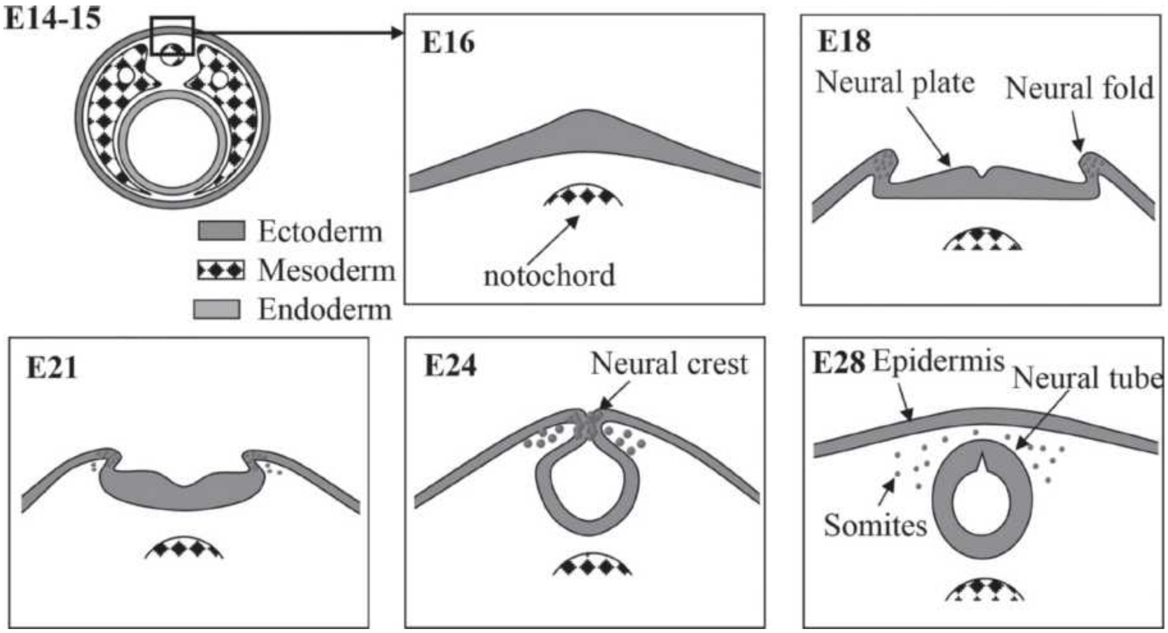

FIGURE 1.4–1. Mechanisms of neurulation. Neurulation begins with the formation of a neural plate in response to soluble growth factors released by the underlying notochord. The neural plate originates as a thickening of the ectoderm that results from cuboidal epithelial cells becoming columnar in shape. With further changes in cell shape and adhesion, the edges of the plate fold and rise, meeting in the midline to form a tube. Cells at the tips of the neural folds come to lie between the neural tube and overlying epidermis, forming the neural crest that gives rise to the peripheral nervous system and other structures.

Another product of neurulation is the neural crest, whose cells derive from the edges of the neural plate and dorsal neural tube. From this position, neural crest cells migrate dorsolaterally, under the skin to form melanocytes, and ventromedially to form dorsal root sensory ganglia and sympathetic chains of the peripheral nervous system and ganglia of the enteric nervous system. However, neural crest gives rise to diverse tissues including cells of neuroendocrine, cardiac, mesenchymal, and skeletal systems, forming the basis of many congenital syndromes involving brain and other organs. The neural crest origin at the border of neural and epidermal ectoderm and its generation of melanocytes forms the basis of the neurocutaneous disorders, including tuberous sclerosis and neurofibromatosis. Finally, another nonneuronal structure of mesodermal origin formed during neurulation is the notochord found on the ventral side of the neural tube. As shown below, the notochord plays a critical role during neural tube differentiation, since it is a signaling source of soluble growth factors, such as sonic hedgehog (Shh), which impact gene patterning and cell determination.

Regional Differentiation of the Embryonic Nervous System

After closure, the neural tube expands differentially to form major subdivisions that precede the major functional divisions of the brain. Different subdivisions are generated according to specific schedules of proliferation, migration, and differentiation. The neural tube can be described in three dimensions, including longitudinal, circumferential, and radial. The longitudinal dimension reflects rostrocaudal (anterior–posterior) organization, and most simply, the brain and spinal cord. Circumferential organization, tangential to the surface, represents two axes: in the dorsoventral axis, cell groups are uniquely positioned from top to bottom. In the medial to lateral axis, there is right–left mirror image symmetry. Finally, the radial dimension represents organization from the inner most cell layer adjacent to the ventricles to the outer most surface, and exhibits region-specific cell layering. At 4 weeks, the human brain is divided longitudinally into three “vesicles” the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain) (Fig. 1.4–2). By 5 weeks, these three “vesicles” divide further into five divisions with the prosencephalon forming the telencephalon (including cortex, hippocampus, and basal ganglia) and diencephalon (thalamus and hypothalamus), the mesencephalon, (midbrain), and the rhombencephalon yielding metencephalon (pons and cerebellum) and myelencephalon (medulla). These morphologic transformations depend on region-specific proliferation of precursor cells adjacent to the ventricles, the ventricular zones (VZs). Proliferation depends on soluble growth factors made by proliferating cells themselves or released from regional signaling centers. Growth factor production and cognate receptor expression also depend on region-specific patterning genes. VZ precursors, which appear morphologically homogeneous, express a checkerboard array of molecular genetic determinants that control the generation of specific types of neurons in each domain (Fig. 1.4–3).

FIGURE 1.4–2. Progression of brain regional differentiation. Early after neurulation, the neural tube differentiates into four regions (forebrain, midbrain, hindbrain, and spinal cord) that gives rise following later divisions and maturation to the different brain structures.

In the circumferential dimension, organization begins very early and extends over many rostrocaudal subdivisions. In spinal cord, the majority of tissue comprises the lateral plates, which later divide into dorsal or alar plates, composed of sensory interneurons, and motor or basal plates, consisting of ventral motor neurons. Two other diminutive plates, termed the roof plate and floor plate, play critical regulatory roles as growth factor signaling centers in the embryo. In response to Shh from the ventrally located notochord, the floor plate produces its own Shh, which induces neighboring cells in ventral spinal cord and brainstem to express region-specific transcription factors that specify cell phenotype and function. For example, floor plate Shh induces midbrain precursors to differentiate into dopamine secreting neurons of the substantia nigra. Similarly, the roof plate secretes bone morphogenetic proteins (BMPs), which induce dorsal sensory neuron cell fate in spinal cord, while in its absence, both cerebellum and midline hippocampus are missing. Finally, in the radial dimension, the organization of layers is subdivision-specific, produced by differential proliferation of VZ precursors and cell migration.

FIGURE 1.4–3. Genetic interactions underlying regionalization of the mammalian telencephalon. A coronal section schematic of the E12.5 mouse telencephalon shows the dorsal and ventral subdomains as defined by their unique patterns of gene expression. Dorsal telencephalic progenitors express high levels of bHLH transcription factors Ngn1, Ngn2, and NeuroD and homeodomain proteins Emx1, Emx2, Lhx2, and Pax6. Ventral progenitors express the bHLH protein Mash1 and homeodomain factors Gsh1, Gsh2, Dlx1, Dlx2, Dlx5, and Dlx6. The LGE can be subdivided into dLGE and vLGE compartments, with higher levels of Pax6, Gsh2, Dlx2, and Mash1 in the dLGE, and Gsh1 expression only in the vLGE. In contrast, MGE progenitors alone express homeodomain transcription factors Lhx6, Lhx7, and Nkx2.1. Important cross-regulatory interactions between Ngn1/2 and Mash1 and Pax6 and Gsh2 participate in the maintenance of telencephalic progenitor identity. *Arrows* denote positive interactions; T-bars denote inhibitory interactions. Primary Proliferative Zones

The distinct patterns of precursor proliferation and migration in different regions generate the radial organization of the nervous system. In each longitudinal subdivision, the final size of the brain region population depends on the interplay of regulated neurogenesis with programmed cell death. Traditional concepts had suggested that excess cell production occurred everywhere, and that final cell number regulation was achieved primarily through selective cell death mediated by target-derived survival (trophic) factors. In fact, patterning genes play major roles in directing regional precursor proliferation that is coordinated with final structural requirements, and programmed cell death occurs at multiple stages. Consequently in diseases characterized by brain regions smaller than normal, such as schizophrenia, there may be a failure to generate neurons initially, as opposed to normal generation with subsequent cell loss.

The generation of specific cell types, the process of neurogenesis, involves proliferation of undifferentiated precursor cells (or progenitors), followed by cessation of proliferation (exit from the cell cycle), migration of cells to final destinations, and expression of specific phenotypic characters, such as neurofilaments and neurotransmitter systems. Precursor proliferation occurs primarily in two densely packed regions during development. The primary site is the VZ lining the walls of the entire ventricular system, which contributes to all brain regions in the rostrocaudal dimension. For select regions, however, including the cerebral cortex, hippocampus, and cerebellar cortex, precursors from the VZ migrate out to secondary zones where they generate a more restricted range of cell types.

In the early embryo, neural tube VZ progenitors are arranged as a one-cell layer thick, pseudostratified neuroepithelium. The bipolar VZ precursors have cytoplasmic processes that span from the ventricular to the pial surface. During the cell cycle, the VZ appears multi-layered, or stratified, because cell nuclei undergo movements, called interkinetic nuclear migration. Precursor cell division (M phase) occurs at the ventricular margin, producing two new cells (Fig. 1.4–4). The progeny then re-enter G1 as they move outward toward the pia. Under influence of extracellular signals these cells become committed to another round of division, marked by re-entry into S-phase, which occurs near the upper VZ margin. After replicating DNA, nuclei move back down during G2 to the ventricular surface where they undergo mitosis and divide. Different fields of study suggest several distinct roles for interkinetic migration: (1) Interkinetic nuclear migration may allow nuclei access to environmental cues produced by postmitotic cells that effect subsequent proliferation and gene expression; (2) Dividing cells at the VZ margin possess primary cilia that sense and respond to local regulatory signals including Shh, Wnt, and Notch; (3) Time lapse analysis suggests that because of the physically limited area of the VZ, and the high density of cells undergoing mitosis, the nuclei of nondividing cells move away from this region, but then return upon their next division. Human genetic mutations that interfere with interkinetic nuclear movement or the mitotic spindle organizer, the centrosome, impair cell migration, and produce heterotopic neurons and epilepsy syndromes.

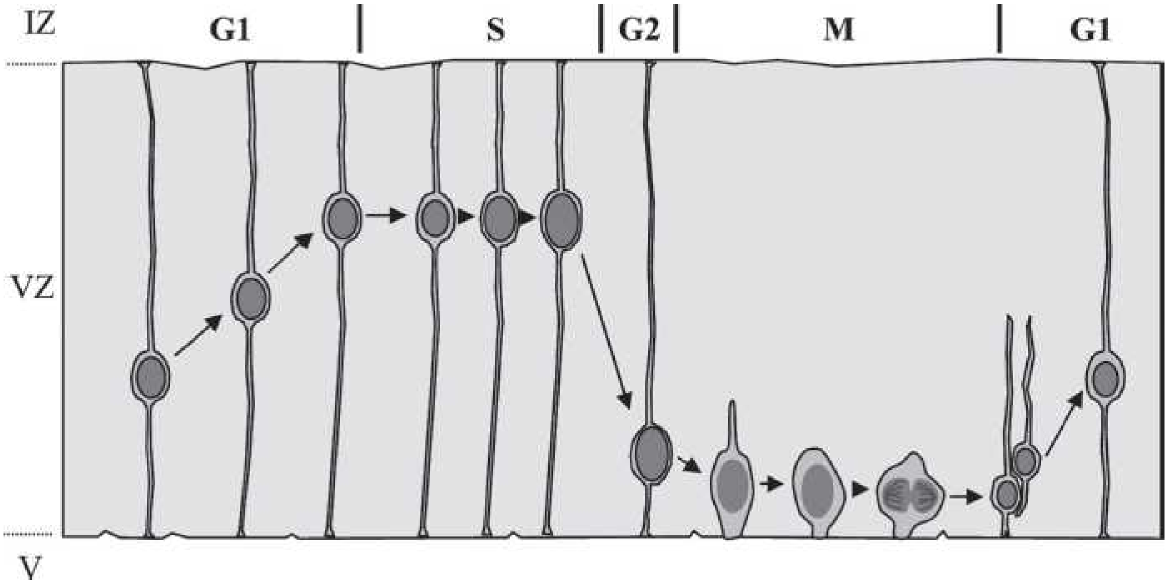

FIGURE 1.4–4. Interkinetic nuclear migration in the ventricular zone. During each cell cycle, nuclei move from the ventricular surface at G1 to the border of the ventricular zone where it enters S phase. Nuclei move down during G2, and reach the ventricular surface where they undergo mitosis. Asymmetric division leads to generation of a postmitotic cell that leaves the ventricular zone to produce a neocortical neuron, while the remaining stem cell continues to divide. IZ, intermediate zone; VZ, ventricular zone; V, ventricle. (Adapted from Nowakowski RS, Hayes NL. Cell proliferation in the developing mammalian brain. In: Rao MS, Jacobson M, eds. *Developmental Neurobiology*. 4th ed. Springer; 2005. doi: 10.1007/0-387-28117-7_2.)

At the earliest stages, VZ cells divide to increase the pool of progenitors. Then, during the period of neurogenesis, a precursor cell divides giving rise to both a postmitotic neuron and another dividing precursor. When neurogenesis ceases, precursor division produces two postmitotic neurons only, greatly increasing neuron production and depleting the precursor pool. Newly born neurons migrate to final destinations, such as cerebral cortical plate, traveling along the processes of radial glial cells (RGCs) (Fig. 1.4–5A). RGCs are bipolar VZ precursors that have one process associated with the ventricular surface and the other contacts the pial surface. The association between newborn neurons and radial glial processes allows cells generated within localized VZ domains that express distinct patterning genes, to migrate to specific cortical functional areas. This model has been termed the cortical "protomap" and was originally proposed by P. Rakic. Precursor cell phenotypic fate is already specified genetically before cells cease division and begin migration. To some degree cells born from the same VZ domain form an associated radial cell column (clonal population) that first exhibit electrical coupling and then preferentially develop chemical synaptic interconnections. This neuroanatomic relationship is one basis of the well-defined functional and neurophysiologic activities observed in cortical columns of rodents and all primates, including humans. Nonetheless the ingrowing thalamic afferents that synapse on cortical neurons also impact their final neuronal fate and function. In the human brain, neuron production generally occurs for the first 4 months of gestation, whereas from then on until birth, neurons undergo migration, whereas glial precursors proliferate, migrate, and begin producing myelin.

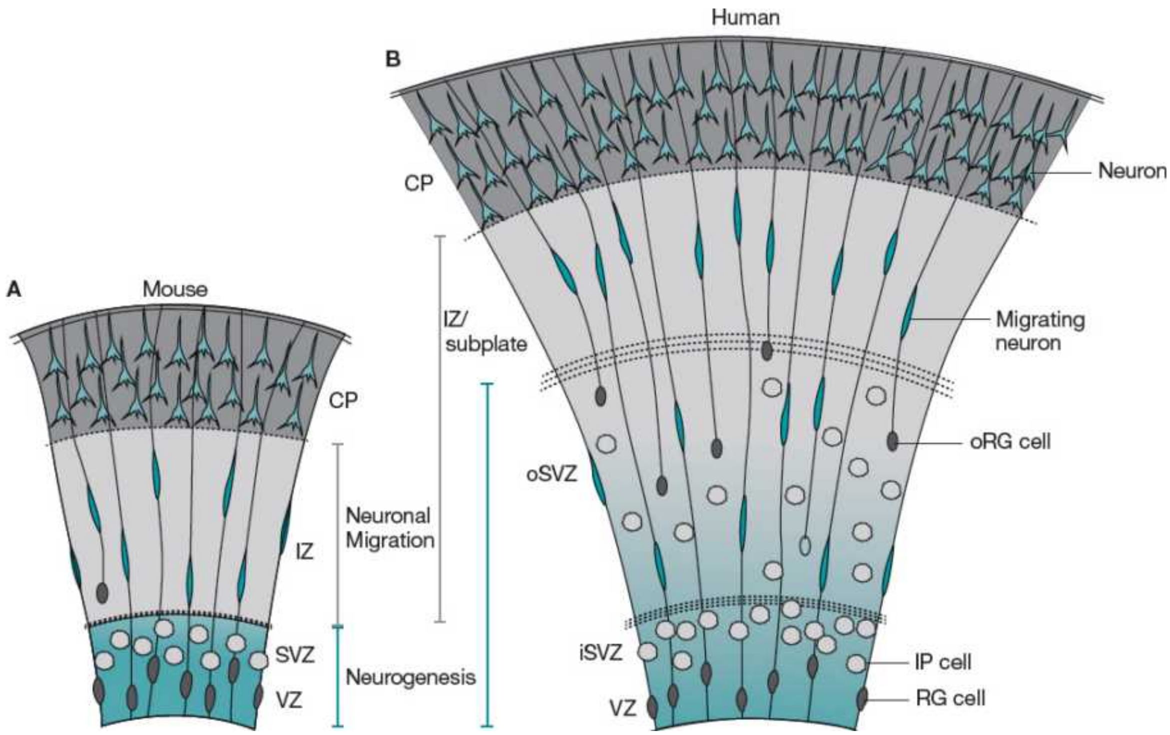

FIGURE 1.4–5. Comparison of the developing mouse and human cortex. **A:** Model of mouse neocortical development. The VZ and SVZ are the primary zones of neurogenesis (*dark gray*) where RG cells and IP cells reside, respectively. Neurons born in the VZ or SVZ migrate along the RG radial fiber scaffold found in the intermediate zone (IZ), the primary zone of neuronal migration (*light gray*) in the mouse, to reach the CP. oRG cells are infrequent and not located in a distinct progenitor zone. **B:** Model of human neocortical development. RG cells, IP cells, and oRG cells are found in neurogenic zones (*dark gray*), which are the VZ, the inner SVZ (iSVZ), and the outer SVZ (oSVZ). Neurons migrate through the OSVZ and IZ/subplate (zones of neuronal migration, *light gray*) to populate the CP. Neurons must navigate a larger distance than in the mouse, and a radial fiber scaffold of increased complexity, to reach the CP. (Reprinted from LaMonica BE, Lui JH, Wang X, Kriegstein AR. OSVZ progenitors in the human cortex: an updated perspective on neurodevelopmental disease. *Curr Opin Neurobiol.* 2012;22(5):747–753, Copyright © 2012, with permission from Elsevier.)

In addition to the general plan of VZ neurogenesis, secondary proliferative zones produce specific neuron populations in particular regions. For example, in cerebral cortex and thalamus, the subventricular zone (SVZ) produces intermediate precursor cells, that can generate oligodendrocytes, diverse astrocytes, and neurons. In hippocampus, the hilus and later the subgranular zone (SGZ) produce dentate gyrus (DG) granule neurons, a lifelong process of adult neurogenesis, though the duration of human adult neurogenesis is a subject of significant controversy (see below). Finally, in newborn cerebellum, the overlying external germinal layer (EGL) generates granule neurons for 7 to 24 months in humans, a population that is affected by medical treatments administered in the neonatal intensive care unit (NICU). In contrast to the VZ, secondary zone cells do not exhibit nuclear movements, suggesting distinct mechanisms of regulation. After neurogenesis is complete, the VZ differentiates into ciliated epithelial cells of the ependymal lining. Underlying the ependyma, undifferentiated cells of the SVZ, referred to as subependyma, have been identified as a neural stem cell (NSC) population, capable of proliferating and generating neurons and glia throughout life. In humans, the magnitude and final destinations of these newly generated neuroblasts are uncertain, but lateral ventricle-derived neuroblasts do migrate to the nearby striatum during adulthood to differentiate into interneurons. Furthermore, their depletion is observed during the advanced stages of Huntington disease.

Similar to the SVZ, humans and other primates have an additional proliferative region in the cortex called the outer subventricular zone (OSVZ), whose extensive proliferation accounts for the massive evolutionary increase in the cerebral cortex. This region first appears during the beginning of the second trimester and becomes the main site of neurogenesis by mid-trimester, surpassing the neurogenic capacity of the SVZ by almost fourfold. The OSVZ contains radial glia-like (oRG) cells that have only one long basal process that contacts the pia, unlike radial glia (RG) of the VZ, which have both apical (touching the ventricle) and basal processes (Fig. 1.4–5B). oRG cells have self-renewing capacity and undergo mitosis during somal translocation in the OSVZ, but do not translocate to the ventricle. They give rise to intermediate progenitor daughter cells that also have proliferative capacity and after migrating up the basal process, differentiate into excitatory neurons of upper cortical layers, II-IV. The OSVZ has a role in forming the gyrencephalic (highly folded) brain, where cortical folding allows the much larger cortical surface area found in higher vertebrates to fit into a limited cranial space. Therefore, the OSVZ appears to have evolved in higher functioning organisms to increase neurogenic capacity in the cortex, allowing for more complex functioning. Recent studies suggest that newly evolved primate genes, including NOTCH2NLA and its paralogs, underlie the expansive neurogenesis in humans by augmenting proliferation in the VZ and OSVZ to increase generation of cortical populations and gyrification.

Radial and Tangential Patterns of Neurogenesis and Migration

The different regions of the brain are generated through three well-recognized spatiotemporal patterns of neurogenesis. There are two radial patterns of precursor cell proliferation and cell migration away from the VZ that are called inside-to-outside and outside-to-inside patterns. The third involves nonradial or tangential migration of cells. Experimentally, one follows the localization of cells that were previously labeled in vivo by incorporating a thymidine analog into DNA that is synthetized prior to cell division. These analogs include tritiated (^{3}H)-thymidine or bromodeoxyuridine (BrdU). When looking at later developmental times, only cells that recently completed mitosis retain the label, because it is lost from cells that continue to divide. The last day a precursor cell incorporates the label is considered its birthday, after which it exits the cell cycle, differentiates, and migrates to its final position.

As a focus of psychiatry, the evolutionarily more recent cerebral cortex is the paradigmatic model of inside-to-outside neurogenesis. Derived from embryonic forebrain telencephalic vesicles, it displays the characteristic six-cell layer organization that represents a common cytoarchitectural and physiologic basis for neocortical function. Within each layer, neurons exhibit related axodendritic morphologies, use common neurotransmitters, and establish similar afferent and efferent connections. In general, pyramidal neurons in layer III establish synapses within and between cortical hemispheres whereas deeper layer V/VI neurons project primarily to subcortical nuclei, including thalamus, striatum, brainstem, and spinal cord (see Chapter 1.2). The majority of cortical neurons, especially glutamatergic excitatory neurons, originate from the forebrain VZ and OSVZ. At the earliest stages of cortex formation, the first postmitotic cells migrate outward from the VZ to establish a superficial layer termed the preplate, which comprises Cajal–Retzius cells that form outermost layer I, and subplate neurons, which lay beneath the future layer VI (Fig. 1.4–6). After its formation the prelate is divided in two by the arrival of the cortical VZ and OSVZ precursors that will form the mature cortical plate. These cortical precursors migrate into the prelate in an inside-to-outside fashion: first layer V/VI neurons arrive, and then later generated neurons migrate past them to form more superficial layers. Thus, the day on which a precursor exits the cell cycle predicts the kind and localization of the neurons generated.

The preplate Cajal–Retzius cells produce the extracellular glycoprotein reelin, an important signal for neuronal migration. When reelin is deleted in mice, cortical neuron migration is inverted so neurons accumulate in reverse pattern, in, outside-to-inside fashion. Significantly, abnormal levels of reelin protein and mRNA have been observed in many disorders, including major depression, bipolar disorder, schizophrenia, autism, and Alzheimer disease. Human reelin mutation is associated with lissencephaly (smooth brain), the absence of gyri and sulci, and abnormalities in cerebellum.

The other preplate component, the subplate neurons are critical for establishing cortical circuitry with distinct prenatal and postnatal roles. Neural circuits in the subplate are initially established by spontaneous neural activity that depends in part on electrical connections between cells mediated by gap junctions composed of connexin proteins. This activity is spontaneous, and is not dependent on nor influenced by external sensory inputs. As development proceeds, early afferent fibers from the thalamus that will later synapse on layer IV cortical neurons first make temporary synapses onto preplate neurons, awaiting arrival of their target cortical neurons. After the thalamic afferents leave the prelate cells, many undergo cell death. Clinically, subplate neurons are particularly vulnerable to perinatal insults during pregnancy and in the NICU, including hypoxia-ischemia, drugs, infection, or inflammation.

In contrast to inside-to-outside neurogenesis, the outside-to-inside pattern occurs in phylogenetically older structures such as hypothalamus, tectum, spinal cord, and hippocampal DG. First formed postmitotic neurons lie superficially and last generated cells localize toward the center. While this pattern might simply reflect passive cell displacement as more cells are generated, radial glia and specific migration signaling molecules are clearly involved. Furthermore, cells do not always lie in direct extension from their locus of VZ generation. Rather, some groups of cells migrate to specific locations, as observed for neurons of the inferior olivary nuclei. In the hippocampus the pyramidal cell layer, Ammon’s Horn CA 1 to 3 neurons, is generated in a typical outside-to-inside fashion in the dorsomedial forebrain for a discrete period, from 7 to 15 weeks of gestation, and exhibits complex migration patterns. In contrast, DG granule neurons start appearing at 18 weeks. Precursors from the forebrain VZ migrate along a subpial route into the DG hilus where they generate both neurons and glia. With time, the granule precursors move to a layer just under the dentate gyrus granule cell layer, termed the subgranular zone, SGZ, which produces neurons throughout life in adult rats, primates, and humans. In rodents, SGZ precursors proliferate in response to cerebral ischemia, tissue injury, seizures, neuropsychiatric drugs, diet, and exercise as well as growth factors. Clinically, the diminished hippocampal volumes reported in schizophrenia and depression raise the possibility that disordered neurogenesis plays a role in pathogenesis, either as a basis for dysfunction, or as a consequence of brain injuries and infections, or environmental and experiential stressors.

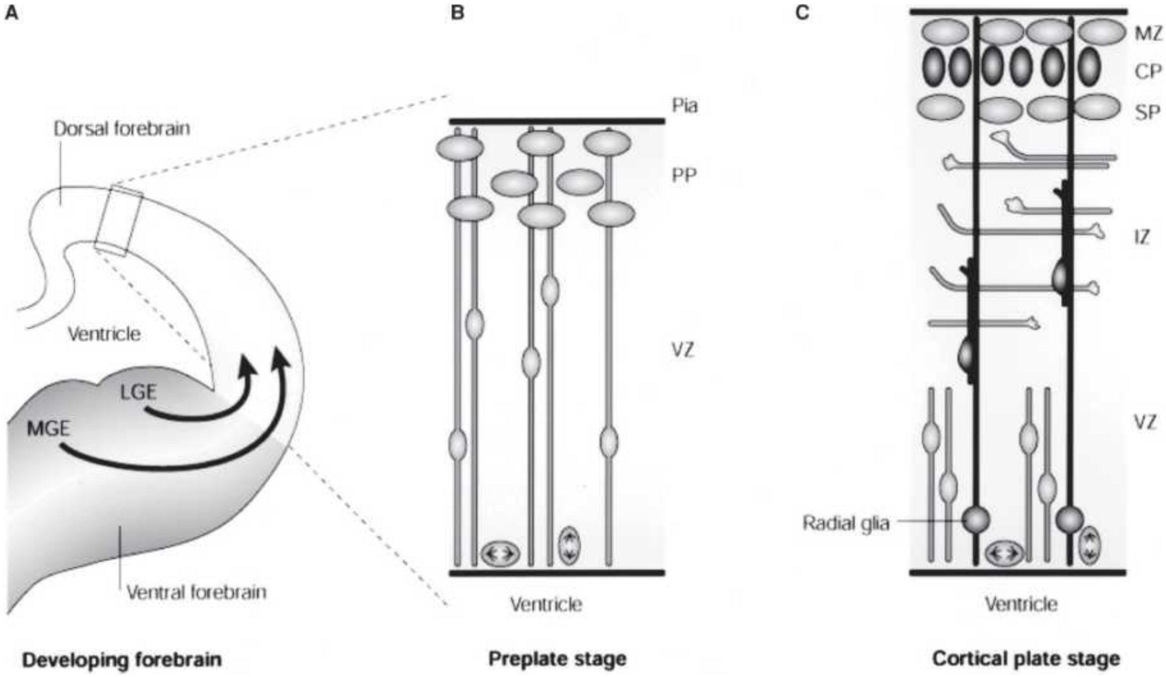

FIGURE 1.4–6. Schematic drawing of radial and tangential migration during cerebral cortex development. **A:** A coronal section of one-half of the developing rat forebrain. The dorsal forebrain gives rise to the cerebral cortex. Medial ganglionic eminences (MGEs) and lateral ganglionic eminences (LGEs) of the ventral forebrain generate neurons of the basal ganglia and the cortical interneurons. The *arrows* indicate the tangential migration route for γ-aminobutyric acid interneruons to the cortex. The boxed area (enlarged in **B** and **C**) shows the developing cortex at early and late stages. **B:** In the dorsal forebrain, the first cohort of postmitotic neurons migrate out from the ventricular zone (VZ) and create a preplate (PP) below the pial surface. **C:** Subsequent postmitotic neurons will migrate along radial glia through the intermediate zone (IZ) and take position in the middle of the preplate, creating a cortical plate (CP) between the outer marginal zone (MZ) and inner subplate (SP). Ultimately, the CP will be composed of six layers that are born sequentially, migrating in an inside-to-outside pattern. Horizontal processes in the IZ represent axon terminals of thalamic afferents. (Reprinted by permission from Springer Nature: Nadarajah B, Parnavelas J. Modes of neuronal migration in the developing cerebral cortex. *Nat Rev Neurosci* 2002;3:423–432, Copyright 2002. doi:10.1038/nrn845.)

A different combination of radial and nonradial migration is observed in cerebellum, which contains ~75 percent of all brain neurons, and that contributes to both motor and nonmotor circuits, with significance for ASDs. Cerebellar development begins at 4 weeks of gestation and continues until 2 years of age. The major GABAergic neurons, including Purkinje cells and deep nuclei, originate from the primary VZ surrounding the fourth ventricle, coincident with other brainstem neurons. This occurs in humans from 5 to 15 weeks of gestation. In contrast, glutaminergic neurons of the cerebellum including granule neurons and some interneurons are generated from precursors that originate in the rhombic lip, a dorsal structure distinct from the VZ that surrounds the roofplate of the fourth ventricle. Rhombic lip precursors migrate dorsally to cover the surface of the cerebellum at 8 to 9 weeks gestation, establishing a secondary proliferative zone, the EGL, which generates neurons with restricted neural fates, and persists until 2 years. When an EGL precursor stops proliferating, the cell body sinks below the surface, grows bilateral processes that extend transversely in the molecular layer, and then the soma migrates further down into the internal granule layer (IGL). Cells reach the IGL along specialized Bergmann glia, which serve guidance functions similar to the radial glia. Clinically, this postnatal population in infants makes cerebellar granule neurogenesis vulnerable to infectious insults of early childhood, and an undesirable target of therapeutic drugs, such as steroids, or cancer chemotherapy, which inhibit cell proliferation. Proliferation control of this stem cell population is lost in the common childhood brain tumor, medulloblastoma (Fig. 1.4–7).

Developmental Cell Death

During nervous system development, cell death is a reproducible, and spatially and temporally restricted death of cells whose elimination is required to coordinate the proportions of interacting neural cells. Three types of cell death have been described: (i) Phylogenetic cell death that removes structures in one species that served evolutionarily earlier ones, such as the tail; (ii) Morphogenetic cell death, which sculpts the fingers from the embryonic paddle and is required to form the optic vesicles as well as caudal neural tube; and (iii) Histogenetic cell death, a widespread process that allows removal of select cells in specific brain regions. Histogenetic cell death can impact between 20 and 80 percent of neurons depending on brain region. A major role for developmental cell death was proposed in the 1980s based on the paradigm of nerve growth factor (NGF). A competitive process was thought to ensure proper matching of new neuronal populations with the size of their final target field. After neurogenesis, survival of differentiating neurons was considered absolutely dependent on axons reaching targets to obtain limiting amounts of the NGF trophic (survival) factor. While demonstrably true for peripheral populations such as sympathetic and sensory neurons, a more complex process regulates cell death during neurodevelopment, and occurs at all stages that precede target innervation, including proliferation, migration, and differentiation of neural precursors. Programmed cell death is a necessary process during neurodevelopment, as genetic deletion of mediating enzymes, the caspases, in embryonic mice produces enlarged and disorganized brains with marked regional specificity.

Three types of programmed cell death based on morphologic criteria have been described. "Apoptotic cell death," is the most common, and is characterized by chromatin condensation and membrane blebbing, followed by nuclear fragmentation and cell shrinkage. "Autophagic degeneration” involves contiguous groups of degenerating cells and features large autophagic vacuoles and pyknotic nuclei. Much less common is “cytoplasmic-type cell death,” that exhibits similarities to necrosis.

As the major type of developmental cell death, apoptotic mechanisms have been extensively examined. Apoptosis involves activation of a series of protease enzymes, the cysteine-containing **asp**artate-specific prote**ases**, also called caspases, that elicits a sequence of intracellular events. A large number of signals (both pro- and antiapoptotic) converge to regulate common signaling pathways that consist of three phases. First, a regulatory phase, termed “initiation,” involves numerous extracellular and intracellular factors that promote either survival or cell death. Then, in the case of cell death ignition, the second phase called “execution” begins. The effector enzymes, caspases 3 and 7 are activated which cleave specific substrates leading to the last and irreversible step of apoptosis. During this final programmed degeneration, caspase-activated DNAse (CAD) cleaves exposed chromosomal DNA located between the nucleosomes, cytoskeletal components are disassembled, and plasma membranes swell into vesicles termed apoptotic bodies. The cell is then dismantled and phagocytosed without any release of its contents, which would otherwise induce an inflammatory response. Historically, two main pathways were described: (i) The “extrinsic pathway,” which mediates effects of death factors such as tumor necrosis factor α (TNF-α) and Fas ligand and involves caspase-8; (ii) The “intrinsic pathway” that involves release of mitochondrial factors, such as cytochrome C, and activation of caspase-9. It is now clear that in most cases cell death results from interactions between multiple factors, involving multiple pro- or antiapoptotic signaling molecules, exerting positive or negative regulation of one another.

Both developmental and pathologic cell death involve many of the same signaling cascades. A failure to inhibit apoptosis is involved in cancers and autoimmune diseases (multiple sclerosis), while excess stimulation of apoptosis is observed in neurodegenerative diseases during development (Huntington disease, lysosomal diseases, leukodystrophy) and aging (Alzheimer’s, Parkinson’s). Apoptosis is also observed during developmental brain injuries such as hypoxia-ischemia, fetal alcohol syndrome, or exposure to ionizing radiations, inhalant anesthetics, and neurotoxicants. Thus dysregulation of apoptotic cell death during development can lead to severe brain abnormalities, which may only become manifest later as mature functional impairments.

THE CONCEPT OF NEURAL PATTERNING

Ever since tools to reveal gene expression in tissues were developed 50 years ago, and specific gene knockout methods were perfected 20 years later, neurobiologists have searched for the genes responsible for determining different brain regions and associated functions. The following sections briefly review the bounty of molecular genetic studies performed primarily in mice, with relevance for human neurodevelopment. However, this focus on defining effects of single genes on brain development almost necessitates that deletions produce major disruptions that are readily and reproducibly observed. These studies delineate the primary interactions of genes expressed in neighboring regions and provide a foundation for regulatory principles. On the other hand, this reductionist approach fails to encompass the greater than 85 percent of protein-coding genes in the human genome (>19,000) that are expressed in the developing brain. Another chapter in this book titled “Functional Genomics of Human Brain Development” describes the gene transcriptional profile of the human brain and the regulatory mechanisms and it is recommended as companion reading.

Principles of Function

Nervous system development is controlled by interactions between extracellular factors and intrinsic genetic programs. Early on extracellular signals are primarily soluble growth factors secreted from regional signaling centers (i.e., notochord, floor or roof plates, surrounding mesenchymal tissues). The precursor’s ability to respond (competence) depends on cognate receptor expression, which is determined by patterning genes whose proteins regulate gene transcription. Patterning genes also control transcription of other genes whose products include other transcription factors or proteins involved in cellular processes (i.e., proliferation, migration, differentiation). Transcription factor proteins contain primarily two domains: a DNA-binding domain that binds promoter or enhancer regions of genes, and a trans-activating domain, which interacts with proteins that can activate or repress gene transcription. Transcription factors frequently form multimeric protein complexes which enable single transcription factors to play roles in multiple cell types and processes, as well as at distinct developmental stages. Consequently, altering expression of a single patterning gene will lead to a diversity of functional outcomes. Furthermore, protein interactions depend on protein–protein affinities. At low concentrations a transcription factor may associate primarily with one partner, but at a higher titer with yet another. The multimeric nature of regulatory complexes allows a single factor to stimulate one process while simultaneously inhibiting another. For instance, a patterning gene protein may promote one event by stimulating one gene promoter, while simultaneously sequestering another factor from a different promoter whose activity is required for an alternative phenotype. Finally, the factors frequently exhibit cross-regulatory activity, where one factor negatively regulates expression of another. This activity leads to the establishment of tissue boundaries, allowing the formation of regional subdivisions.

Patterning genes act in hierarchical fashion by exhibiting distinct temporal sequences of expression and function. To define such hierarchies, researchers use genetic manipulations (either deleting a gene [loss of function] or over-/ectopically expressing it [gain of function]) and observe the developmental consequences. In general, regionally restricted patterning genes participate in specifying the identity, and therefore function, of cells in which they are expressed. These genes regulate multiple developmental decisions including: (1) determining that ectoderm will give rise to nervous system (as opposed to skin), (2) defining the dimensional character of a region, such as positional identity in dorsoventral or rostrocaudal axes, (3) specifying cell class, such as neuron or glia, (4) defining when proliferation ceases and differentiation begins, (5) determining specific cell subtype, such as GABA interneuron, as well as projection pattern, and (6) defining laminar position, such as observed in cerebral cortex.

Transcription factors that pattern the nervous system belong to protein families highly conserved throughout evolution, with many discovered in Drosophila where they mediate body and organ segmentation and morphogenesis, or regulate neural development. In mammals, the Hox family delineates the anterior–posterior axis from tail to midbrain, defining segments of the hindbrain (rhombomeres) and its cranial nerves. The basic helix-loop-helix (bHLH) family, binding DNA and proteins through the basic and helix regions, respectively, regulates multiple stages from neural plate to neurogenesis. Other families bear names reflecting protein interaction domains and include LIM homeodomain (*Lhx*), zinc finger, paired domain (*Pax*), winged helix (*BF1 = Foxg1, Foxa2 = Hnf3ß*), and *Pou.*

Finally, patterning gene expression is regulated by environmental signals, especially growth factors released from regional signaling centers. Focal growth factor release establishes tissue gradients of these proteins that provide positional information (dorsal or ventral), impart cell specification, and/or control proliferative growth. Examples include the BMPs, the Wingless-int proteins (Wnts), Shh, fibroblast growth factors (FGFs), and epidermal growth factors.

Patterning the Embryonic Forebrain

In this section, we briefly review some of the transcription factors that determine brain region identities, also noting the roles of signaling center growth factors. Even at the third week of gestation, the neural plate stage, induction of the CNS begins when the underlying notochord and mesenchyme, and surrounding epidermal ectoderm produce signaling molecules that affect neighboring cell identity. Perhaps surprisingly, neural differentiation is the default state of early embryonic tissues unless it is inhibited. To prevent its own neural differentiation, the neighboring ectoderm produces BMPs that instead promote epidermal differentiation. To elicit neural differentiation, Hensen node, a signaling center at the rostral end of the primitive streak, secretes inhibitory proteins that block the BMP-mediated epidermis-inducing activity. Once the neural tube closes, the roof plate and floor plate become new signaling centers, organizing dorsal and ventral neural tube, respectively. As stated previously, the same ligand/receptor system is used sequentially for multiple functions during development. As a case in point are the BMPs: they prevent neural development at neural plate stage, while after neurulation, the factors are produced by the dorsal neural tube/roof plate itself to induce sensory neuron fates.

The dorsal forebrain structures include the hippocampus medially, cerebral cortex dorsolaterally, and entorhinal cortex ventrolaterally, whereas in basal forebrain, the globus pallidus lies medially and striatum laterally. In the mouse embryo, the forebrain is divided into a checkerboard-like pattern of transcription factors arranged in longitudinal columns and transverse segments that produce unique combinations within each subdivision (Fig. 1.4–3). Many of the genes, including*, Emx2, Pax6, FoxA2,* and *Dlx2,* are first expressed even before neurulation in the neural plate and are then maintained, comprising the "protomap" determinants of the VZ. Initial forebrain gene expression is influenced by an array of soluble factors derived from signaling centers, including (1) FGF8 and Shh from the anterior neural ridge (cranial mesenchyme), (2) BMPs and Wnts from midline structures, including cortical hem and commissural plate, and (3) FGF7, Wnt antagonists, and neuregulins and retinoic acid from the lateral junction of the dorsal and ventral palliums, the anti-hem. Shh also derives from the ventral midbrain region (Fig. 1.4–8). The influence of these localized sources diminishes as brain size increases.

As indicated, regional patterning genes including bHLH and homeodomain proteins frequently exhibit cross-regulatory activity, where one factor negatively regulates expression of its neighbors (Fig. 1.4–3). Thus loss of one factor leads to expansion in the boundaries of others. For example, the rostral/lateral cortex expresses high levels of homeodomain gene *Pax6,* whereas caudal/medial cortex exhibits *Emx2, Lhx2,* and *Lhx5.* A prediction would be that altering gene expression should cause a change in cortical areas, especially the proportions of motor to sensory cortex. Indeed, motor cortex markers are markedly diminished in mice mutant for *Pax6,* as is downstream bHLH transcription factor, *Ngn2*. Conversely, there is proportionate increase in caudal sensory cortex markers. Moreover, there are also changes in the dorsoventral dimension: Genes of the ventral striatum and pallidum, *Gsh* and *Dlx,* are now expressed ectopically in dorsal territory. A similar dorsal shift occurs with deletion of other dorsal transcription factors, *Ngn1/2* and *Gli3,* yielding loss of the cerebral cortex. Within the ventral forebrain, mutation of Nkx2.1 protein results in the acquisition of striatal-like properties by the presumptive pallidum, suggesting that Nkx2.1 both specifies the medial ganglionic (MGE; globus pallidus) fate and inhibits lateral ganglionic eminence (LGE) phenotypes. These observations indicate that patterning genes exert reciprocal inhibitory functions in several dimensions.

As expected, mutations in patterning genes and signaling molecule pathways lead to human brain malformations that are also observed in rodent models. *PAX6* deletion results in abnormalities of the eyes (cataracts, aniridia, anophthalmia) and the olfactory epithelium and bulbs.

Furthermore, the cerebral cortex is hypoplastic, exhibiting nodules of poorly differentiated cells adjacent to proliferative zones. Disruption of roof plate signaling causes holoprosencephaly (HPE), characterized by a single forebrain ventricle with a continuous cerebral cortex across the midline. HPE is linked to mutations in several components of the Shh inductive cascade, including *SIX3* and *ZIC2*. Both these transcription factors are upstream of Shh gene expression. HPE is also the consequence of mutations in the Shh Patched (*PTC*) receptor gene, and *TGIF,* a downstream component of the TGF-β family. Shh and *SIX3* are co-expressed in the anterior neural ridge and the ventral midline, whereas *Zic2* is expressed in the dorsal roof plate. *SIX3* and *SHH* are also mutated in some cases of schizencephaly. Finally, *FOXG1* (*BF1*) gene mutations cause microcephaly, corpus callosum dysgenesis and delayed myelination, associated with severe intellectual disability, motor delay, dyskinetic movements, and epilepsy.

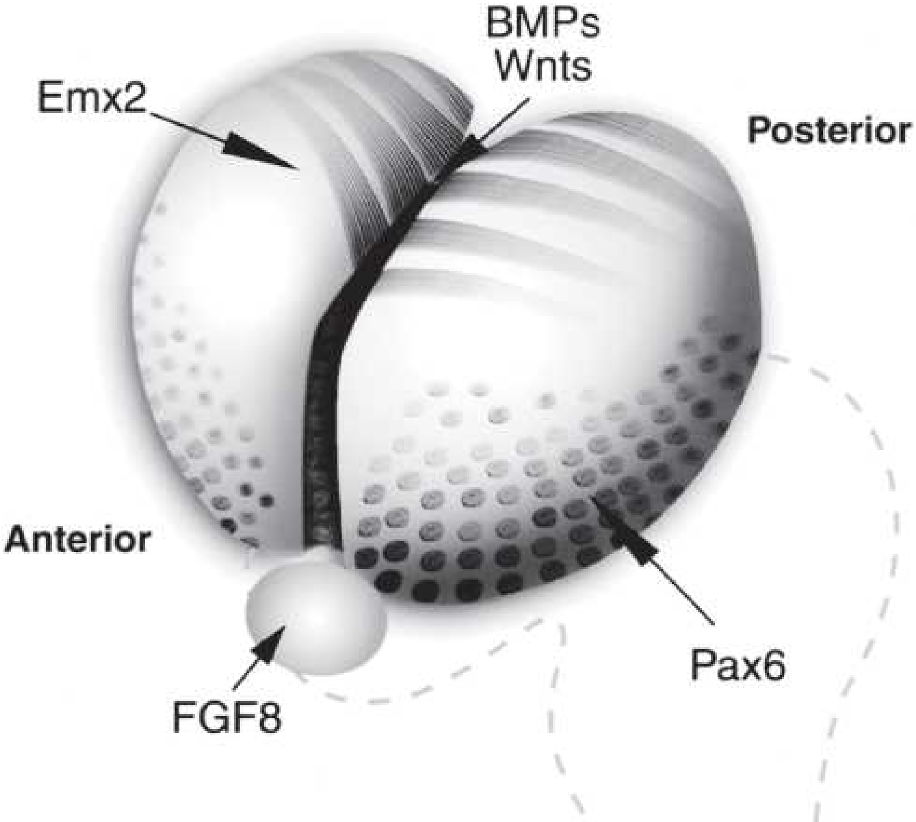

FIGURE 1.4–8. Patterning genes and signaling centers in the developing cerebral cortex. This schematic diagram shows a lateral-superior view of the two cerebral hemispheres of the embryonic mouse, sitting above the midbrain and hindbrain (*broken lines*). *Circles* indicate the anterior-lateral extent of Pax6 gene expression. The posterior-medial domain of Emx2 expression is indicated by stripes. The genes exhibit continuous gradients of expression that decrease as they extend to opposite poles. The signaling factor fibroblast growth factor 8 (FGF8) is produced by and released from mesenchymal tissue in the anterior neural ridge, which regulates Pax6 and Emx2 expression. In the midline, bone morphogenetic proteins (BMPs) and Wingless-Int proteins (Wnts) are secreted from other signaling centers, including the roof plate and the cortical hems. (Courtesy of E. DiCicco-Bloom and K. Forgash.)

Given the substantial role of molecular determinants (“protomap”) in regulating areal specification, do ingrowing thalamic afferents contribute to cortical development? In two different mouse mutants of ventral forebrain genes, *Gbx2* and *Mash1,* thalamocortical innervation is disrupted, yet the expression of cortical patterning genes is not altered, suggesting they have a limited prenatal role. However, after birth, thalamic axons interact with local regional cues and modify their outgrowth to establish proper connections that conform to cortical molecular identities. Furthermore, the developing cortex exhibits a remarkable level of flexibility: in the ferret, eliminating the thalamic lateral geniculate nucleus to which retinal ganglion axons project causes them to reroute to the auditory cortex, which then successfully mediates vision!

Layer-Specific Generation of Neurons during Cortical Development. Despite early determination of cortical areal identities by "protomap" patterning genes, the cerebral cortex exhibits a common six-layered cytoarchitecure that was classically described by histologic analysis, and is now characterized by "layer-specific" molecular markers. Many of the markers, which are highly conserved in mammals and primates including humans, are transcription factors that determine when neural precursors exit the cell cycle and or initiate neuron- and layer-specific cell differentiation. After neural precursors commit to a postmitotic fate, the diversity of cortical projection neurons suggests the critical importance of accurately timing the activation of intrinsic genetic programs. Glutamatergic projection neurons in the cortical layers target specific brain structures. Lower-layer (V–VI) neurons mainly project subcortically, with axons establishing synapses in the thalamus, brain stem, and spinal cord. Upper-layer (II–IV) neurons project intracortically, either within the ipsilateral hemisphere or to the contralateral hemisphere via the corpus callosum. During this period, upper-layer neurons express *Cux1/2*, *Satb2*, and *Brn1*, whereas lower-layer neurons exhibit *Ctip2*, *Foxp2*, *Tle4*, and *Fezf2* (Fig. 1.4–9). As with cortical areal determinants, genetic studies using gain- and loss-of-function approaches indicate their fate-specifying roles and their cross-regulatory actions. For example, in upper-layer neurons, when *Satb2* is deleted, axons do not extend to contralateral cortex via the corpus callosum, but instead project to subcortical targets, just like lower layer neurons. Indeed, these upper-layer neurons up-regulate levels of lower-layer factor, *Ctip2*. Conversely, reduction of *Ctip2* in lower-layer neurons prevents their normal projection to the spinal cord. Similarly, silencing of lower-layer *Fezf2* transcription factor also prevented corticospinal tract axons from reaching their targets, whereas ectopic overexpression of *Fezf2* in upper-layer neurons mis-directed axons to subcortical sites. Thus the cerebral cortex exhibits interacting as well as sequential arrays of transcription factors during development.

The Hippocampus

Genetic experiments have defined patterning genes localized to the cortical hem and hippocampal primordia, whose deletions result in a variety of morphogenetic defects. In mice lacking growth factor Wnt3a expressed in the cortical hem, the hippocampus is either completely missing or greatly reduced, while neighboring cerebral cortex is preserved. A similar phenotype results from deleting intracellular factor downstream of Wnt receptor activation, the *Lef1* gene, suggesting the Wnt3a-*Lef1* pathway is required for hippocampal cell specification and/or proliferation. When another cortical hem gene, *Lhx5* (also *Lhx2),* is deleted, mice lack both the hem and neighboring choroid plexus, both sources of growth factors. However, in this case, cortical hem cells proliferate in excess, and the hippocampus is disorganized due to abnormalities in proliferation, migration, and differentiation. Finally, a sequence of bHLH transcription factors plays roles in postnatal hippocampal neurogenesis: DG differentiation is defective in *NeuroD* and *Mash1* mutants. Significantly, all hippocampal-patterning genes are regulated by locally secreted factors including FGF8, Shh, BMPs, and Wnts.

The Basal Ganglia and the Origins of Inhibitory Interneurons

The genes patterning the ventral forebrain regions were described above, and featured in Figure 1.4–3. However, in addition to motor and cognitive functions, the basal ganglia are important because they are the embryonic origin of GABA interneurons that reach the neocortex through tangential migration (Fig. 1.4–6). As a simplified model in mice, the MGE expresses primarily *Nkx2.1* and gives rise to GABA interneurons of the cortex and hippocampus, whereas the LGE expresses *Gsh2* and generates GABA interneurons of the SVZ and olfactory bulb. When *Nkx2.1* is deleted, LGE transcription factor expression spreads ventrally into the MGE, and there is 50 percent reduction in neocortical and striatal GABA interneurons. In contrast, deletion of *Gsh2* leads to ventral expansion of the dorsal cortical molecular markers and concomitant decreases in olfactory interneurons. Finally, *Pax6* mutation causes both MGE and LGE to spread laterally and into dorsal cortical areas, yielding increased interneuron migration.

FIGURE 1.4–9. A simplified schematic of the laminar organization of neocortical projection neurons. Glutamatergic projection neurons represent approximately 85 percent of all neocortical neurons and exhibit a six-layered format. Neuron subpopulations are characterized by specific molecular identities, dendritic morphologies, and terminal targets corresponding to each layer. Projection neurons that are born during later stages of prenatal neurogenesis localize to upper layers II–IV, express specific transcription factors such as CDP/Cux1, and project solely intracortically, forming the corpus callosum and ipsilateral intrahemispheric tracts. In contrast, earlier born projection neurons localize to lower layers V–VI, express TLE4 and FEZF2, and project subcortically to form the corticothalamic tract (CTT) or corticospinal tract (CST). In the subventricular zone (SVZ), adult progenitors are found giving rise to olfactory cortex neurons. (Reprinted from DeBoer EM, Kraushar ML, Hart RP, Rasin MR. Post-transcriptional regulatory elements and spatiotemporal specification of neocortical stem cells and projection neurons. *Neuroscience* 2013;248:499–528. Copyright © 2013 IBRO.)

Other transcription factors in the MGE and LGE (Fig. 1.4–3) regulate both the timing and type of interneurons generated. *Mash1* is expressed in early born cells, whereas *Dlx1/Dlx2* appears in later maturing neurons, having as targets other family members, *Dlx5/Dlx6.* In the *Dlx1/Dlx2* double knock out, there is 75 percent reduction in neocortical interneurons, and complete absence in the hippocampus, while olfactory neurons are preserved. A regulatory cascade has been suggested since *Mash1* can regulate *Dlx* expression, while *Dlx2* can induce expression of the GABA synthetic enzyme, glutamic acid decarboxylase. Indeed, *Mash1* deletion mutants exhibit reduced cortical GABA interneurons and striatal cholinergic interneurons. Similarly, *Nkx2.1* loss leads to complete absence of all cortical interneurons expressing NPY, somatostatin, and NOS. These studies suggest that transcription factors play roles at multiple stages in neuronal production including generic neuronal fate specification, as well as neuron subtype determination.

Neuronal Specification

Transcription factors regulate decisions of neural cell type, neuron or glial cell, as well as neuron subtypes. For example, *Mash1* can promote a neuronal over a glial fate, as well as induce the GABA interneuron phenotype. *Neurogenin2 (Ngn2)* can promote glutamatergic excitatory neuron fate. However, another bHLH factor, *Olig1/2,* can promote oligodendrocyte development in the forebrain, whereas it promotes motor neuron differentiation in the spinal cord, indicating that the variety of factors expressed in a specific cell leads to combinatorial effects and diverse outcomes for cell differentiation.

REGULATION OF NEURODEVELOPMENT BY EXTRACELLULAR FACTORS

Extracellular factors that regulate cell proliferation, migration, differentiation, and survival interact with intrinsic genetic determinants to control region-specific neurogenesis. This section focuses on precursor proliferation as one example. Patterning genes control the expression of growth factor receptors and the molecular machinery of the cell division cycle. Growth factors stimulate or inhibit proliferation of VZ precursors and are termed as autocrine, paracrine, and endocrine, meaning they originate from the cells themselves, neighboring cells/tissues, and from the general circulation, respectively. Although defined initially in cell culture, mitogenic growth factors are now well characterized in vivo. There are those that stimulate proliferation, such as bFGF, Wnt, IGF-I, Shh, as well as signals that inhibit cell division, including leukocyte inhibitory factor (LIF), pituitary adenylate cyclase–activating polypeptide (PACAP), GABA, glutamate, interferon-gamma, and glial-derived neurotrophic factor. A recent integrated transcriptomic and proteomic analysis of embryonic cortical precursors and neurons by Yuswa et al. (2016) has newly identified growth factors that elicit cell cycle exit while promoting neurogenic differentiation. In addition to acting as mitogens, extracellular signals also act as trophic factors, which enhance proliferation by promoting survival of the mitotic population. Stimulation of both pathways is necessary to produce maximal cell numbers. Several of the neurotrophins, especially BDNF and neurotrophin-3 (NT3), promote survival of mitotic precursors as well as the newly generated progeny.

Altering the expression and activity of mitogens and their receptors during development can elicit profound and permanent consequences. For example, growth factor administration to developing rodent embryos or pups induces changes in proliferation in prenatal cortical VZ, postnatal cerebellar EGL, and hippocampal DG that produce lifelong alterations in brain region size, cell composition, and function. Environmental factors (hypoxia, maternal/fetal infection, drug or toxicant exposure) can also dysregulate mitogenic pathways and produce major deficits. In humans, the previous practice of steroid treatments to promote lung maturation for mothers with preterm deliveries was discontinued when negative effects on cerebellar granule neurogenesis and cognition were clarified. Similarly, cancer regimens including chemotherapy and radiation have long been known to inhibit perinatal neurogenesis. Changes in regional neurogenesis may be relevant to structural differences observed in neuropsychiatric disorders: abnormalities in FGF ligand and receptor system expression have been found consistently in brain samples from those with major depressive disorders (MDDs), as well as many animal models of stress and depressive behavior. Finally, mitogens regulating cerebellar granule neurogenesis in animals include bFGF, Shh, and PACAP, whereas genetic mutations in both *SHH* and *WNT* determine the severity and prognosis of medulloblastoma in children.

It is well known that neurologic development may be delayed in children experiencing serious systemic illness that is associated with numerous inflammatory cytokines, and one may wonder whether this reflects interference with neurogenesis and concomitant processes, potentially producing long-term differences in cognitive and motor development. Similarly, maternal infection during pregnancy is a known risk factor for schizophrenia and possibly autism, and cytokines that cross the placental barrier may directly affect fetal brain cell proliferation and differentiation as well as cell migration, axon target selection, and synapse maturation as shown in animal models, eventually leading to multiple brain and behavioral abnormalities in the adult offspring.

Cell Migration

The movement of immature neurons from proliferative areas to their definitive positions in the brain is an essential process of neurodevelopment. The orientation and directionality of cell migration can be described as radial (cortex), tangential (inhibitory GABA interneurons from MGE/LGE), or through a migratory stream (granule interneurons of the olfactory bulb). Regardless of migration type, there are guidance cues that influence the direction, speed, and cell behavior of these motile cells. These cues are broadly categorized as: extracellular factors, adhesion molecules, and cytoskeletal-regulating molecules.

Much of our knowledge about these guidance cues originates from animal models. For example, the best characterized examples are mice with deficient levels of the extracellular factor reelin, a large, secreted glycoprotein produced embryonically by the earliest neurons in the cortical preplate, Cajal–Retzius cells. The mouse cortex exhibits dysregulated neuronal migration resulting in inverted cortical laminar structure, generated in outside-to-inside fashion. Further, there is ectopic hippocampal neurogenesis, resulting from aberrant migration into the hilus and molecular layer. Reelin binds and activates two receptors, the very–low-density lipoprotein receptor (VLDLR) and the apoprotein E receptor 2 (ApoER2), and the intracellular adapter protein, disabled 1 (Dab1). The roles of the VLDL and ApoE2 receptors are intriguing considering their well-known contributions to genetic risk for Alzheimer disease. Interestingly, postmortem brain protein levels have been reported as abnormal in schizophrenia and autism, though recent genomic studies do not reveal genome-wide significance for reelin gene variant in disease risk. Another extracellular factor important for neuronal migration is the polypeptide hormone, insulin-like growth factor 1 (IGF-1). Knock out mouse models have revealed a suspension of progenitors in a multipolar state, resulting in failed neuronal migration to upper cortical layers.

Adhesion molecules that participate in neuronal migration can be divided into cell–matrix and cell–cell interacting molecules. Cell–matrix adhesion molecules, such as integrin, participate in mediating the binding of cell surfaces and different ligands at the extracellular matrix. As for cell–cell adhesion molecules, there are the cadherins, which mediate

Ca^{2+}-dependent cell–cell adhesion. N-cadherin in particular is turned on during neurulation and its absence results in disorganized radial glia and intermediate progenitor cells across the cortex. Ca^{2+}-independent cell–cell adhesion molecules include nectins and nectin-like molecules, which are immunoglobulin-like cell adhesion proteins. These molecules are expressed in the hippocampus, cerebellum, and neocortex, and have been identified as components of the reelin-signaling pathway to instruct radial migration of Cajal–Retzius cells.

Many of the molecules described above regulate the cytoskeleton, which is critical for neurite outgrowth and migration. The neuronal cytoskeleton is comprised of actin, intermediate filaments, and microtubules (MTs). Actin filaments play a critical role in cell migration, with particular importance for growth cone exploration (discussed in next section). The dynamic nature of actin filaments is regulated by Rho GTPases, including Rac1, RhoA, Rnd2, and cdc42. Rnd2 inhibits RhoA to promote radial migration and neurite extension, whereas Rac1 and cdc42 play more of a role in axonal guidance and polarity. MTs are dynamic, polarized intracellular filaments that are highly abundant in neurons and generate the energy needed to propel the nucleus forward to aid in migration. Missense mutations in both murine and human MT subunit, *Tuba1a/TUBA1A*, results in an accumulation of neurons in proliferative regions, which fail to emigrate out, and are associated with several neuropsychiatric disorders. Further, MTs are regulated by microtubule-associated proteins (MAPs), which play a major role in ensuring that there is normal progression of cell migration and outgrowth. Disruptions in extracellular factors, adhesion molecules, and cytoskeletal regulators can lead to malformations in cortical development. For example, patients with lissencephaly often have brains devoid of sulci and gyri, originating from defects in neuronal migration. This disorder can be caused by single mutations in four different genes (*DCX, RELN, LIS1, ARX*) and a partial chromosomal deletion (Chr 17p—Miller–Dieker syndrome). Mutations in doublecortin (*DCX*), a well-characterized MAP, results in X-linked lissencephaly in males and bands of heterotopic neurons in white matter in females, appearing as a “double cortex” on imaging studies, and producing severe mental retardation and epilepsy. Studies utilizing human-induced pluripotent stem cell models revealed that loss of *LIS1* results in altered neuronal migration by dysregulating MT stability and their motor protein, dynein. Mutations in *DCX* and *LIS1* are suggested to account for about 75 percent of lissencephaly cases while *TUBA1A* accounts for approximately 4 percent of cases.

Differentiation and Neuronal Process Outgrowth

Once newly produced neurons and glial cells reach their final destinations, differentiation into a mature state can begin, peaking around 5 months of gestation. For neurons, this involves outgrowth of dendrites and extension of axonal processes, formation of synapses, and production of neurotransmitter systems, including receptors and selective neurotransmitter reuptake sites. This outgrowth begins with a break in polarity, where the distal tip of an immature neurite begins to protrude and respond to guidance cues. This structure is known as the growth cone, which was discovered and named by Santiago Ramón y Cajal.

The structure of the cone is subdivided into two domains: the central domain, which contains mitochondria and MTs, and the peripheral domain, containing veil-like lamellipodia and spike-like filopodia and populated primarily by actin (Fig. 1.4–10). Growth cone protrusion and motility is largely driven by the cyclical polymerization and depolymerization of actin filaments. When there is more polymerization or myosin activity, the growth cone extends, whereas depolymerization and retrograde movement results in retraction of the growth cone. Abnormalities in actin-modulating proteins (Arp2/3, Profilin, Cofilin) and related kinases (LIM, SRC) involved in rapid growth cone movements may contribute to language and cognitive disorders, such as *LIMK* kinase whose mutation causes Williams syndrome. During the first several years of life, many neuronal systems exhibit exuberant process growth and branching, which is later decreased by selective “pruning” of axons and synapses dependent on experience, while myelination continues for several years after birth and into adulthood.

Much of growth cone movement is influenced by a variety of attractive and repulsive extracellular guidance cues, including secreted extracellular matrix proteins, such as netrins, slits, and semaphorins, and cell–cell adhesion molecules, such as ephrins, cadherins, and nectins. For example, region-specific expression of guidance molecules, such as cadherins, is regulated by patterning genes *Pax6* and *Emx2.* These cues interact with filopodial receptors to cause growth cones to move forward, turn, or retract. Netrin proteins serve as bifunctional cues, where they can induce attractive and repulsive signals depending on their receptors.

Netrin-1 in particular is involved in the migration of GABAergic interneurons, while Netrin-4 influences the maturation of cortical neurons. Slit molecules act via binding to Robo receptors and act primarily as a repulsive axon guidance cue, enabling commissural axons to cross the midline only once, ensuring proper projection. Similar to Slits, Semaphorins also serve as repulsive cues for developing commissural axons. When their expression is altered, aberrant axonal projection occurs from failed pathfinding.

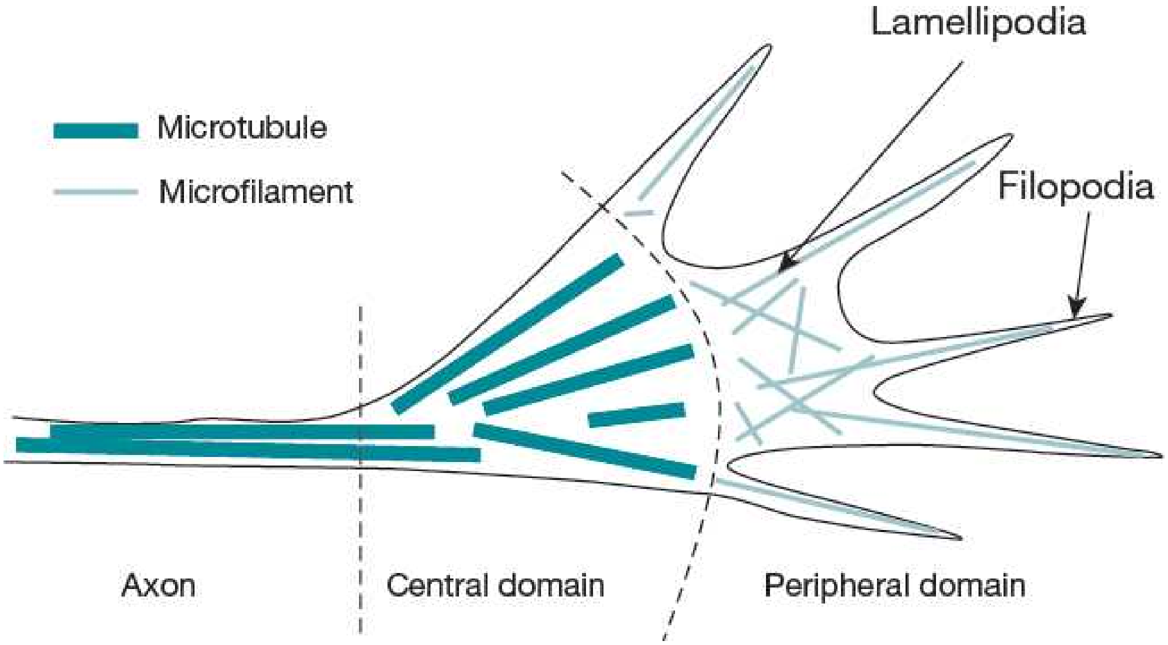

FIGURE 1.4–10. Structure of the growth cone. The cone is subdivided into two domains: the central domain, which contains mitochondria and microtubules, and the peripheral domain, containing veil-like lamellipodia and spike-like filopodia. In the lamellipodia, microfilaments consisting of actin form a meshwork, while in filopodia, they have the same orientation. Cell surface receptors on growth cone processes sense extracellular guidance cues to control navigation.

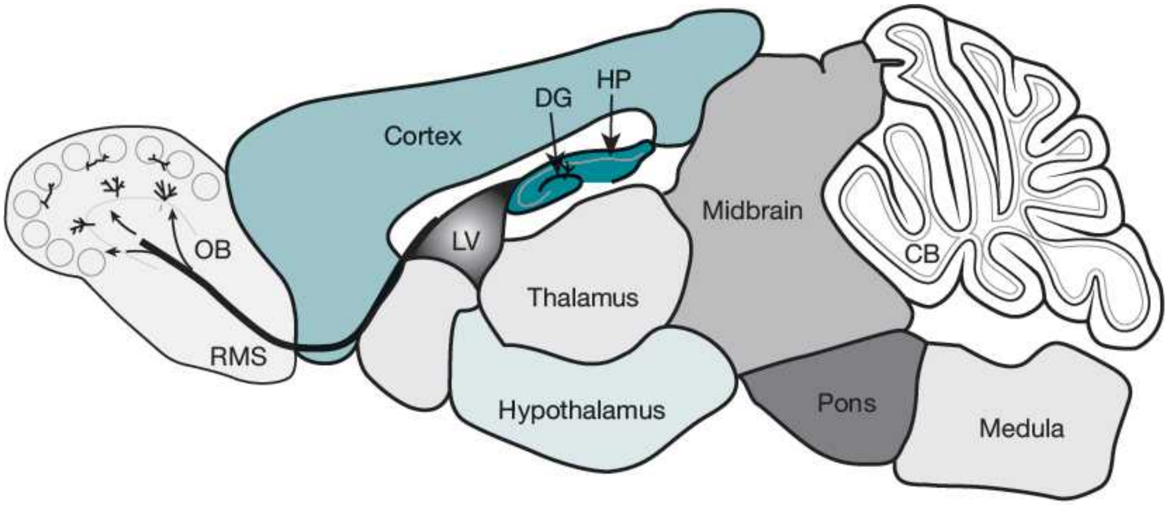
Ephrins frequently serve as chemorepellent cues, negatively regulating growth by preventing developing axons from entering incorrect target fields. For example, the optic tectum (superior colliculus) expresses ephrins A2 and A5 in decreasing gradients from posterior to anterior, whereas innervating retinal ganglion cells express a gradient of Eph receptors. Ganglion cell axons from posterior retina, which possess high Eph A3 receptor levels, preferentially innervate the anterior tectum because the low-level ephrin expression does not activate the Eph kinase that causes retraction. The role of cadherins and nectins in regulating axonal guidance and target recognition has been more deeply characterized in structures outside of the neocortex, including the spinal cord and motor or sensory nerves. However, a recent study demonstrated that absence of N-cadherin in thalamic and cortical co-cultures resulted in altered innervation patterns of thalamocortical axons, confirming the role of cadherins in the guiding axonal pathfinding.

POSTNATAL NEUROGENESIS IN MAMMALS: SUBVENTRICULAR ZONE AND HIPPOCAMPAL DENTATE GYRUS

Adult neurogenesis is the generation of new neurons from neural precursors in the brain. This process is restricted to two regions: the SVZ lining the lateral ventricles, and a narrow proliferative zone underlying the DG granule cell layer termed the subgranular zone, SGZ, in the hippocampus (Fig. 1.4–11). It is a highly plastic process that can be altered by various physiologic, pathologic, environmental, and pharmacologic stimuli. In mice, rodents, and monkeys, newly produced neurons migrate from the SVZ in an anterior direction toward the olfactory bulb to become GABA (and dopamine)-containing interneurons, and also into striatum under certain conditions.

Studies in rodents have demonstrated that adult neurogenesis is regulated by extracellular signals (such as EGF, bFGF, IGF-I, BDNF, LIF/CNTF) that control precursor proliferation and or cell survival. For example, peripheral administration of both bFGF and IGF-I stimulate neurogenesis, selectively increasing mitotic labeling in the SVZ and hippocampal SGZ, respectively. More classical studies were performed by application of growth factors via intracerebroventricular injections and demonstrated direct cellular actions. Interestingly, models of pregnancy indicate that both prolactin and oxytocin hormones enhance maternal neurogenesis which contributes to learning of their offspring identity. These studies typically utilize thymidine analogs BrdU and EdU, which can be injected into living animals and then detected by immunohistochemistry. Use of endogenous cell markers can also be used to label proliferating cells, including Ki-67 and proliferating cell nuclear antigen (PCNA).



Factors that stimulate neurogenesis	Factors that inhibit neurogenesis
Antidepressants/Antipsychotics	Stress/Glucocorticoids
Exercise	Isolation
Enriched environments	Sleep deprivation
Oxytocin/Prolactin	Drugs of abuse

FIGURE 1.4–11. Adult neurogenesis in the hippocampal dentate gyrus and the subventricular zone. A sagittal section view of an adult rodent brain highlighting the two restricted regions that exhibit active adult neurogenesis: dentate gyrus (DG) in the hippocampal formation (HP), and the lateral ventricle (LV) subventricular zone to the rostral migratory stream (RMS) to the olfactory bulb (OB). (Adapted from Ming G, Song H. Adult neurogenesis in the mammalian brain: Significant answers and significant questions. *Neuron* 70(4):687–702. Copyright © 2011, with permission from Elsevier.)

As discussed in earlier sections, doublecortin (DCX) is a MAP expressed by neuronal precursor cells and immature neurons. This marker in particular has been extensively used to characterize the possibility of human adult hippocampal neurogenesis (AHN) in postmortem brain tissue. Improvements in methodology and resources have allowed researchers to decipher this complex question, which has led to an ongoing debate within the last few years. A handful of labs have concluded to find thousands of immature neurons (DCX+ cells) in variable stages of maturation within the DG of the hippocampus of healthy humans up to the ninth decade of life. Although these studies have used state-of-the-art technology and brain tissue from healthy humans, they have reported that detection of AHN markers in the human DG are reduced when brain tissue is in a fixative solution for a prolonged period of time, which is typically the case at brain banks worldwide. Studies that refute the hypothesis have used similar techniques and reported that numbers of young neurons decreased in density by age 13 years to undetectable levels in adulthood (18+). However, the analyzed brain tissue samples included those from humans with epilepsy, which often results in destruction of the neurogenic niche, perhaps contributing to the lack of AHN reported. Additional studies that take the history of the sample into account (neuropsychiatric disease, tissue fixation solution and time) and include rigorous methods (unbiased stereology, bioinformatics, non-invasive *in vivo* studies in humans) are needed to adequately support or refute the possibility of AHN.

The discovery of adult neurogenesis naturally leads to questions about whether new neurons can integrate into the complex cytoarchitecture of the mature brain, and the functional significance. Extensive analysis has shown that newly born neurons indeed integrate into hippocampal circuits and establish typical synaptic connections. From a functional perspective, the generation and/or survival of new neurons correlate strongly with multiple instances of behavioral learning and experience. For example, survival of newly generated neurons is markedly enhanced by hippocampal-dependent learning tasks and by an enriched, behaviorally complex environment. Of perhaps greater importance, a reduction in DG neurogenesis impairs the formation of trace memories, that is, when an animal must associate stimuli that are separated in time, a hippocampal-dependent task. From clinical and therapeutic perspectives, scientists have observed that changes in neurogenesis can contribute to disease or help the brain recover from injury. A neurogenetic response has been shown for multiple pathologic conditions in the adult, including brain trauma, stroke, and epilepsy. For instance, ischemic stroke in the striatum stimulates adjacent SVZ neurogenesis (Fig. 1.4–11), with neurons migrating to the injury site. These studies raise the possibility that newly produced neurons normally participate in recovery, and may be stimulated as a novel therapeutic strategy. However, neurogenesis can also play roles in pathogenesis. In a kindling mouse model of epilepsy, newly generated neurons migrated to incorrect positions and formed aberrant neuronal circuits, re-enforcing the epileptic state. Human samples from surgical resection of the DG in epilepsy reveal similar abnormalities. Conversely, reductions in neurogenesis can contribute to several conditions that implicate dysfunction or degeneration of the hippocampal formation. DG neurogenesis is inhibited by increased glucocorticoids levels observed in aged rats and is reversed by steroid antagonists and adrenalectomy. These observations are potentially relevant to the correlation of elevated human cortisol levels with reduced hippocampal volumes and the presence of memory deficits. Similarly, stress-induced increases in human glucocorticoids may contribute to decreased hippocampal volumes seen in schizophrenia, depression, and posttraumatic stress disorder (PTSD). Some studies have shown that antidepressants, antipsychotics, and/or physical exercise can reverse the decreased neurogenesis phenotype. For example, administration of the selective serotonin reuptake inhibitor (SSRI) antidepressant, fluoxetine, in mice led to an increase in neural progenitor cells, which eventually became new neurons in the hippocampus. Although successful antidepressant treatment response in humans has been associated with increased hippocampal volume on structural MRI analysis, evidence supporting a causative role of AHN in humans in clinical trials will be needed.

1.5 Cellular and Synaptic Basis of Neural Signaling

CHARLES F. ZORUMSKI, M.D., AND STEVEN MENNERICK, PH.D.

Neuropsychiatric disorders involve dysfunction in intercellular communication and neural networks. Although these defects often reflect synaptic communication between neurons, changes in the intrinsic excitability of neurons also contribute. Thus, pharmacologic and neuromodulation therapies aimed at neuronal excitability are becoming commonplace in the treatment of neurologic and psychiatric disorders. Furthermore, there is growing appreciation that psychotherapy alters specific aspects of neural communication to effect benefit.

Neurons use electrical signals to send and receive information. These electrical signals regulate the brain's local and network properties and involve the flow of ions across cell membranes through macromolecular ION CHANNELS. Neurons express two major classes of ion channels, gated and nongated. Nongated (or leakage) channels are open at rest and contribute to the cellular RESTING MEMBRANE POTENTIAL. The opening and closing of most ion channels are regulated (GATED) by changes in transmembrane voltage, extracellular chemicals, or intracellular messengers. VOLTAGE-GATED SODIUM CHANNELS open and close rapidly and provide the basis for communication within and between neurons. Rapid signaling via sodium channels results in "all or none" ACTION POTENTIALS that are generated near the neuronal cell body and transmitted with little decrement in amplitude along axons to nerve terminals. This high-fidelity signal propagation reflects action potentials regenerated by voltage-gated channels along the length of the axon. In myelinated axons, action potential propagation is enhanced by

SALTATORY CONDUCTION, the ability of electrical signals to “jump” between axonal nodes of Ranvier.

At nerve (synaptic) terminals, the wave of action potential–mediated depolarization opens VOLTAGE-GATED CALCIUM CHANNELS, and the influx of calcium promotes the release of a chemical neurotransmitter into the extracellular space, where the transmitter then influences a receptive cell. NEUROTRANSMITTERS bind two broad classes of RECEPTORS and alter neuronal excitability via actions on ion channels. LIGAND-GATED ION CHANNELS are directly opened by neurotransmitter binding, whereas G-PROTEIN–COUPLED RECEPTORS (GPCRs) influence ion channels indirectly via guanine nucleotide-binding proteins (G-proteins) or intracellular chemical messengers. This chapter outlines the basic principles of cellular electrophysiology and discusses the importance of electrical signals in brain function and neuropsychiatric illnesses.

PRINCIPLES OF CELLULAR ELECTROPHYSIOLOGY

Resting Membrane Potential

The concentration of potassium ion [K^+] is much higher inside cells than outside, reflecting the selective permeability of most cell membranes at rest to K^+. The expression of nongated (leak) K^+ channels in the cell membrane is the basis for this selective permeability. Potassium channels are a class of membrane-spanning proteins that have a hydrophilic pore that selectively conducts K^+ across the membrane through open pores of leak channels. Under baseline conditions, K^+ ions are attracted into the cell by the presence of large, impermeant intracellular anions (acids and proteins). As K^+ accumulates in the cell, the transmembrane electrical potential (electrical charge separation) of the cell becomes depolarized (less negative) and results in less K^+ entry because of electrorepulsion (like charges repel). Intracellular concentrations of K^+ reach levels of ~100 mM while extracellular [K^+] is between 2 and 6 mM; this unequal distribution establishes a chemical gradient, which, by itself, would result in net K^+ efflux from the cell. Thus, there are two gradients that act on K^+: intracellular electronegativity promoting K^+ influx and a chemical gradient driving K^+ efflux. At a specific membrane potential (around −90 mV), the electrical and chemical gradients for K^+ are equal and opposite. This membrane potential is known as the EQUILIBRIUM POTENTIAL (also called the NERNST POTENTIAL) for K^+. The equilibrium potential for an ion species is the transmembrane potential at which electrical and chemical gradients are balanced, and there is no net flux of the ion. In a cell whose membrane is exclusively permeable to K^+, the resting potential of the cell would be equal to the equilibrium potential for K^+.

The situation in most neurons is more complex because other ions, with different electrochemical gradients, are slightly permeant through ion channels that are open in the resting cell membrane. Each of these ions has its own characteristic equilibrium (Nernst) potential depending on ion concentrations inside and outside the cell. The cations Na^+ and Ca^{2+} are present at higher concentrations outside than inside the cell. Thus, at negative membrane potentials, both electrical and chemical gradients for these cations are inwardly directed, and the equilibrium potentials are positive to 0 mV. Chloride (Cl^-) concentrations are usually higher outside the cell, but because of this ion's negative charge, the equilibrium potential for chloride is near the resting potential (Fig. 1.5–1). The actual resting potential of a cell is determined by the average of the equilibrium potentials of all the permeant ions, weighted by the relative permeability of each ion. At rest, K^+ and Cl^- are much more permeant than other ions, so the resting potential is closest to the equilibrium potentials for these ions. Na^+ and Ca^{2+} are less permeant and contribute less to the resting potential, but the small permeability of nongated channels to these cations renders the actual resting potential more positive than the equilibrium potentials of K^+ or Cl^-. Typical values for neuronal resting potentials are between −55 and −70 mV. Astrocytes, by contrast, have a membrane more purely permeable to K^+ and, therefore, a more deeply negative resting membrane potential (∼−90 mV), very close to the K^+ equilibrium potential.

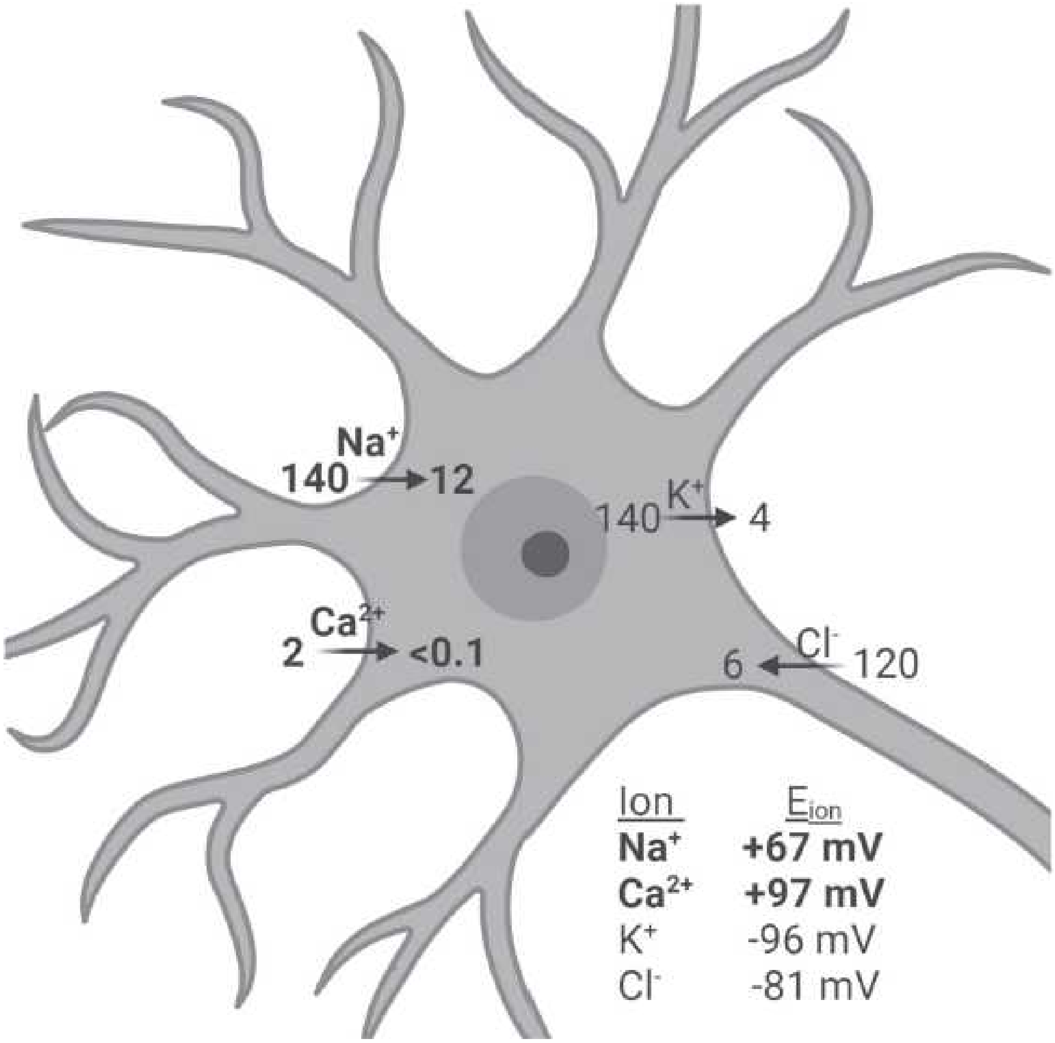

FIGURE 1.5–1. The figure shows the distribution of Na$^+$, K$^+$, Ca^{2+}, and Cl$^-$ across the membrane of a neuron; the *arrows* show the direction of the current flow down the electrochemical gradient. Depolarizing influences are shown on the **left**; hyperpolarizing influences are shown on the **right**. At the indicated ion concentrations, the equilibrium (Nernst) potentials at 37 °C are shown at the lower **left**. Excitatory influences are bolded. (Created with BioRender.com.)

The concepts of equilibrium potential and membrane potential outlined above are described quantitatively by the Nernst equation. The equilibrium potential for any ionic species is calculated based on the ion concentrations on either side of the membrane. For K$^+$, the equilibrium potential (designated E_K) is expressed as: $\mathbf{E_K = (RT/zF) \times \ln([K]_o/[K]_i)}$, where **R** is the ideal gas constant (8.31 joules/degree/mole), **T** is the temperature in degrees Kelvin, **z** is the valence of the ion, F is Faraday's constant (96,500 coulombs/mole, the charge on a mole of monovalent ions), and **$[K]_o$** and **$[K]_i$** are the concentrations of K^+ outside and inside the cell. At 37 °C, the equilibrium potential for K^+ is −96 mV, E_{Na} is +67 mV, E_{Cl} is −81 mV, and E_{Ca} is greater than +97 mV. These equilibrium potentials are important in determining how the membrane potential changes when an ion channel that is permeable to a specific ion species opens or closes because the opening of a specific ion channel drives the membrane potential toward the equilibrium potential for that ion. For example, when K^+-selective ion channels open, the neuronal membrane potential moves toward its equilibrium potential of −96 mV. This makes the inside of the cell more negative, an effect called HYPERPOLARIZATION. Na^+ and Ca^{2+} channel opening have the opposite effect, making the inside of the cell less negative (DEPOLARIZATION).

Because resting cell membranes are permeable to more than one ion, the true membrane potential is never exactly equal to the equilibrium potential for any one ion. The Goldmann/Hodgkin/Katz (GHK) equation describes the actual resting potential as the average of the various equilibrium potentials, weighted by the relative permeability of each ion. The equation is of the form:

$$E_m = \frac{RT}{F} \ln \frac{P_k[\mathrm{K}]_o + P_{Na}[\mathrm{Na}]_o + P_{Cl}[\mathrm{Cl}]_i}{P_k[\mathrm{K}]_i + P_{Na}[\mathrm{Na}]_i + P_{Cl}[\mathrm{Cl}]_o}$$

Most of the variables are familiar from the Nernst equation described above. E_m is the membrane potential, and P_{ion} is the permeability of the membrane to the ion. The resting membrane potential is thus a reversal potential (potential at which no net inward or outward current flows) for the various conductances open at rest.

The bulk ionic solutions on either side of the membrane are electrically neutral, with most intracellular negative charge contributed by large intracellular organic anions (acids and proteins). The differential distribution of ions across neuronal membranes is maintained by membrane pumps that use energy from hydrolysis of adenosine triphosphate (ATP) to move ions against their concentration gradients into or out of the cell. The best-characterized pump is the Na^+-K^+ ATPase (SODIUM PUMP) that transports 3 Na^+ out of and 2 K^+ into the cell during each cycle. Because an unequal amount of charge is moved during each cycle, the pump is ELECTROGENIC and contributes to intracellular negativity of the membrane potential. Na^+-K^+ ATPase activity is a major driver of brain energy utilization, with as much as 40% of brain oxygen consumption reflecting the pump activity required to re-establish ionic homeostasis following action potential firing and synaptic transmission. The cardiac glycosides, digoxin, and ouabain inhibit Na^+-K^+ ATPase in the heart and improve myocardial contractility by depolarizing cardiac myocytes and increasing intracellular Ca^{2+}.

The resting membrane potential is relatively static and represents the potential energy available for neuronal signaling. Negative resting potentials are not unique to excitable cells, but neurons and other excitable cells make unique use of the energy stored as the resting potential to generate transient membrane potential *changes*, the true currency of neuronal information exchange. A membrane potential change is typically initiated by a change in current flow across the membrane, usually resulting from the opening or closing of specific ion channels discussed below. The number of ions needed to change the membrane potential is very small relative to concentrations in bulk intracellular and extracellular solutions. For example, a potential change of 100 mV across a 1 cm^2 area of membrane requires the movement of only about 10^{-12} moles of a monovalent (singly charged) ion. By comparison, Na^+ and K^+ are present at about 10^{-1} M in the extra- and intracellular fluids, respectively.

Passive Membrane Properties

One way to conceptualize how electrochemical gradients, ion channels, and the unequal distribution of charges across the membrane are related is to view the cell membrane as an electrical circuit of resistors (conductors), batteries, and capacitors (Fig. 1.5–2). The use of the equivalent circuit allows the prediction of how the membrane potential will change in response to stimulation or channel opening. Because ions flow through ion channels and do not directly penetrate cell membranes, ion channels can be viewed as variable resistors. These ion channels are characterized by their SELECTIVITY (which ions flow through the channel) and their CONDUCTANCE (relative ease of passing ions). Conductance (g) is the inverse of RESISTANCE (R) in an electrical circuit ($g = 1/R$). The different types of ion channels are part of an electrical circuit in parallel with each other and with the membrane capacitance. The presence of a voltage across the membrane provides an electrical force driving ions through their channels and resulting in a transmembrane

CURRENT. The relationship among voltage (V), ionic current (I), and resistance (conductance) is given by a version of Ohm's law: $\mathbf{I_{ionic} = g(V_m - E_{rev})}$, where $\mathbf{V_m}$ is the membrane potential, $\mathbf{E_{rev}}$ is the equilibrium (Nernst) potential for the ion(s) flowing through the channel, and $\mathbf{(V_m - E_{rev})}$ is the DRIVING FORCE for ion flow.

CAPACITANCE is another important passive membrane electrical property. A capacitor is a device with two conductors separated by an insulating material that can store charges of opposite signs on the two conductors. In neurons, the conductors are the extra- and intracellular fluids, while the lipid membrane is the insulator. Whenever current flows through the membrane, some current must charge the membrane capacitance (C_m). The expression describing this capacitive current is: $\mathbf{I_{cap} = C_m(dV/dt)}$. Note that capacitive current flows only when the membrane potential is changing (i.e., there is some change in voltage [**dV**] over time [**dt**]). The total current flowing across a membrane at any given time is a sum of $\mathbf{I_{cap}}$ and $\mathbf{I_{ionic}}$. The membrane capacitance, along with the leak conductance of the membrane at rest, helps to define the low-pass filtering property of neurons. A major tool used to study ionic currents is a VOLTAGE CLAMP, often implemented using the PATCH CLAMP method. These techniques use specialized amplifiers to hold membrane potential constant and eliminate capacitive currents by preventing changes in voltage, making it possible to measure ionic currents, currents through ion channels, directly.

Active Membrane Properties: Action Potentials

Changes in membrane potential have important effects on excitability because some ion channels are regulated (gated) by voltage changes. When neurons depolarize, specific Na^+ channels open rapidly and drive the membrane potential toward the Na^+ equilibrium potential (~+66 mV). Because of leakage channels that are open at rest, there is initially a balance between leakage currents and the currents flowing through Na^+ channels opened by depolarization. At a specific depolarized membrane potential, the current flowing through Na^+ channels exceeds the current through the leak channels. The membrane potential at which Na^+ currents exceed leakage currents is called the THRESHOLD POTENTIAL, typically between −45 mV and −30 mV in neurons. At membrane potentials depolarized from the threshold, the entry of more Na^+ produces further depolarization and opens more Na^+ channels in a positive-feedback cycle. The membrane potential becomes more positive than 0 mV but never reaches the Na^+ equilibrium potential for three reasons. First, leak channels continue to play a role in determining the membrane potential during the action potential. Because of the relative K^+ selectivity of these channels, the membrane potential never reaches the Na^+ equilibrium potential. Second, during depolarization, Na^+ channels not only activate but also rapidly inactivate. INACTIVATION is a process by which voltage-gated channels enter a nonconducting state despite the continued presence of the activating stimulus (in this case, depolarization). Third, the depolarization produced by Na^+ entry also opens voltage-gated K^+ channels that drive the membrane potential toward the K^+ equilibrium potential (~ -90 mV). The net effect of activation and inactivation of Na^+ channels and delayed opening of voltage-gated K^+ channels is that the neuronal membrane potential rapidly changes to values more positive than 0 mV and then returns rapidly to the resting membrane potential. This rapid sequence occurs over several milliseconds and is called an ACTION POTENTIAL (or sodium SPIKE) (Fig. 1.5–3). The fact that the membrane potential transiently exceeds 0 mV is called an OVERSHOOT. To a first approximation, action potentials represent all-or-none increases in electrical excitability and are important contributors to information transfer within and between neurons. Because they propagate (see below), action potentials allow the neuronal cell body to communicate rapidly with its axon terminals. In axon terminals, the spike provides the depolarization that promotes Ca^{2+} channel opening and hence Ca^{2+}-dependent release of neurotransmitters.

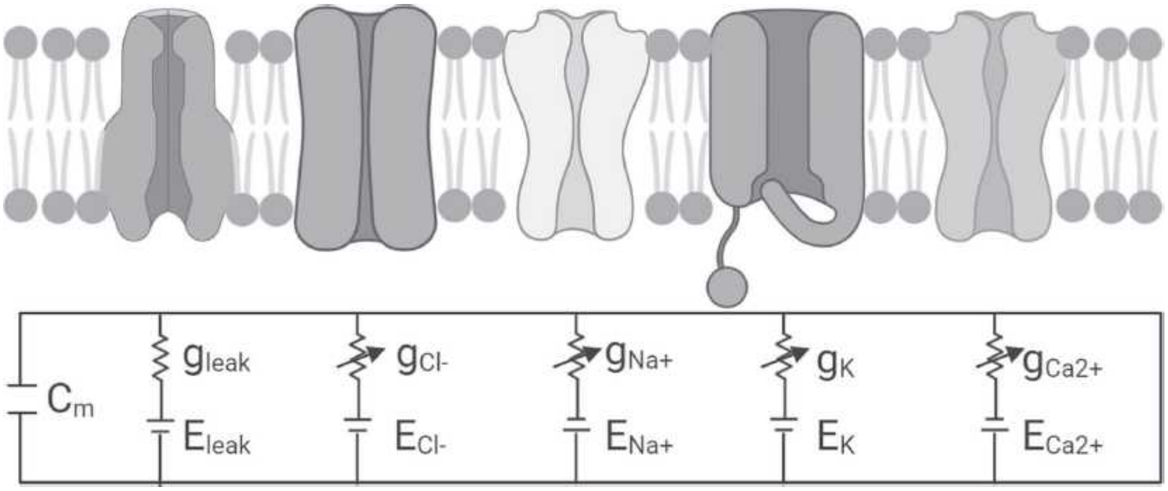

FIGURE 1.5–2. Ion channels are protein pores that span the lipid bilayer of cell membranes (**upper panel**). Because of the selective permeability of the membrane to potassium and because of membrane pumps, the intracellular surface of the membrane has a net negative charge with respect to the extracellular surface. The figure shows a membrane schematic that includes major leak and/or voltage-activated ion channels and the predominant direction of ion flux under physiologic conditions. As a result of the transmembrane potential and the presence of ion channels, the neuronal membrane can be described as an equivalent electrical circuit in which each ion channel is a variable resistor (conductor, g_x) in series with a battery (E_x) (**lower panel**). The leak conductance (g_{leak}) is represented as a constant resistance. Different ion channels are electrically in parallel with each other and in parallel with the membrane capacitance (C_m). FIGURE 1.5–3. The trace shows a neuronal action potential as recorded by an intracellular microelectrode. The portions of the action potential are described in the text. The right portion of the figure shows the sequence of events underlying an action potential. Na_V and K_V represent voltage-gated sodium channels and potassium channels, respectively. (Created with BioRender.com.)

In most neurons, the K^+ equilibrium potential is negative with respect to the resting membrane potential. Thus, action potentials are often followed by a transient UNDERSHOOT (or AFTERHYPERPOLARIZATION [AHP]) resulting from open voltage-gated K^+ channels that gradually close as the membrane hyperpolarizes (see Fig. 1.5–3). Following an action potential, there is a time during which depolarization either cannot elicit an action potential or during which it takes a very strong depolarization to evoke an action potential. These are called the ABSOLUTE and RELATIVE REFRACTORY PERIODS. The absolute refractory period results from nearly complete inactivation of Na^+ channels immediately following an action potential. The relative refractory period reflects the time it takes for voltage-gated K^+ channels to close following membrane repolarization.

Action Potential Conduction in Axons

Action potentials are typically generated in the initial segment of the axon (also called the AXON HILLOCK) within about 50 μm of the neuronal cell body. Because action potentials are initiated at a distance from nerve terminals where neurotransmitters are released, an important question concerns how action potentials propagate to synaptic terminals. In a strictly passive nerve fiber, leakage of current across the membrane results in DECREMENTAL CONDUCTION, with the signal (voltage change) fading over a distance that is determined by the longitudinal (axial) resistance of the fiber, the membrane capacitance, and the transmembrane resistance. This passive decremental conduction is more typical of how voltage changes spread along dendrites toward the neuronal cell body, although dendrites also express voltage-gated ion channels that support back-propagating action potentials and that play important roles in modifying synaptically generated voltage changes in dendrites.

Many, but not all, axons are encased in myelin sheaths that allow them to transmit action potentials more efficiently than bare (unmyelinated) axons. As a result of myelination, axons are electrically insulated except at NODES OF RANVIER, where there are dense collections of the voltage-gated Na^+ channels involved in action potential generation (Fig. 1.5–4). Myelin increases transmembrane resistance and decreases membrane capacitance. This diminishes leakage of current from the axon, making it easier for current to flow down the length of the axon and reach the nerve (axon) terminal, where neurotransmitter is stored. Action potentials propagate rapidly, and the wave of depolarization jumps from node to node in a form that transmits the signal with high fidelity to nerve terminals. This process of action potential spread through myelinated axons is called SALTATORY CONDUCTION (from the Latin word *saltare* meaning “to jump”) and is important because of the speed and fidelity with which electrical information is passed from a neuronal cell body to its terminals. Note that while the opening of voltage-gated channels is time dependent, reflecting changes in channel conformational state, the passive current flow between nodes is essentially instantaneous, despite the loss of fidelity. Thus, the passive spread of current longitudinally down the axon is important in determining the conduction speed. A typical value for conduction velocity in large myelinated axons is ∼100 m/s, while propagation in small unmyelinated fibers is only ∼0.3 m/s. In certain human illnesses, including multiple sclerosis and Guillain–Barre syndrome, demyelination of axons produces changes in axon conduction and specific neurologic defects.

ION CHANNELS

Structure and Function of Voltage-Gated Ion Channels

Voltage-gated ion channels allow the flow of ions in response to changes in transmembrane voltage and are key elements in regulating neuronal excitability. Although ion channels can usually pass more than a single ionic species, voltage-gated channels are named according to their predominant permeant ion, Na^+, K^+, Ca^{2+}, or Cl^-. Certain channels, including those opened by neurotransmitters such as glutamate and acetylcholine, are selective for positively charged ions (Na^+, K^+, and Ca^{2+}) but exclude Cl^-, and thus are NONSELECTIVE CATION CHANNELS. The family of voltage-gated ion channels has about 150 members encoded by genes in the human genome. Only the GPCRs and protein kinases have more members. The International Union of Basic and Clinical Pharmacology (IUPHAR) maintains a website with updated nomenclature on ion channels and receptors.

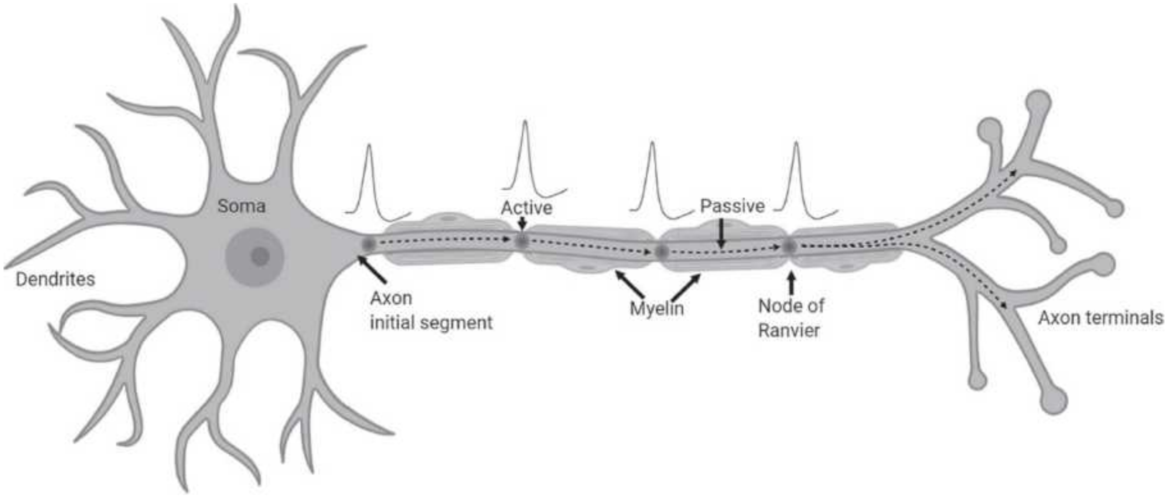

FIGURE 1.5–4. The diagram depicts saltatory conduction of an action potential in a neuron with a myelinated axon. The action potential is generated in the axon initial segment. As the waveform moves along the axon, current tends to leak from the cell diminishing the amplitude. However, myelin insulates the axon and markedly diminishes current leakage, thus enhancing axial current flow (*dashed arrows*) to the first node of Ranvier. At the nodes of Ranvier, Na^+ channels open in response to the wave of depolarization and reproduce (regenerate) the all-or-none action potential. The sequence is repeated at subsequent nodes of Ranvier until the action potential reaches the axon terminals to initiate transmitter release. (Created with BioRender.com.)

Sodium (Na^+) Channels

The opening of Na^+ channels in response to membrane depolarization underlies the fast upstroke of neuronal action potentials and thus are critical determinants of neuronal information processing. In some neurons, Na^+ channels also contribute to smaller depolarizations and pacemaker firing. Pacemaker activity refers to the ability of some neurons to depolarize spontaneously and to coordinate activity in a network of connected cells. As noted earlier, Na^+ channels ACTIVATE (open) rapidly in response to depolarization and most also INACTIVATE rapidly and nearly completely in response to prolonged depolarization.

Na^+ channels expressed in the brain typically have three protein subunits—a main (α) subunit with a molecular weight of 240 to 280 kilodaltons (kDa) and two minor (β) subunits with molecular weights of 30 to 40 kDa expressed in a 1:1:1 ratio. The α-subunit is a glycoprotein with four structurally similar domains that have six membrane-spanning (transmembrane) regions, S1 to S6 (Figs. 1.5–5 and 1.5–6). The α-subunit, when expressed alone, can form a functional channel. Unlike voltage-gated K^+ channels, which, as discussed below, are tetramers of distinct subunits with each subunit containing six transmembrane domains, functional sodium channels arise from a single α-subunit gene product. There are at least 10 mammalian genes that encode sodium channel α-subunits, Na_v 1.1 to 1.9 and Na_x. Na_v 1.1 to 1.3 and Na_v 1.6 to 1.9 are neuronal channels; Na_v 1.4 is expressed in muscle, and Na_v 1.5 is expressed in the heart. Some neuronal channels are expressed primarily in the central nervous system (CNS), and others in the peripheral nervous system (PNS). The properties of voltage dependence, ion permeation, pharmacologic sensitivity, activation, and inactivation are conferred by specific regions of these proteins.

Relationships between primary protein structure and ion channel function in Na^+ channels have been determined by site-directed mutagenesis of specific amino acid residues. Both the amino- and carboxy-terminals of α-subunits are located intracellularly. The fourth membrane-spanning region (S4) contains several electrically charged amino acid residues that sense transmembrane voltage changes and promote channel opening. Between the S5 and S6 membrane-spanning regions, a segment of hydrophobic amino acids does not completely traverse the membrane bilayer. This group of amino acids (called a "P-loop") lines the ion channel PORE (see Figs. 1.5–5 and 1.5–6). The P-loop is a feature shared by other voltage-gated ion channels and some nonselective cation channels (Figs. 1.5–7 and 1.5–8). A short intracellular loop between the third and fourth homologous domains plays a role in channel inactivation and physically blocks the ion pore during longer periods of depolarization. A high-resolution crystal structure of a bacterial

Na+ channel (NavAb) provides insights into structure–function relationships. This channel has a large external vestibule, a narrow ion selectivity filter, and a large, water-filled central cavity lined by S6 segments. The ion selectivity filter is formed by negatively charged side chains of glutamate residues that remove most, but not all, waters of Na+ hydration. An intracellular activation gate involves crossing parts of the S6 segments.

Sodium channel β−subunits (termed β1 to β4) are glycoproteins with a large extracellular amino terminus, a single transmembrane domain, and a short intracellular carboxy-terminus. Two β-subunits associate with a single α-subunit and regulate functional expression, channel kinetics, and gating. The large extracellular N-terminus is involved in cell adhesion via an immunoglobulin-like fold. A mutation in a cysteine residue in this extracellular fold is linked to a form of familial epilepsy. Studies using cryo-electron microscopy (Cryo-EM) have elucidated the structure of mammalian sodium channels complexed with a β-subunit.

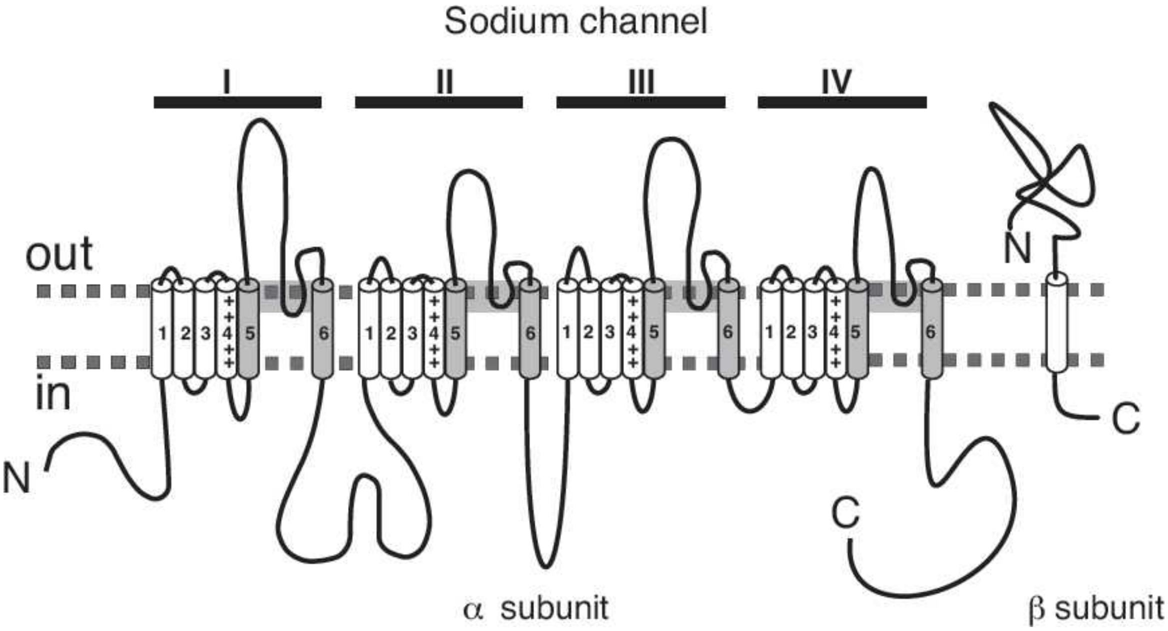

FIGURE 1.5–5. The diagram shows the schematized secondary structure of voltage-gated Na+ channels. The pore-forming α-subunit (**left**) consists of four homologous domains (I, II, III, and IV), each of which has six membrane-spanning regions (numbered 1 to 6). Both the amino (N) and carboxy (C) terminals are located intracellularly. A stretch of amino acids between S5 and S6, called the P-loop, forms two antiparallel β-sheets that line the ion channel pore. Positive charges in the fourth membrane-spanning (S4) region comprise the voltage sensor. An accessory (β) subunit is shown to the right.

Na^+ channels contain at least seven sites at which neurotoxins and clinical drugs act. Most, but not all, Na^+ channels contain an extracellular site at which tetrodotoxin (TTX) and saxitoxin (STX) block ion flow. TTX is a neurotoxin isolated from puffer fish that is commonly used in physiology experiments to block Na^+ channel function. At a site on Na^+ channels distinct from the TTX site, α-scorpion and sea anemone toxins act to modulate gating. α-scorpion toxins slow channel inactivation while α-scorpion toxins, acting at a distinct site, shift the voltage of activation to allow channels to open at voltages closer to the resting potential. The net effect of the scorpion toxins is to enhance excitation, contributing to the increased firing in pain fibers and paralysis associated with a scorpion sting. Mutations in α-subunits of skeletal muscle Na^+ channels cause the human disorder hyperkalemic periodic paralysis. Like anemone and α-scorpion toxins, these mutations slow channel inactivation.

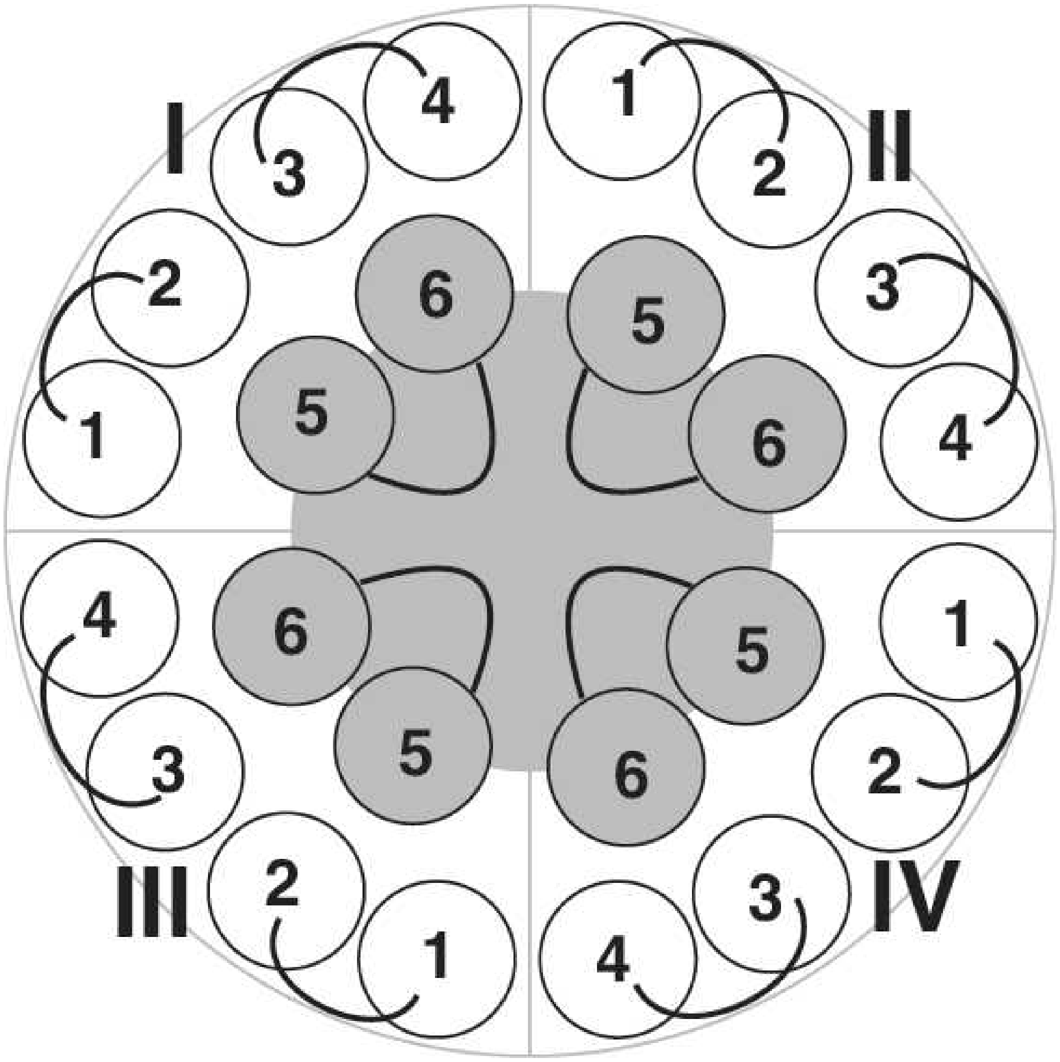

FIGURE 1.5–6. The diagram is a simplified depiction of the four homologous repeats (I to IV) in the cell membrane. The view is looking at the channel en face from the outside of the cell. Transmembrane helices are labeled 1 to 6. Extracellular linker regions are depicted by connecting lines. The P-loop is depicted as the linker between S5 and S6. Note the P-domains from each of the four homologous repeats contribute to lining the ion channel located at the center of the diagram. A more realistic depiction of the skeletal muscle form of the channel complexed with a β-subunit is available from cryo-electron microscopy work.

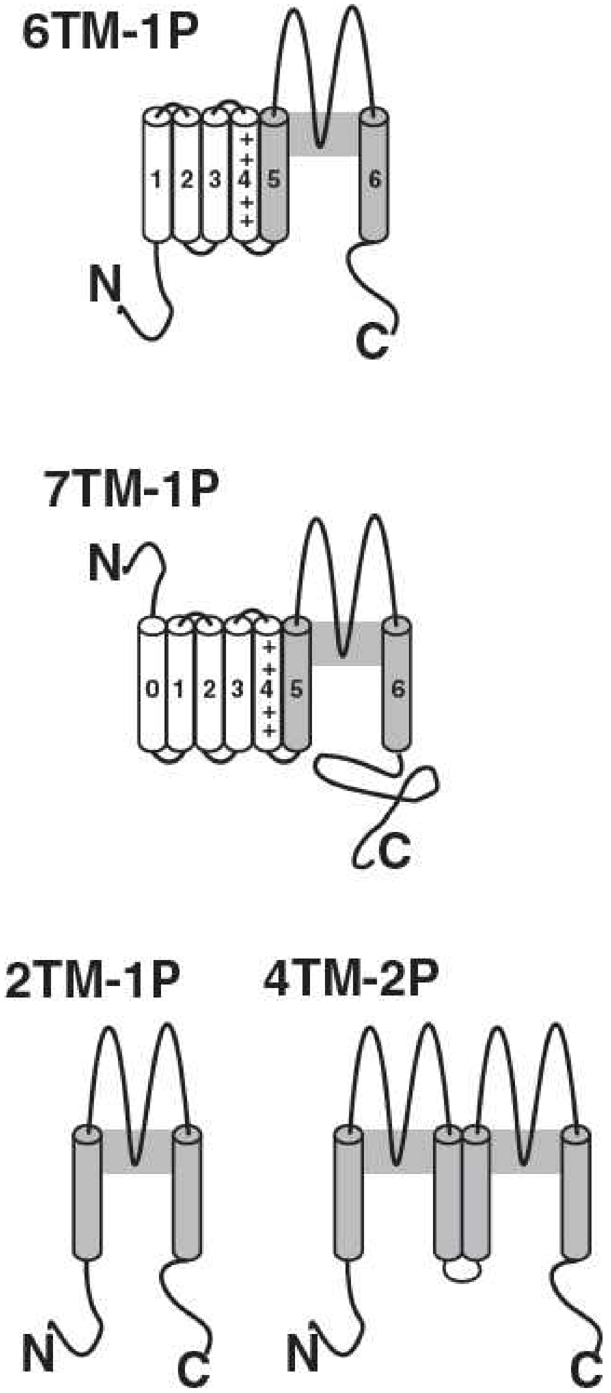

FIGURE 1.5–7. Potassium channels have diverse molecular structures. Four families of K$^+$ channels defined by the number of transmembrane (TM) domains, and the number of P-domains are shown. Of the channels described in the text, classical depolarization-gated K$^+$ channels, and KCNQ subunits are members of the six TM domain, one P-domain family. Some Ca^{2+}-dependent K$^+$ channels are also members of this family, but the BK Ca^{2+} and voltage-dependent channels are members of a separate family because of an extra TM domain and an extracellular N-terminus. Inward rectifiers, including

K_{ATP} and astrocyte leak channels, are members of the two TM domain, one P-domain family. The tandem pore (or TWIK) family of K^+ channels has TM regions and two P-domains.

FIGURE 1.5–8. The diagrams show the schematized structure of receptor subunits for several neurotransmitters, including a $GABA_A$ receptor (member of the cys-loop family; heteropentameric functional receptor structure), an ion-channel–linked glutamate receptor (tetrameric structure), a channel gated by extracellular ATP (P2X; trimer) and a G-protein–coupled receptor (GPCR; often dimers). The ligand-binding domains of the subunits are depicted by the circles in the extracellular regions.

Other toxins from the buttercup family (aconitine), the lily family (veratridine), and frogs used for arrow poisons in South America (batrachotoxin) promote the direct opening of Na^+ channels and prolong the duration that channels stay open. The net effect is similar to the scorpion toxins. Certain local anesthetic drugs, including lidocaine and procaine, block Na^+ channels by binding to sites within the hydrophobic regions of the ion channel. The blockade of Na^+ channels contributes to local anesthetic effects and to antiarrhythmic effects in the heart. Certain clinically important anticonvulsants (carbamazepine, lamotrigine, phenytoin, riluzole) bind a site similar to that bound by procaine and have become important psychotherapeutic agents. All blockers described above, with the exceptions of TTX and STX, block Na^+ channels in a USE-DEPENDENT manner. That is, the drugs become more effective as cells become more depolarized. Mechanistically, this may be achieved by drugs stabilizing an inactivated state (conformation) of the channel, resulting in a clinically beneficial situation in which normal activity is relatively spared but abnormal excitation is blocked. Further clinical benefit from these drugs may result from their ability to dampen excitatory synaptic transmission selectively while sparing inhibitory transmission by mechanisms not fully understood. It is important to emphasize that not all Na^+ channels in neurons are sensitive to all of the above agents. For example, TTX-insensitive Na^+ channels exist in some excitable cells and play a prominent role in certain nociceptive neurons.

Potassium (K^+) Channels

K^+ channels are the most diverse family of ion channels and determine the resting and firing properties of neurons. At least 75 different K^+ channels are expressed in various cells. Among these are 40 mammalian genes for voltage-activated K^+ channels grouped in 12 families according to their major (α) subunit (termed K_v1 to K_v12). The various families have distinct properties and structural motifs (see Fig. 1.5–7). These include six transmembrane domain/1 P-domain channels (classical depolarization-gated channels), inwardly rectifying channels with two transmembrane domains, two-pore channels with four transmembrane domains, and two-pore channels with eight transmembrane domains (found in invertebrates). A fifth class of K^+ channels is regulated by calcium and depolarization and are known as BK (for their big single-channel conductance); these channels are similar to six transmembrane domain channels but also have a seventh membrane-spanning domain (S0 region) and an extracellular amino terminus. Adding to the diversity, there is evidence for both homo- and heteromeric K^+ channels. There are also several auxiliary subunits (β_1 to β_3) that associate with the α-subunits in an α4β4 stoichiometry. The diversity of potassium channels is daunting, and molecular and structural differences among these channels have broad functional implications, including the pattern of membrane potential changes in response to input signals.

K^+ channels with six transmembrane domains are particularly important in neurons, with depolarization-gated channels representing a major subgroup. Voltage-gated K^+ channels have several subfamilies, K_V1 (sometimes called *Shaker* for the *Drosophila* gene), K_V2 (*Shab*) K_V3 (*Shal*), and K_V4 (*Shaw*), each with constituent subunits (e.g., $K_V1.1$ to 1.4). A functional channel is a tetramer of four subunits from the same subfamily. Specific domains in the amino-terminal regions are responsible for forming tetramers and regulate gating, inactivation, and interactions with accessory proteins.

A common structural motif among voltage-gated K^+ channels is the presence of six membrane-spanning domains (S1 to S6) with a re-entrant loop (P-domain) between S4 and S5. The re-entrant loops of the four subunits line the ion channel pore. Carbonyl groups in the P-domain interact with K^+ and determine ion selectivity. These interactions mimic the hydration shell for K^+, and no water molecules intervene between K^+ and the carbonyl groups, differing from ion selectivity in Na^+ channels. The specificity of the interactions within the channel pore imparts selectivity for K^+ over other ions, and high-efficacy channel permeation involves electrostatic ion–ion repulsions of adjacent K^+. A re-entrant P-loop is common to all families of K^+ channels.

Voltage-gated K^+ channels help to define the spike shape and firing pattern of subtypes of neurons. The fast repolarization mediated by certain K^+ channels allows an increased rate of action potential firing that can then be used in frequency-dependent information coding (Fig. 1.5–9). Most neurons express multiple types of K^+ channels that differ in activation and inactivation kinetics, voltage dependence, and pharmacology. Because the equilibrium potential for K^+ is about −90 mV, the opening of K^+ channels results in K^+ efflux, membrane hyperpolarization, and a decrease in excitability.

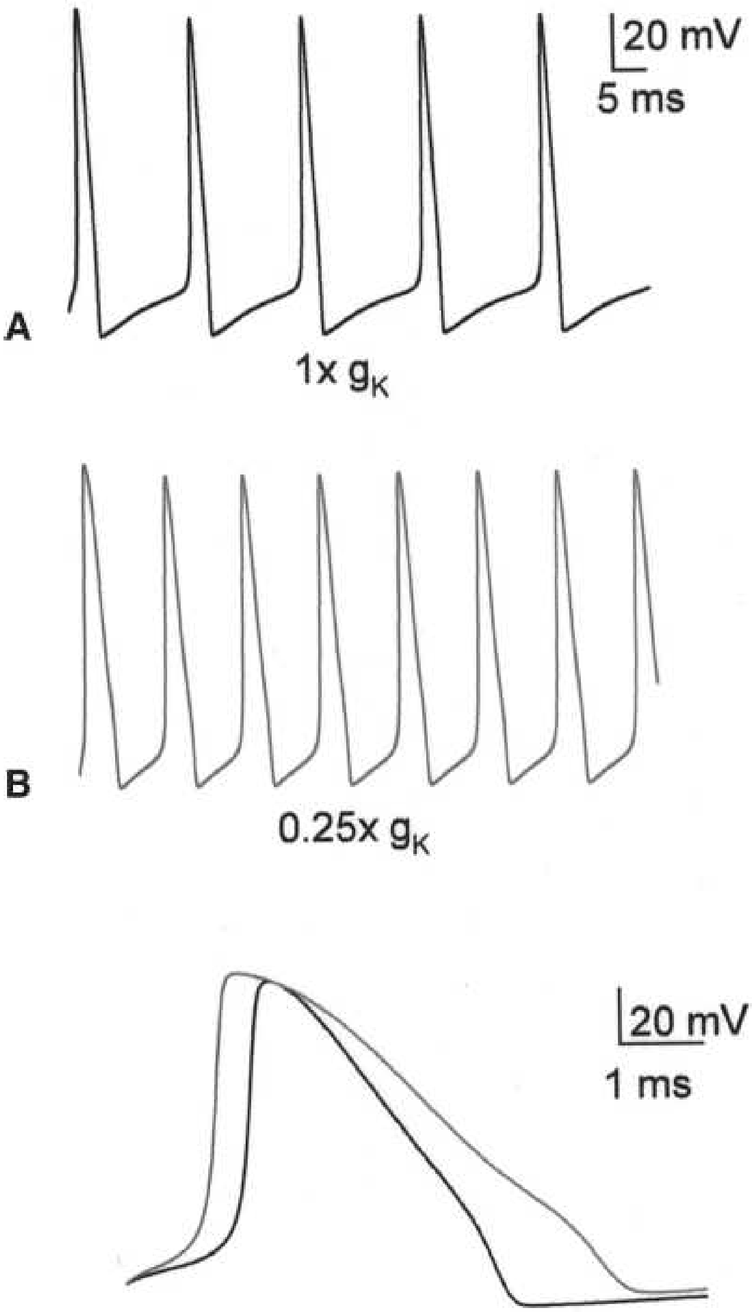

FIGURE 1.5–9. **A:** The traces show the effect of inhibiting K^+ channels involved in action potential repolarization. The traces were constructed using a simulation program that includes nongated leak channels and voltage-gated sodium and potassium channels similar to those described by Hodgkin and Huxley. The simulation includes a sustained depolarizing current injection of fixed amplitude to elicit spiking. The gray traces show the effect of reducing the delayed rectifier potassium conductance (g_K) to 25% of the initial baseline level (*black traces*). Note that with fewer voltage-gated potassium channels, the cell is hyperexcitable, exhibiting more action potentials to the same depolarizing input. **B:** The bottom panel shows the first 7 ms of the

simulations superimposed. Following K^+ channel block, individual action potentials are broadened and show a diminished undershoot.

The first K^+ channel identified physiologically was called a DELAYED RECTIFIER. These channels were predicted in the experiments of Hodgkin and Huxley on squid giant axons and were so named because their currents activate more slowly than the Na^+ channels that produce the upstroke of the action potential; channel opening is “delayed” relative to Na^+ channel opening. A “rectifier” (diode) is an electrical device that passes current better at certain voltages than at others; in other words, conductance varies with voltage. The K^+ current is a rectifier because the channel is more effective in allowing K^+ ions to exit than to enter the cell by virtue of depolarization opening the channels. Delayed rectifier channels show little inactivation during prolonged depolarization. These channels help to determine the frequency with which neurons fire action potentials in response to sustained depolarization. For instance, “fast-spiking” interneurons of the hippocampus and cortex possess a rapidly activating and deactivating delayed rectifier channel encoded by Kv3 family members. These channels are largely responsible for the narrow spike and brief refractory period of this interneuron class. Structurally, delayed rectifiers are members of the six transmembrane K^+ channel subfamily.

Experiments in squid axons indicated that delayed rectifiers were the primary K^+ channels involved in action potential repolarization. In mammalian neurons, the situation is more complex, with additional K^+ channels contributing significantly. These include two classes of CALCIUM-ACTIVATED K^+ CHANNELS that are opened by increases in intracellular Ca^{2+} (some are also opened by depolarization). These channels are important in action potential repolarization and in generating an AHP characteristic of some neurons. In cells that possess it, the AHP is responsible for the process of ACCOMMODATION (adaptation) that diminishes repetitive action potential firing during prolonged depolarization (see Fig. 1.5–9). The AHP has several temporal components that are mediated by big conductance (BK) and small conductance (SK) calcium-activated K^+ channels. BK channels mediate the fast component of the AHP and have a large single-channel conductance. BK channels belong to the SLO family of channels named for the *slowpoke* gene in *Drosophila* and include Ca^{2+}, Na^+, and H^+ sensitive K^+ channels. The large conductance of these channels results from a ring of negative charges in the inner and outer pore regions and a large inner pore. Some evidence suggests an association between a defect in the α-subunit of BK channels and autism with intellectual dysfunction. SK channels (SK1 to 3 in the CNS) are gated by intracellular Ca^{2+} but are voltage insensitive and contribute to the medium and slow components of the AHP. Some evidence has associated SK channel variants with schizophrenia and other psychotic disorders.

A-TYPE K^+ CHANNELS rapidly activate with depolarization to potentials positive to −60 mV and rapidly inactivate at depolarized potentials. A-channels help to regulate the interspike frequency with which neurons fire and contribute to action potential repolarization. They are important for frequency coding, the encoding of input strength in the firing frequency of a neuron. The *Shaker* A-channel from *Drosophila* was the first K^+ channel cloned.

M-CHANNELS are activated in a time- and voltage-dependent fashion and are inhibited by the neurotransmitter acetylcholine, acting at muscarinic receptors. These channels activate slowly and contribute little to action potential repolarization, but their activation at negative membrane potentials slows repetitive firing. In pyramidal neurons, M-channels are expressed in perisomatic regions where they regulate synaptic integration and adaptation to repetitive firing. M-currents arise from the heteromeric association of two members of the six transmembrane domain groups, *KCNQ2* and *KCNQ3* (members of the K_v7 subfamily), and possibly other KCNQ family members. Mutations in KCNQ subunits underlie benign familial neonatal convulsions (BFNC), deafness, and a form of cardiac long QT syndrome. The name of the subunits in this class of channels (KCNQ) derives from their role in long QT syndrome. Retigabine, an anticonvulsant, potently opens M-channels and slows their closing; studies in rodents suggest that agents of this type may have antidepressant activity.

In the sea snail *Aplysia californica*, K^+ channels that contribute to action potential repolarization are inhibited by the neurotransmitter serotonin and are called S-CHANNELS. S-channel activity is diminished during acute behavioral sensitization of the gill-withdrawal reflex in *Aplysia*, and studies of the role of these channels in synaptic function provided important insights into the cellular basis of certain forms of learning and memory.

Some K^+ channels (K_{ir} family) are opened by hyperpolarization instead of depolarization and are called INWARD RECTIFIERS (anomalous rectifiers) because they allow K^+ to more easily enter than exit the cell and strongly rectify near the equilibrium potential for K^+. The primary mechanism underlying this rectification is channel block by positively charged intracellular magnesium or polyamines. This channel block is relieved by K^+ influx through the channel, accounting for rectification that follows the K^+ equilibrium potential. Despite their inward rectification, the physiologic importance of these channels for neurons likely lies in passing small outward (hyperpolarizing) currents because neurons are rarely hyperpolarized beyond the K^+ equilibrium potential. Inward rectifiers are members of the two transmembrane domain groups of K^+ channels; this class has a single pore region and lacks a voltage sensor (see Fig. 1.5–7).

Brain astrocytes express inwardly rectifying K^+ channels of the $K_{ir}4$ and possibly $K_{ir}2$ subfamily that help to buffer extracellular increases in K^+ during neuronal activity. The expression of inward rectifiers in these cells helps to siphon K^+ away from axons and axon terminals where extracellular accumulation may occur. The unique properties of these channels favor the influx of K^+. Note that the influx of K^+ ions through these channels is caused by the change in equilibrium potential for K^+ rather than by channel opening. Transient conditions of elevated extracellular K^+ represent a rare situation in which the resting potential of surrounding astrocytes is more negative than the equilibrium potential for K^+.

Adding to the complexity of K^+ channels is the observation that certain neurotransmitters alter their function via GPCRs. For example, acetylcholine, acting via muscarinic receptors, inhibits several K^+ currents resulting in enhanced neuronal excitability. At different muscarinic receptors, acetylcholine activates inwardly, rectifying K^+ channels in multiple tissues, including the heart and brain. In the hippocampus and other brain regions, the neurotransmitters γ-aminobutyric acid (GABA), serotonin, and adenosine indirectly open inwardly, rectifying K^+ channels. These G-protein-regulated, inwardly rectifying channels (GIRKs) allow divergent synaptic inputs to exert regulatory influences over neuronal firing through a single class of ion channels.

In peripheral tissues and in some neurons, the $K_{ir}6$ subfamily of two transmembrane domain inward rectifiers is regulated by intracellular ATP (see Fig. 1.5–7). In the pancreas, K_{ATP} channels are a site of action of the hypoglycemic sulfonylurea drugs (tolbutamide and glibenclamide) that inhibit these channels and promote insulin release via membrane depolarization and calcium influx. Diazoxide, an antihypertensive drug that increases blood glucose levels, has opposite effects on pancreatic ATP-sensitive K^+ channels, opening the channels and diminishing insulin release. Sulfonylurea drugs do not interact directly with K_{ir} subunits of K_{ATP} channels but rather bind high-affinity sulfonylurea receptors (SURs) that combine with $K_{ir}6$ subunits in heteromeric complexes of four K_{ir} subunits and four SURs. K_{ATP} channels are also expressed in the CNS and regulate the release of certain neurotransmitters and perhaps determine neuronal responses to changes in intracellular energy levels. These channels are also expressed in mitochondrial membranes and may play a role in regulating apoptotic cell death.

HCN (hyperpolarization and cyclic nucleotide-gated) or H-CHANNELS are nonselective cationic channels structurally related to K^+ channels. These channels show high expression in certain neurons, including dopaminergic neurons of the substantia nigra and ventral tegmental area, cells implicated in motor behavior, arousal, attention, reward, motivation, and addiction. H-currents contribute to resting membrane potential and pacemaker firing and are expressed in dendrites of some pyramidal neurons, where they help to modulate synaptic inputs. HCN channels are similar to K_{ir} channels in that they activate at hyperpolarized voltages and close with depolarization. HCN channels differ in being permeable to both K^+ and Na^+, providing a depolarizing current at membrane potentials near rest. H-channels help stabilize neuronal membrane potentials, resisting changes that depolarize or hyperpolarize the cell. The anticonvulsant and mood stabilizer, lamotrigine, activates dendritic H-channels in pyramidal neurons as one of its potential mechanisms of action, and the dissociative anesthetic and antidepressant, ketamine, blocks these channels at concentrations relevant to some of its clinical effects. HCN channels differ structurally from K_{ir} channels but are similar to other voltage-activated channels with six membrane-spanning regions, an S4 voltage sensor, and a re-entrant P-loop. H-channels have an intracellular cyclic nucleotide-binding domain near their carboxy-terminus, and the binding of cyclic AMP shifts the voltage range for channel gating.

The K^+ channels described above have either two or six membrane-spanning regions and a single P-loop. Another class has four membrane-spanning regions and two P-domains (see Fig. 1.5–7). These TANDEM

PORE (K_{2P}) channels are widely expressed in the brain and periphery, and serve, at least in part, as leak conductances that help to establish the resting membrane potential. These subunits form functional dimers, and 18 members of this family have been identified. K_{2P} channels vary in electrical properties and sensitivity to activating stimuli (e.g., neurotransmitters, second messengers, arachidonic acid, acid, heat, stretch). The functional channels have a variety of names based on TWIK (tandem pore weak inward rectifying K^+) channels that were the first cloned. For example, TWIK-related arachidonic acid-sensitive K^+ channels are called TRAAKs, while acid-sensitive channels are called TASKs. Channels of this class are activated by certain volatile anesthetics and anticonvulsants (riluzole).

As noted, members of the TWIK family are activated by a host of novel stimuli, including acidic pH, heat, and mechanical activity. Another class of channels, called ASICs (acid-sensing ion channels), is also responsive to these stimuli. ASICs have two membrane-spanning domains with an apparent re-entrant loop between domains. At least nine mammalian family members falling into five subfamilies have been identified. Unlike TWIKs, ASICs are voltage-insensitive nonselective cationic channels that are more permeable to Na^+ than to K^+ and least permeable to Ca^{2+}. ASICs appear to form functional trimers and participate in peripheral sensory processing, including touch, heat, taste, and pain, and also contribute to certain forms of long-term synaptic plasticity in the hippocampus and amygdala, where they are involved in fear-associated learning.

Calcium (Ca^{2+}) Channels

The divalent cation, Ca^{2+}, is a critical contributor to cellular function, serving as both a regulator of intracellular chemistry (enzyme activity, metabolism, transmitter release) and an electrical signal for membrane depolarization. In some neurons, Ca^{2+} influx can drive action potentials (“calcium spikes”). However, excessive and prolonged increases in intracellular Ca^{2+} contribute to neurodegeneration. Under some conditions, prolonged deficiency of Ca^{2+} influx may also result in neuronal death, particularly in developing neurons. Thus, regulation of intracellular Ca^{2+} levels is vital to cellular function and survival.

Voltage-activated Ca^{2+} channels provide a major source of the Ca^{2+} that regulates cellular function and, in conjunction with Ca^{2+}-permeable ligand-gated ion channels (e.g., N-methyl-D-aspartate [NMDA]-type glutamate receptors and neuronal nicotinic acetylcholine receptors), represent major conduits for Ca^{2+} entry from the extracellular environment. Neurons express multiple classes of voltage-gated Ca^{2+} channels that are classified according to biophysical and pharmacologic properties. LOW-VOLTAGE–ACTIVATED (LVA, Ca_v3) Ca^{2+} CHANNELS are activated by relatively small depolarizations over the range of −80 to −50 mV. LVA channels inactivate rapidly and are largely insensitive to dihydropyridine Ca^{2+} channel blockers, such as nifedipine and nimodipine. LVA channels are also called T-TYPE Ca^{2+} CHANNELS because of their "transient" (inactivating) currents. Because LVA Ca^{2+} channels are activated at membrane potentials near rest, these channels contribute to burst firing and oscillatory neuronal activity. Oscillatory firing helps to drive coordinated movements and maintain complex behavioral states such as wakefulness. LVA channels are also expressed in neuronal dendrites and contribute to synaptic integration and spike-timing–dependent forms of synaptic plasticity. With a few exceptions, LVA channels do not participate in neurotransmitter release at axon terminals. LVA channels may be a target for the actions of some antipsychotic drugs, and the diphenylbutylpiperidines, pimozide, and penfluridol inhibit LVA channels at concentrations similar to those affecting D2 dopamine receptors. Other antipsychotics also inhibit LVA channels but do so at concentrations above those required at dopamine receptors.

HIGH-VOLTAGE–ACTIVATED Ca^{2+} CHANNELS (HVA, Ca_v1, and Ca_v2 family members) are activated by membrane depolarizations positive to −50 mV. In many neurons, even when voltage-gated Na^+ channels are blocked, HVA channels can produce regenerative spikes. These calcium spikes are slower in onset and longer in duration than Na^+ spikes, reflecting the slower kinetics of HVA channels.

HVA channels are heterogeneous with several major subtypes. L-TYPE Ca^{2+} CHANNELS (Ca_v1 family; named for their "long-lasting" responses) show slow inactivation during sustained depolarizations and are sensitive to block by dihydropyridines. L-type channels provide sufficient Ca^{2+} influx during action potentials to activate Ca^{2+}-dependent second messengers and gene expression. N-TYPE Ca^{2+} CHANNELS ($Ca_v2.2$ named because they were "neither" L- nor T-type) are HVA channels that regulate neurotransmitter release from some presynaptic terminals, particularly those of sensory neurons in the retina and inner ear. N-type channels are blocked irreversibly by ω-conotoxin GVIA, poison from the snail, *Conus geographicus*. Another conotoxin, ω-conotoxin MVIIA (Prialt), is a reversible N-channel blocker that is used to treat chronic pain. P/Q-TYPE CHANNELS ($Ca_v2.1$) are the third class of HVA channels and are named because of their presence in Purkinje cells of the cerebellum and pyramidal neurons of the hippocampus and cortex. P/Q-channels are insensitive to dihydropyridines and ω-conotoxin GVIA but are blocked by ω-Aga-IVA, a toxin from the funnel-web spider, *Agelenopsis aperta.* P/Q-channels, like N-channels, regulate the release of neurotransmitters in the CNS. N- and P/Q-type channels have an intracellular loop between channel domains II and III that binds certain presynaptic proteins, including syntaxin 1, Rim, and synaptotagmin 1. This site is referred to as a "synprint" region and plays a role in allowing synaptic proteins to modulate channel function.

R-TYPE CHANNELS ($Ca_v2.3$) also contribute to CNS function, but their actions are less well understood. R-type channels are resistant to the Ca^{2+} channel antagonists described above but are inhibited by SNX-482, a toxin derived from the African tarantula, *Hysterocrates gigas*. Although their presynaptic role is not as prominent as N- and P/Q-channels, R-channels participate in transmitter release at fast excitatory synapses in the CNS.

Skeletal muscle HVA Ca^{2+} channels were the first of these channels cloned and serve as a model for understanding the structure of other voltage-gated Ca^{2+} channels. These channels are involved in excitation–contraction coupling at neuromuscular junctions and consist of five distinct subunits, α1 (165 to 195 kDa), α2 (~150 kDa), δ (17 to 25 kDa), β (50 to 60 kDa), and γ (25 to 35 kDa) arranged in a 1:1:1:1:1 stoichiometry. The δ-subunit is produced by cleavage of α2/δ peptides while the other subunits are encoded by separate genes. α1-Subunits have about 30% sequence homology to voltage-gated Na^+ channels and form the ion channel pore. A recurring theme in α1-subunits is the existence of four homologous internal repeats that each contain six membrane-spanning regions and a pore-forming P-loop (see Figs. 1.5–5 and 1.5–6). The skeletal muscle HVA α1-subunit contains the dihydropyridine binding site. Point mutations in the α1-subunit of skeletal muscle T-tubule Ca^{2+} channels ($Ca_v1.1$) and the skeletal muscle Na^+ channel ($Na_v1.4$) cause the human disorder, hypokalemic periodic paralysis. The critical mutations occur in the S4 region of the channel involved in voltage sensing and result in a gain of function current that is open at rest and results in membrane depolarization and potential action failure; similar pore mutations may occur in other channelopathies. The functions of the β (β_{1-4}) and γ (γ_{1-8}) subunits are less certain but appear to regulate membrane expression and trafficking of α1-subunits. Loss of the γ2-subunit (*stargazin*) in the stargazer mouse markedly diminishes cell surface expression of certain glutamate receptors. The importance of auxiliary subunits in the function of Ca^{2+} channels is highlighted by evidence that analgesic effects of the anticonvulsants gabapentin and pregabalin involve binding to specific residues in α_2–δ_1-subunits.

Ten different α1 genes have been identified. These include four different α1 subtypes contributing to L-type channels (Ca_v1.1, 1.2, 1.3, 1.4), three α1 genes contributing to P/Q-, N-, and R-type channels (Ca_v2.1, 2.2, 2.3), and three variants of T-type Ca^{2+} channels (Ca_v3.1, 3.2, 3.3). Adding to this complexity, human genes typically go by other names. For example, the skeletal muscle L-type channel Ca_v 1.1 is referred to as α1S and CACNA1S; other human calcium channel genes are named accordingly. The importance of calcium channels to neuropsychiatric disorders is highlighted by the finding that mutations in the human CACNA1A gene encoding the α1-subunit of P/Q calcium channels are associated with familial hemiplegic migraine.

An important question concerns how channels establish selectivity for one ion over another. At one level, ionic charge and charged amino acid residues in ion channel proteins help select cations over anions. It is a more difficult problem for channels to select among different cations. In Ca^{2+} channels, this is particularly vexing because hydrated Ca^{2+} ions are significantly larger than Na^+ or K^+ ions. Thus, the size of the channel pore cannot determine selectivity for Ca^{2+}. Rather, selectivity in Ca^{2+} channels involves high-affinity binding of divalent cations within the channel. When Ca^{2+} is present, its binding within the pore excludes monovalent cations, rendering the channels selective for Ca^{2+}. As might be expected, when Ca^{2+} is not present, these channels will pass monovalent cations. This principle of ions binding to specific sites within a channel to regulate permeability and gating is a recurring theme that can sometimes be exploited for the development of drugs that modulate channel function.

In some regions of the CNS, particularly retinal photoreceptors and olfactory epithelial cells, intracellular cyclic nucleotides (e.g., cyclic AMP and cyclic GMP) gate specific classes of ion channels. These cyclic nucleotide-gated (CNG) channels have structural features similar to voltage-gated channels, including the presence of six transmembrane regions and a P-loop that lines the channel. CNG channels also have an S4-like voltage-sensing region, although these channels are not regulated by voltage. CNG channels are nonselectively permeable to cations. Like voltage-gated calcium channels, they bind divalent cations in the external pore region as a means of restricting the flow of monovalent cations, thereby selecting Ca^{2+} permeation over Na^+. CNG channels have structural similarities to HCN channels but have higher calcium permeability. Mutations in retinal photoreceptor CNG channels contribute to color blindness in humans.

The TRP SUPERFAMILY represents another class of cationic channels with six membrane-spanning regions and high calcium permeability. This family contains more than 25 members in at least seven subfamilies (TRPC, TRPV, TRPM, TRPML, TRPP, TRPA, and TRPN) that participate in multiple processes in the nervous system and in nonexcitable cells, ranging from sensory processing to vascular and cell cycle control. TRP channels are named for the first member to be identified, the *trp* (transient receptor potential) gene in *Drosophila*, and are linked to human disorders including polycystic kidney disease and mucolipidosis, a neurodegenerative illness. TRP channels are regulated by intracellular and extracellular signals, including changes in pH, temperature, capsaicin (the active ingredient in hot peppers), and anandamide (an endogenous ligand for cannabinoid receptors). Endogenous lipid mediators like the endocannabinoid anandamide are important regulators of the TRPC/VM subfamilies. TRPC1 and TRPC4 also contribute to “store-operated” channels that mediate extracellular calcium influx following calcium release from intracellular stores.

Chloride (Cl^-) Channels

In most neurons, Cl^- is present at higher concentrations outside than inside cells, and the equilibrium potential for Cl^- is near the resting membrane potential. Thus, the opening of Cl^- channels tends to maintain the membrane potential near rest and, in conjunction with K^+ channels, serves as a mechanism to dampen neuronal excitability. Some Cl^- channels also conduct bicarbonate, another physiologic anion. Cl^- channels contribute to the resting membrane potential in certain neurons and muscle cells. These channels spontaneously open at resting membrane potentials and exhibit weak voltage dependence. In muscle fibers, the background Cl^- conductance is the largest resting conductance and the transmembrane distribution of Cl^- is near equilibrium. There are three main families of Cl^- channels, voltage-gated Cl^- channels (ClCs), the cystic fibrosis (CF) transmembrane conductance regulator (CFTR), and ligand-gated Cl^- channels. The ClC family includes nine different channels that have 10 or 12 membrane-spanning regions and no defined S4 voltage-sensing region as in voltage-gated cation channels. Crystallographic studies indicate that ClC channels are double-barreled homodimers, with each subunit containing its own pore. In the human illness, myotonia congenita, an abnormality of a muscle Cl^- channel (ClC-1) results in abnormally low Cl^- conductance leading to increased muscular excitability and fatigue with exercise.

There are at least five activating stimuli for Cl^- channels. These include changes in membrane voltage (depolarization or hyperpolarization), increases in intracellular Ca^{2+}, ligand binding (usually GABA or glycine), cellular swelling, and phosphorylation by cyclic-AMP–dependent protein kinase (PKA). Ca^{2+}-activated Cl^- channels may help to determine the interspike firing frequency of neurons, while swelling-activated channels help to protect cells from damage during osmotic stress. These channels are pentamers with a single ion pore and a hydrophobic neck that forms the channel gate controlling ion flow. Ca^{2+} binds to a large cytosolic region of the protein to regulate channel opening. Cl^- channels also serve important functions in secretory cells, providing a major source of Cl^- in tears, sweat, and digestive juices. A defect in CFTR secretory Cl^- channels that renders the channels insensitive to activating stimuli is involved in CF. CFTR has a structure that differs from the ClC family and belongs to a larger family of ATP-binding cassette (ABC) proteins that require phosphorylation by protein kinase A and hydrolysis of ATP for activation. CFTR is the only member of the ABC family that also serves as a Cl^- channel. CFTR has two repeats with six membrane-spanning regions (12 transmembrane regions in total), a nucleotide-binding domain, and a regulatory domain. Drugs that combine agents that promote trafficking of CFTR to the cell surface with agents that enhance CFTR function have been approved for the treatment of patients with an F508 (phenylalanine) deletion that is the most common cause of CF. These agents are a major step forward for CF patients and a proof of concept for the ability to modulate defective ion channels for therapeutic purposes.

Mitochondrial membranes express unique voltage-dependent anion channels (VDACs) that pass negatively charged ions and have unusual gating properties, being open at potentials near 0 mV and closing with voltage changes in either direction. VDACs (or PORINS) participate in releasing metabolites from mitochondria and are components of the mitochondrial permeability transition pore (PTP) that regulates apoptotic cell death. PTP is a multiprotein complex that includes adenine nucleotide translocase, hexokinase, cyclophilin D, and a VDAC. PTP activity is regulated by mitochondrial benzodiazepine receptors (now called translocator protein 18 kDa, TSPO). VDACs may also be expressed in plasma membranes and may be complex with some neurotransmitter receptors, although the function of plasma membrane VDACs remains uncertain. Three VDACs (VDAC 1 to 3) have been identified and are β-sheet proteins that differ from the α-helical configuration of most ion channels.

NEUROTRANSMITTERS AND ION CHANNELS

Classes of Neurotransmitters

Most information transfer between neurons occurs via chemical synapses. These connections use a wide array of chemical messengers (NEUROTRANSMITTERS) that are released in a Ca^{2+}-dependent fashion from presynaptic terminals and act on specific membrane proteins (RECEPTORS) to produce biochemical and excitability changes. There are two primary groups of neurotransmitters—low-molecular-weight amines and neuroactive peptides. These agents act on two classes of receptors, ligand-gated ion channels, at which binding of the transmitter directly opens an ion channel, and GPCRs, where an activated G-protein modulates ion channels or alters biochemical SECOND MESSENGER SYSTEMS. Synaptic transmission can also be classified according to the speed of transmission (fast or slow) and according to the excitability change (excitatory or inhibitory). FAST transmission occurs on a time scale of up to several 100 milliseconds and is mediated primarily by amine neurotransmitters acting at ligand-gated ion channels. SLOW synaptic communication occurs on a scale of seconds to minutes or longer, usually through the actions of amine or peptide transmitters acting on GPCRs.

The specific ion channels involved and the electrochemical gradients of the permeant ions determine whether effects are EXCITATORY (depolarizing) or INHIBITORY (hyperpolarizing). Moreover, an excitatory synaptic input can exert a net inhibitory influence on regional excitability and vice versa. For example, the release of an excitatory neurotransmitter onto an inhibitory neuron can stimulate the inhibitory neuron and dampen the activity of a local network. Conversely, inhibition of inhibitory neurons (disinhibition) can enhance regional excitability.

There are at least nine low-molecular-weight amines that serve as neurotransmitters. These include GLUTAMATE, the major fast excitatory transmitter in the mammalian brain, ACETYLCHOLINE, the excitatory transmitter at the vertebrate neuromuscular junction, GABA, and GLYCINE, the major fast inhibitory transmitters in the brain and spinal cord, respectively, and the biogenic amines, DOPAMINE, NOREPINEPHRINE, EPINEPHRINE, SEROTONIN, and HISTAMINE. Purines, ADENOSINE, AND ATP can also act as transmitters. A large number of NEUROACTIVE PEPTIDES modulate neuronal excitability. It is uncertain, however, whether all of these substances function as bona fide neurotransmitters. Many peptides, including vasopressin and cholecystokinin, were first identified as hormones in the vasculature and gut. ATP and certain neuroactive peptides coexist with amine neurotransmitters in some nerve terminals and can be co-released. Thus interactions between classes of neurotransmitters may determine the ultimate effects of a presynaptic neuron on its postsynaptic target.

Conductance Mechanisms Underlying Neurotransmitter Actions

Neurotransmitter actions can also be described by effects on membrane conductances. Transmitters that act at ligand-gated ion channels increase the conductance of cell membranes (open channels) to specific ions. Excitatory transmitters, such as acetylcholine and glutamate, directly activate nonselective cation channels, increasing the flow of Na^+, K^+, and, in some cases, Ca^{2+}. Because of the mixed permeability of these channels, the reversal potential of currents generated by these channels is a weighted average of the equilibrium potentials of the individual permeant ions, typically near 0 mV. Thus, at membrane potentials negative to 0 mV, channel opening depolarizes (excites) the cell by allowing the inward flow of cations. If sufficient numbers of the channels open, they will drive the membrane potential toward 0 mV, exceeding the action potential threshold.

In contrast, the fast inhibitory transmitters, GABA and glycine, open ligand-gated channels permeable to Cl^-. Because Cl^- usually has an equilibrium potential near the resting membrane potential, the opening of these channels resists depolarization toward the spike threshold, decreasing (inhibiting) the likelihood of spike initiation and shunting excitatory influences. Note that the excitatory or inhibitory nature of transmitter actions is dictated by the electrochemical gradients of the permeant ions. Early in development, many neurons possess a sufficiently high intracellular Cl^- concentration that the Cl^- equilibrium potential is positive relative to the spike threshold, resulting in excitatory effects of GABA and glycine. With maturation and changes in the expression of specific Cl^- transporters, intracellular Cl^- levels diminish, and GABA and glycine become inhibitory transmitters. There are pathologic conditions, including behavioral stress, that alter the expression of Cl^- transporters. Under these conditions, GABA (and Cl^- channel opening in general) becomes excitatory. This is thought to contribute to the epileptogenesis associated with human brain tumors.

A second group of transmitters indirectly increases membrane conductance through G-proteins. For example, GABA, serotonin, and adenosine, by binding GPCRs, promote G-protein–mediated opening of inwardly rectifying K^+ channels (GIRKs). A third set of transmitter actions involves indirect effects on voltage-gated or leakage ion channels. These transmitters typically decrease membrane conductance by activating chemical second messenger systems via GPCRs. Certain voltage-gated K^+ and Ca^{2+} channels are specific targets of this inhibition, resulting in cellular excitation or inhibition, respectively. Most transmitters that act on GPCRs exert at least some of their effects by these decreased conductance mechanisms. The electrical principles underlying synaptic excitation or inhibition are identical to those described for other ion channels and are based on the relative permeabilities of the ion channels and the equilibrium potentials of the ions involved.

Several transmitters (e.g., GABA, glutamate, acetylcholine, and serotonin) act at both ligand-gated ion channels and GPCRs. Thus, receptors for these neurotransmitters and their effects are heterogeneous, with the nature of the effect depending on the specific receptor to which the transmitter binds. Receptors for most neurotransmitters are structurally varied, with multiple receptor subtypes being the rule rather than the exception. Further variability arises from RNA splicing differences and posttranslational modifications of receptor function. Thus, at the receptor level, there is tremendous flexibility in determining the effects of a neurotransmitter on a single neuron or on a set of neurons.

Structure of Neurotransmitter Receptors

Most transmitter-gated ion channels are multimeric proteins consisting of several (usually four or five) subunits that have multiple (two to five) membrane-spanning regions (see Fig. 1.5–8). Functional receptors typically have large amino-terminal regions that extend into the aqueous extracellular environment and participate in neurotransmitter binding. Intracellular regions of the receptor often contain sites at which phosphate groups can be attached. Phosphorylation is a mechanism by which second messenger systems modulate receptor and ion channel function. Many receptors are multiprotein complexes in which the receptor subunits that comprise the ion channel pore are in physical proximity with intracellular proteins (in some cases, 100 or more intracellular proteins). The intracellular proteins regulate receptor trafficking and expression as well as ion channel function and participation in intracellular signaling processes.

The neuromuscular nicotinic acetylcholine receptor was the first transmitter-gated channel to be purified and cloned, and five neuromuscular nicotinic receptor subunits have been identified. Each of these subunits has four membrane-spanning regions, and a pair of cysteine residues located 13 amino acids apart in the extracellular region of the protein (see Fig. 1.5–8). These cysteine residues form a disulfide bridge that contributes to transmitter binding. The nicotinic ion channel is a nonselective cation channel permeable to Na^+, K^+, and Ca^{2+}. Membrane-spanning regions form the ion channel, with the second transmembrane region lining the channel pore. Muscle nicotinic subunits assemble to form a pentamer with a stoichiometry of $\alpha 2$, β, δ, and γ or ε depending on the age of the animal. Nicotinic receptors are part of a superfamily that includes $GABA_A$, glycine, and serotonin type 3 (5HT-3) receptors. $GABA_A$ and glycine receptors are anion selective, passing primarily Cl^- in physiologic solutions, whereas nicotinic and 5HT-3 receptors are cation selective. Because all members of the family contain the characteristic extracellular cysteine residues, the family is referred to as the CYS-LOOP family. Differences in charges on amino acids at the entrance to the channel pore determine whether the channel passes cations or anions. A crystal structure of a human homomeric β3 $GABA_A$ receptor shows the GABA channel to have a cylindrical structure about 110 Å high and 60 to 80 Å wide, extending 65 Å into the extracellular space. A positively charged ring of amino acids halfway down the channel allows anion binding and determines ion selectivity. A closed gate at the base of the pore provides a mechanism for desensitization. Cryo-EM and crystallization studies continue to reveal nuances of structure–function relationships in these receptors.

Ligand-gated ion channels gated by extracellular ATP (P2X receptors) have structures somewhat similar to inwardly rectifying K^+ channels (see Figs. 1.5–7 and 1.5–8). ATP receptors have two membrane-spanning regions and a pore-forming region (P-loop) connected by a large loop of extracellular amino acids. A major difference between P2X receptors and inwardly rectifying K^+ channels is that P2X receptors are mostly extracellular, whereas the bulk of the K^+ channel is intracellular. P2X channels are cation selective and have high Ca^{2+} permeability. These receptors participate in fast excitatory synaptic transmission in certain regions of the CNS, including the thalamus. Native ATP receptors may consist of combinations of P2X subunits.

Ionotropic glutamate receptors differ from cys-loop receptors in having three membrane-spanning regions and a re-entrant P-loop between the first and second transmembrane regions that does not completely cross the membrane (see Fig. 1.5–8). The P-loops in glutamate-gated channels, like those in voltage-gated ion channels, line the ion channel. A difference from voltage-gated channels is that glutamate receptor P-loops enter the membrane from the cytoplasmic side. Crystallographic data on AMPA-type glutamate receptors indicate that these channels contain four subunits, each of which binds a glutamate molecule. Subunits form a dimer of dimers, and the receptor resembles a letter “Y” when viewed perpendicular to the membrane. The glutamate binding region has a hinged cleft resembling a venus flytrap. When agonists bind, the cleft closes to varying degrees depending on the ligand. This imparts structural changes necessary for ion channel opening. Competitive antagonists that block glutamate binding stabilize the open cleft configuration of the binding pocket, providing an explanation for how an agent can bind to the agonist recognition site but not produce the conformational changes that cause channel opening. A crystal structure for heterotetrameric GluN1-GluN2B NMDA receptors reveals differences from AMPA receptors with a more tightly packed amino-terminal domain and ligand-binding domain, possibly explaining why the amino terminus more effectively regulates ion channel activity in these receptors. In contrast to the Y-like shape of AMPA receptors, NMDA receptors resemble a hot-air balloon with an extracellular "balloon" and a transmembrane "basket." Further complicating the picture, it appears that the majority of NMDA receptors have a triheteromeric structure with GluN1 subunits in combination with two different GluN2 subunits. All glutamate receptors share a highly conserved motif that regulates channel gating despite major differences in how gating occurs in different receptor subtypes and modulation of gating by pharmacologic agents. There are also a variety of genetic mutations that alter the gating of glutamate receptors and result in complex neuropsychiatric illnesses.

GPCRs have structures that differ completely from ligand-gated ion channels. These receptors have seven membrane-spanning regions (see Fig. 1.5–8), and many GPCRs exist as homo- or heterodimers. Transmitter binding occurs in a pocket formed by the intramembranous domains of the receptor, except for the glutamate family of GPCRs, where binding is in a large extracellular amino-terminal region. The coupling of GPCRs to their G-protein occurs at intracellular loops of the receptor. Adding to the complexity of signaling, the binding of certain neurotransmitters to receptors that are ligand-gated ion channels can also trigger intracellular effects akin to GPCRs in the absence of ion flux through the channels. Examples of metabotropic effects via ligand-gated channels include glutamate acting at NMDA and kainate receptors.

CLINICAL ASPECTS OF ION CHANNELS

Rapid signal processing in the brain requires action potential firing and fast neurotransmission and hence depends critically upon the activity of ion channels. In this final section, we highlight some areas where understanding the function and mechanisms of ion channels is particularly important for psychiatry.

Oscillatory Neuronal Firing and Complex Behavioral States

Complex behavioral states, including wakefulness, attention, mood, and sleep, require a coherent activity within and between neural circuits. Neuronal networks show rhythmic activity (oscillations) over a wide range of frequencies from less than 1 to several 100 cycles/s (Hz). These oscillations provide energy-efficient mechanisms that determine optimal input and output frequencies of brain regions and provide coherence in functional networks. Activity in oscillating circuits involves the interplay of intrinsic electrical properties of neurons, the local balance of excitatory and inhibitory inputs (E/I balance), and sustained effects of more diffusely acting neuromodulator systems, including muscarinic and monoaminergic systems. Certain neurons express voltage-gated conductances that allow them to fire rhythmically and spontaneously, thus having properties of a PACEMAKER or OSCILLATOR. For example, cerebellar inferior olivary neurons fire action potentials spontaneously and sustain this firing for relatively long periods in the absence of external inputs. These neurons fire conventional fast Na^+ spikes that provide the depolarization needed to open HVA Ca^{2+} channels. In turn, Ca^{2+} influx activates a Ca^{2+}-dependent K^+ conductance that rapidly hyperpolarizes the membrane. When the membrane hyperpolarizes, LVA Ca^{2+} channels open and depolarize the membrane potential to the threshold for firing Na^+ spikes, which then activates another cycle. In inferior olivary neurons, it is the properties of the LVA Ca^{2+} channels that foster oscillatory firing. LVA channels are inactivated at the neuronal resting membrane potential but become activatable when the membrane is hyperpolarized to rest. Thus, hyperpolarization becomes a priming stimulus that promotes LVA channel opening. Pacemaker firing of inferior olivary neurons drives Purkinje neurons in the cerebellum to RESONATE at the inferior olivary neuron's preferred firing frequency. This resonating circuit contributes to the physiologic resting tremor that oscillates at about 10 cycles/s.

In thalamocortical neurons, network oscillations are driven by intrinsic pacemaker conductances in coordination with synaptic connections. This activity drives EEG changes during different stages of sleep and vigilance. Thalamocortical neurons exhibit two distinct activity states. During sleep, neurons show synchronized rhythms that resemble δ (1- to 3-Hz activity) and other slow waves on the EEG. During wakefulness and rapid eye movement (REM) sleep, these neurons exhibit tonic activity. LVA calcium channels are important contributors to thalamocortical network activity. The transition from sleep to wakefulness is mediated by the depolarization of thalamic reticular neurons and the inactivation of LVA channels. Specific abnormalities in thalamocortical neurons also contribute to the generation of 3 Hz spike and wave activity observed in childhood absence epilepsy. In spike-wave discharges, the interplay between LVA currents and H-currents appears to be critical in generating abnormal firing. Drugs targeting these channels (e.g., ethosuximide, an inhibitor of LVA channels, and lamotrigine, an activator of H-channels) are useful clinically. Mutations in Cav3.2 LVA channels have been associated with absence epilepsy.

In some brain regions, outputs of pacemaker cells are mediated by fast excitatory or inhibitory transmitters. However, some neurons can fire bursts of action potentials. BURSTS are periods of frequent spike firing followed by quiescent periods. This type of firing can drive activity in a local or distributed neural network and in the subiculum, contributing to synaptic plasticity via LVA Ca^{2+} channels. In addition, burst-like firing can provide sufficient intracellular Ca^{2+} to stimulate the release of peptide transmitters. In turn, the slow actions of certain neuropeptides can alter the frequency of oscillatory firing and bursting. An example of this is the repeated firing that occurs when spike frequency adaptation is inhibited by blocking Ca^{2+}-activated K^+ conductances. In this case, both the intrinsic electrical properties of neurons and the effect of modulatory transmitters conspire to determine a background level of activity (or tone) in specific neuronal systems.

There is considerable interest in understanding cellular, synaptic, and network mechanisms contributing to neuro-oscillations, and these mechanisms hold significant promise for translating observations in animals to human brain function and behavior. An example involves recent studies of behavioral dissociation induced by ketamine. Ketamine is an anesthetic, and ketamine-induced dissociation in rodents is associated with the generation of 1- to 3-Hz rhythms in layer 5 neurons of the retrosplenial cortex, an area important in circuits governing vigilance and conscious effort. These changes result from the effects of ketamine on HCN-1 pacemaker channels. Intriguingly, similar localized rhythms in the deep posteromedial cerebral cortex were observed in a patient who experienced dissociative symptoms prior to seizures, providing a proof of concept for extrapolation of the rodent studies to humans. Other studies have emphasized the increased power of γ-oscillations as a possible hallmark of ketamine’s antidepressant effects.

“E/I Balance” and Psychiatric Illnesses

While the pathophysiology of psychiatric disorders remains uncertain, there is increasing interest in determining whether shifts in relative regional excitation (E) and inhibition (I) (E/I BALANCE) contribute to psychiatric symptoms at a neural network level. According to this hypothesis, both synaptic and intrinsic excitability changes contribute to neurocircuitry abnormalities. In schizophrenia and autism, there appears to be augmented excitation relative to inhibition in certain brain regions, and this increased E/I ratio may account for abnormal hyperactivity in frontal and hippocampal circuits that underlie cognitive and social defects. The E/I balance hypothesis is consistent with functional neuroimaging findings and increases in high-frequency cortical oscillations recorded by electroencephalography (EEG) and magnetoencephalography (MEG). Changes in β- and γ-oscillations (activity above 20 Hz) are thought to contribute to defects in sensory processing and learning and inefficient information transfer within and between neural networks. Specific classes of inhibitory GABAergic interneurons play a critical role in regulating these high-frequency rhythms by influencing the firing frequency of excitatory glutamatergic (pyramidal) neurons.

There are few direct tests of the E/I balance hypothesis in humans, but studies in mouse models have provided tentative support. Studies using optogenetics employing cell type–specific expression of light-activated ion channels (e.g., channelrhodopsins) to depolarize specific neuronal types for prolonged periods have reproduced increases in high frequency (30- to 80-Hz) cortical γ-oscillations and some altered social behaviors akin to those observed in human illnesses. These electrical and behavioral changes are reversed by increasing the activity of specific GABAergic inhibitory interneurons that express the calcium-binding protein parvalbumin (PV). PV^+ interneurons are fast-spiking cells that serve as a model for understanding how the expression of specific classes of ion channels drives unique functions, allowing interneurons to regulate rhythmic activity within and across brain regions. Simulation studies provide further support for the E/I balance hypothesis and indicate that local feedback inhibition enhances information capacity and discrimination accuracy of more global and distributed networks. These studies suggest that E/I balance within specific brain regions helps to regulate regional spontaneous activity and information transfer across brain regions at large-scale levels.

While the E/I balance hypothesis is still under investigation, this concept has a significant influence on clinical neuroscience. Efforts to manipulate E/I balance and the plasticity of excitatory (glutamate) synapses are leading to novel ideas about the treatment of developmental neurocognitive disorders that have heretofore proven therapeutically intractable, including fragile X syndrome, Rett syndrome, and autism spectrum disorders, among others.

Ion Channels and Neuropsychiatric Disorders

There is increasing evidence that defects in ion channels (CHANNELOPATHIES) contribute to the pathophysiology of neuropsychiatric illnesses. Channelopathies involve the altered function of specific ion channels as a result of genetic mutations, transcriptional abnormalities, protein folding defects, or immune processes, and multiple ion channels have been implicated as causes of various syndromes.

Given the importance of ion channels in neuronal excitability, the observation that epilepsy, a group of disorders characterized by recurrent bouts of abnormal electrical activity, is associated with mutations in specific ion channels is not surprising. BFNC are associated with mutations in K^+ channel genes, *KCNQ2* and *KCNQ3*. These proteins (Kv7.2, 7.3) form M-channels that produce slowly activating and slowly inactivating K^+ currents that blunt neuronal firing. The expression of a single mutant allele of either gene—BFNC is a dominantly inherited disorder—decreases channel expression sufficiently to result in neuronal hyperexcitability. Generalized epilepsy with febrile seizures plus (GEFS+) is an autosomal dominant illness that results from mutations in Na^+ channel subunits. The role that ion channels play in these rare genetic syndromes suggests that idiopathic epilepsy might also reflect channelopathies and perhaps result from interactions between genetic defects in ion channels and adverse environmental exposures. An exome sequencing study examining more than 230 ion channel genes in sporadic idiopathic epilepsy, the most common neuronal excitability disorder, found rare missense variants in both epilepsy patients and unaffected individuals, including deleterious mutations in both groups. These results strongly suggest that ion channel genes confer illness risk, but illness expression depends on other factors. Identification of defective channel genes, nonetheless, offers an opportunity to improve clinical outcomes based on the potential for personalized treatments.

The calcium channel *CACNA1A* gene that encodes the α_1-subunit of HVA P/Q-type Ca^{2+} channels ($Ca_v2.1$) is associated with several rare genetic diseases. Familial hemiplegic migraine is an autosomal dominant illness with childhood onset and auras that include transient hemiparesis or hemiplegia. In some families, the disorder is associated with progressive ataxia. Familial hemiplegic migraine is genetically heterogeneous, with about 50% of cases involving mutations in *CACNA1A*; more than a dozen mutations are associated with illness risk. How the mutations cause, illness is not entirely clear because the most frequently identified mutation reduces Ca^{2+} currents, while another mutation increases Ca^{2+} flux. Episodic ataxia type 2 (EAT2) is another dominantly inherited disorder associated with mutations in *CACNA1A*. Patients with EAT2 experience episodes of nystagmus and ataxia; for some, the disorder is progressive and results in cerebellar atrophy, with about 50% of patients having migraine. Most mutations associated with EAT2 grossly disrupt protein expression, although several are point mutations that change only a single amino acid. Expression of the gene with one of the point mutations results in complete loss of function without a change in protein expression. Finally, a type of autosomal dominant spinocerebellar ataxia (SCA6) is linked to a mutation that causes expanded glutamine repeats in the carboxyl terminus of the $Ca_v2.1$ protein. The diverse syndromes associated with altered *CACNA1A* gene highlight the heterogeneity that is expected from the exploration of genes for psychiatric disorders.

Genetic studies indicate that certain pain syndromes are also channelopathies involving altered Na^+ channel function and expression. Mutations in the *SCN9A* gene on chromosome 2 that encodes $Na_v1.7$ are implicated in both paroxysmal extreme pain disorder (PEPD) and congenital inability to experience pain. In the case of PEPD, the causative mutations result in fast inactivation of the channel with a persisting tonic Na^+ current. In pain insensitivity disorder, the mutations result in loss of function. These syndromes are instructive not only from the perspective of ion channels and disease but also in guiding future work aimed at developing more specific pain therapies.

Some evidence indicates that mutations in ion channels also contribute to illnesses that present with psychiatric symptoms. For example, polymorphisms in SK calcium-activated K^+ channels are associated with certain forms of psychosis. A polymorphism in the *KCNH2* gene that encodes a K^+ channel is associated with schizophrenia and predicts lower intelligence and altered memory-related changes in functional neuroimaging. Other work suggests the involvement of BK channels in a form of autism and mental retardation, and mutations in T-type (LVA) calcium channels have been linked to autism. Similarly, a polymorphism in the α5 neuronal nicotinic acetylcholine receptor subunit is linked to nicotine dependence. This latter polymorphism is in a coding region of the protein in a position that influences ion channel kinetics. Large-scale studies have revealed genetic loci in schizophrenia that likely code several voltage-gated ion channels, including α1C- and β2-subunits of L-type (HVA) Ca^{2+} channels, Kv2.1 delayed rectifier K^+ channels, ClC-3 voltage-activated Cl^- channels and HCN1 channels, among others. These observations suggest that understanding how genetic and environmental factors influence membrane excitability will become increasingly important in psychiatry. Changes in ion channel function are likely to contribute to diagnosis, pathophysiology, and response to psychotropic medications, including predispositions to serious side effects, including cardiac arrhythmias.

Certain autoimmune disorders affecting ion channel expression and function can also result in complex neuropsychiatric syndromes, including new-onset psychosis, delirium, and seizures. Perhaps the best example is anti-NMDA receptor encephalitis (NMDARE), now thought to be the most common cause of autoimmune encephalopathy. In this disorder, patients develop antibodies against the NMDAR GluN1 subunit that result in receptor cross-linking and internalization, leading to NMDAR hypofunction and defects in synaptic plasticity. Defects in synaptic potentiation appear to contribute to defects in working memory observed in these patients. Most patients with NMDARE improve with immunotherapies, but some are left with residual and/or relapsing symptoms. Thus, there is interest in whether agents that enhance NMDAR ion channel function could be alternative treatment strategies; preclinical studies provide early proof of concept for the use of NMDAR-positive modulators. Autoantibodies have also been found against other receptors and ion channels, including AMPA-type glutamate receptors, certain GABA receptors, and voltage-activated ion channels.

Homeostatic Plasticity and Psychiatric Therapeutics

The brain is a remarkably plastic organ capable of learning, remembering, and adapting to complex environments. Much of this plasticity involves short- and longer-term, use-dependent changes in the function of synapses, although changes in neuronal excitability can also contribute. Learning is typically thought to involve experience-dependent synaptic changes that require coordinated pre- and postsynaptic activity (called "Hebbian" plasticity after Donald Hebb, who postulated the importance of these types of changes for learning). Hebbian plasticity includes long-term potentiation (LTP) and long-term depression (LTD), which result from coincidental activity of pre- and postsynaptic neurons and are typically triggered by activation of NMDA-type glutamate receptors. Defects in Hebbian plasticity are thought to contribute to defects in learning that occur in the context of stress and neuropsychiatric disorders.

Brain regions can also alter their function by non-Hebbian mechanisms in which neurons and networks adjust excitability in response to persistent increases or decreases in activity. These "homeostatic" changes reflect adjustments to help maintain E/I balance and optimal function of brain networks. These changes include alterations in synaptic function (called synaptic scaling) as well as changes in neuronal excitability (including changes in the function and expression of ion channels). Unlike Hebbian plasticity, homeostatic plasticity is unlikely to drive information storage but rather helps maintain longer-term function in response to local changes in excitation and inhibition. Some of these changes do not require input from other cells and are called "cell autonomous." In recent years, there has been interest in determining whether certain treatments in psychiatry modulate neural networks via homeostatic mechanisms. For example, the antidepressant ketamine rapidly upregulates excitatory synaptic responses in the hippocampus and cortex in a non-Hebbian fashion, while lithium dampens synaptic function in a similar way. There is also interest in determining whether other psychiatric treatments have similar homeostatic effects, including ECT and other brain stimulation methods (see below).

Another form of plasticity in neural circuits appears not to result directly in persisting changes in synaptic responses or excitability but rather modulates the ability to induce Hebbian plasticity. This latter form of neuronal modulation is called "metaplasticity" (or "plasticity of plasticity") and involves shifting the relative ease with which Hebbian changes can be induced. Metaplastic regulation shares molecular mechanisms with

Hebbian and homeostatic plasticity and appears to contribute to the dampening of Hebbian plasticity and learning observed under certain physiologic, pathologic, and pharmacologic conditions, including ongoing excitatory synaptic activity, stress, and exposure to certain drugs, including ethanol and ketamine. Taken together, the three general forms of plasticity outlined here offer potentially novel targets for therapeutics that could help to improve cognitive, emotional, and motivational dysfunction associated with psychiatric illnesses. Importantly, however, defects in these forms of plasticity may not be the primary causes of neuropsychiatric illnesses but rather provide strategies to improve neural network function for therapeutic purposes.

Neural Excitability and Brain Stimulation Methods in Neuropsychiatry

Brain stimulation (neuromodulation) methods are playing an increasing role in the treatment of psychiatric and neurologic disorders. These methods include electroconvulsive therapy (ECT), vagus nerve stimulation (VNS), repetitive transcranial magnetic stimulation (rTMS), deep brain stimulation (DBS), and transcortical direct current stimulation (tDCS). The selection of optimal stimulation parameters for these treatments requires knowledge about factors that regulate neuronal excitability and the effects of electrical stimulation on neuronal function. A major advance in ECT was the recognition that electrical stimuli play a key role in therapeutic and adverse effects. Because the goal of an ECT session is to cause a generalized brain seizure while minimizing cognitive side effects, understanding factors that determine seizure threshold and optimizing stimulus parameters becomes extremely important. To stimulate nerve cells, brief square-wave pulses of electrical current (0.1 to 2.0 ms) are much more effective than prolonged pulses or sine-wave stimuli. The rate of delivery of the current pulses is also important, with lower frequencies (30 to 40 Hz) being more efficient than very high-frequency trains (>100 Hz). These features reflect the fact that the entrainment of neurons in a seizure is more likely using parameters that mimic neuronal firing patterns. Long current pulses (particularly sine waves) are inefficient because of the relatively slow onset and offset of the stimulus allowing neuronal adaptation and because much of the stimulus is delivered during the absolute and relative refractory periods when neurons are less excitable. Similarly, very high frequencies of stimulation result in pulses being delivered during refractory periods. For reasons that are unclear, ultrabrief electrical pulses (~0.2-ms duration) are effective for unilateral but not bilateral ECT. The degree to which electrical doses exceed the seizure threshold is also important. For bilateral ECT, electrical doses that are ~1.5 times the threshold result in highly effective treatments that minimize cognitive impairment. For nondominant hemisphere (unilateral) ECT, these same electrical doses are ineffective, and stimuli that are five to six times the seizure threshold are required for clinical improvement. These observations indicate that electrical dosing and stimulation parameters have an important impact on ECT outcomes, and both bilateral and unilateral ECT can be made effective or ineffective depending on the electrical stimulus.

More recent additions to brain stimulation methods, particularly DBS, also require an understanding of the effects of electrical stimulation on neuronal activity and raise interest in the potential role of homeostatic plasticity as a therapeutic mechanism. The parameters used for DBS typically employ brief (0.06 ms) pulses administered continuously at a high frequency (>100 Hz). Modeling studies suggest that this stimulation has complex effects on network function with suppression of intrinsic firing at neuronal cell bodies in the stimulated region but enhanced axonal responses and increased efferent output to downstream targets. Advances in DBS are exploring a variety of targets for modulation of mood, memory, and other complex neuropsychiatric functions, including the use of stimulation frequencies and closed-loop techniques that more closely mimic ongoing brain rhythms to enhance neural physiology.

Progress is also being made in developing more effective ways to use other neuromodulation methods, including rTMS and VNS. rTMS involves the administration of electromagnetic pulses to specific brain regions (typically dorsolateral prefrontal cortex) that either excite (10 to 20 Hz to the left hemisphere) or inhibit (1 Hz to the right hemisphere) cortical function. These parameters mimic stimulus parameters used to induce LTP (high frequencies) or LTD (low frequencies) in preclinical studies in the hippocampus and cortex. Advances in rTMS are using stimuli that more closely mimic intrinsic brain rhythms (e.g., intermittent θ-pulse stimulation) and the use of neuroimaging-guided localization of the magnetic coil to direct rTMS pulses to specific cortical networks that contribute to attention and cognitive control; some evidence suggests that targeting different cortical networks based on clinical subtypes of depression may lead to more effective treatments.

VNS remains an intriguing but poorly understood form of neuromodulation that involves chronic, intermittent stimulation of afferent connections of the vagus nerve via an electrical pulse generator implanted in the chest. VNS has been used to treat refractory epilepsy for over 20 years and has been approved for use in treatment-resistant major depression. Again, optimal stimulation parameters are not completely defined at present, but VNS has several intriguing features that warrant study, including observations that full effects of VNS may take more than 6 months to a year of use to manifest but, once manifest, may persist for long periods of time (years) with continuing stimulation. Mechanisms underlying the long latency to effects and the persisting efficacy of VNS remain uncertain but could reflect homeostatic changes in the function of specific neurocircuits.

Although parameters for clinical benefit continue to be optimized, current neurostimulation/modulation techniques may ultimately prove insufficiently nuanced to manipulate circuits for maximum clinical benefit while limiting undesirable side effects. In this regard, techniques currently in use in animals to manipulate circuits with high selectivity may ultimately find their way to humans as next-generation neurostimulation treatments. For instance, optogenetics allows cell type-selective, local control over circuit behavior. Similarly, chemogenetics employs virally introduced designer receptors responsive to synthetic ligands, allowing experimenters to alter the electrical behavior of restricted, genetically defined populations of neurons. Since their introduction in the early 2000s, these techniques have already revolutionized studies of the role of neural circuits in animal behavior. Hurdles to human implementation include the requirement for gene therapy to introduce foreign channels and implantation of a fiber optic stimulator (optogenetics) or delivery of a foreign chemical (chemogenetics). However, optimizations to increase sensitivity and selectivity of the methods and to decrease invasiveness are published regularly and could reduce barriers to clinical implementation.

SUMMARY

Major advances are occurring in understanding the structure, function, and diversity of voltage-gated and ligand-gated ion channels. The properties of ion channels are being harnessed to yield an unprecedented understanding of the roles of neural circuits in behavior, cognition, and emotion. Efforts to modulate the electrical properties of neurons offer potential new vistas in neuropsychiatric therapeutics and are fundamental to modifying brain networks and to developing innovative treatments. Although electrical properties underlying neuronal excitability are relatively stereotyped, the numerous ion channels contributing to neuronal excitability offer huge flexibility in the control of cellular, regional, and network neural activity. Determining how alterations in ion channels contribute to neurodevelopment, behavior, cognition, and clinical syndromes remains a major goal of work in this field.

1.6 Amino Acid Neurotransmitters

Joseph T. Coyle, M.D.

For over 70 years, the biogenic amines have dominated thinking about the role of neurotransmitters in the pathophysiology of psychiatric disorders. However, over the last two decades, evidence has accumulated from postmortem, brain imaging, and genetic studies that the amino acid neurotransmitters, in particular glutamic acid and γ-aminobutyric acid (GABA), play an important, if not central, role in the pathophysiology of a broad range of psychiatric disorders including schizophrenia, bipolar disorder, major depression, autism spectrum disorder (ASD), Alzheimer disease, and anxiety disorders. The recent ascendance of sufficiently powered genome-wide association studies (GWAS) has had a tremendous impact in linking risk sites on the human genome to genes associated with amino acid neurotransmitters, especially glutamic acid. This is not entirely surprising given the fact that virtually every neuron in the CNS is innervated by GABAergic and glutamatergic neurons. Consistent with this, the brain concentrations of synaptic GABA and glutamate are in the millimolar range, whereas biogenic amine and peptide neurotransmitters are in the micromolar range or lower. The mM concentrations of the neurotransmitter amino acids make them uniquely accessible for measurement in vivo in the human brain by magnetic resonance spectroscopy (MRS), which does not involve exposure to radiation like computer-assisted tomographic (CAT) or positron emission tomographic (PET) scans. The purpose of this chapter is to review the current understanding of amino acid neurotransmitters and to address their potential involvement in psychiatric disorders.

GLUTAMIC ACID

Glutamate mediates fast excitatory neurotransmission in the brain and is the neurotransmitter for approximately 80 percent of brain synapses, particularly those innervating with dendritic spines. The repolarization of neuronal membranes that have been depolarized by glutamatergic neurotransmission accounts for as much as 80 percent of the energy expenditure in the brain. The concentration of glutamate in the brain is 10 mM, the highest of all amino acids, of which approximately 20 percent represents the neurotransmitter pool of glutamate.

The postsynaptic effects of glutamate are mediated by two families of receptors. The first are the glutamate-gated cation channels that are responsible for fast neurotransmission. The second type of glutamate receptor is the metabotropic glutamate receptor (mGluR), which are G-protein–coupled receptors (GPCRs) like α-adrenergic receptors and dopamine receptors. The mGluRs primarily modulate glutamatergic neurotransmission.

Synthesis of Glutamate

Given the excitatory (and potentially neurotoxic) effects of glutamate, it is not surprising that it is excluded from the brain by the blood–brain barrier (BBB). Thus, glutamate in the brain must be synthesized de novo from glucose through the tricarboxylic acid cycle, which generates α-ketoglutarate. The α-ketoglutarate receives an amino group via a transaminase reaction, converting it to glutamic acid. Glutamate is in equilibrium with α-ketoglutarate, and virtually all glucose entering the brain is cycled through glutamic acid. The portion of glutamate dedicated to neurotransmission (approximately 20 percent) is actively sequestered in storage vessels by the vesicular glutamate transporter (vGluT).

A second metabolic pathway is particularly important for replenishing synaptic glutamate. This pathway exploits the intimate relationship between the glutamatergic synapse (i.e., the synaptic bouton and the postsynaptic spine) and the astrocytic endfeet that envelop the synapse. It is the astrocyte and not the glutamatergic nerve terminal that expresses the excitatory amino acid transporters (EAAT1 and 2) that remove glutamate from the synapse, thereby terminating its action. Within the astrocyte, glutamine synthetase, a cytosolic adenosine triphosphate (ATP)-dependent enzyme, catalyzes the conversion of glutamate to generate glutamine. Glutamine synthetase is expressed in glia but not in neurons. Glutamine is then released by the astrocyte and taken up by the glutamatergic terminal, where it is converted back to glutamate by phosphate-activated glutaminase, a mitochondrial enzyme. This process is known as the “glutamine cycle” and accounts for approximately 40 percent of brain glutamate turnover.

Major Glutamatergic Pathways in the Brain

All primary sensory afferent systems use glutamate as their primary neurotransmitter, including retinal ganglion cells, cochlear cells, trigeminal nerve, and spinal afferents. The thalamocortical projections that distribute afferent information broadly to the cortex are glutamatergic. The pyramidal neurons of the corticolimbic regions, the major source of intrinsic, associational, and efferent excitatory projections from the cortex, are glutamatergic. A temporal lobe circuit that figures importantly in the development of new memories is a series of four glutamatergic synapses: The perforant path innervates the hippocampal granule cells that innervate CA3 pyramidal cells that innervate CA1 pyramidal cells. The climbing fibers innervating the cerebellar cortex are glutamatergic as well as the corticospinal tracks.

Ionotropic Glutamate Receptors

Three families of ionotropic glutamate receptors have been identified on the basis of selective activation by conformationally restricted or synthetic analogs of glutamate. These include α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), kainic acid (KA), and N-methyl-ᴅ-aspartic acid (NMDA) receptors (Fig. 1.6–1). Subsequent cloning revealed 16 mammalian genes that encode structurally related proteins, which represent the subunits that assemble into functional receptors. Glutamate-gated ion channel receptors are tetramers, and the subunit composition affects both the pharmacologic and the biophysical features of the receptor.

FIGURE 1.6–1. NMDA receptor ligands.

AMPA receptors (AMPARs) mediate the excitatory (depolarizing) postsynaptic currents (EPSCs) primarily responsible for excitatory neurotransmission and are broadly distributed in the CNS (Fig. 1.6–2). The AMPAR family consists of four subunits of GluR1 to GluR4. However, additional complexities affect AMPAR function. Alternative splicing of a 115 bp cassette for GluR1 to GluR4 messenger ribonucleic acid (mRNA) results in two forms (flip and flop) that give rise to receptors that differ in desensitization rate and regional distribution in the brain. In the second transmembrane domain, GluR1, 3, and 4 have a glutamine (Q) residue that results in high Ca^{2+} conductance, whereas GluR2 has an arginine (R) in this position that severely restricts Ca^{2+} passage and conducts only Na^+. mRNA editing by adenosine deaminase converts the codon for GluR2 from an arginine to a glutamine by a process known as Q/R editing. This radically increases the channel permeability to Ca^{2+} of AMPARs containing the edited GluR2 subunit. Similar mRNA editing mechanisms have been described for kainate receptor subunits GluR5 and 6.

The kainate receptor family consists of five subunits. GluR5 to GluR7 represent subunits that form glutamate-gated cation channels. KA1 and KA2 exhibit negligible channel activity but associate with GluR5 to GluR7 to form high-affinity kainate receptors. The role of kainate receptors is less clearly defined than that of AMPARs, but with their presynaptic localization on glutamatergic terminals, kainate receptors reduce glutamatergic neurotransmission when activated. Notably, kainate receptors can also function as GCPRs.

Seven genes encode subunits that comprise the NMDA receptor family. The NMDA receptor has several unique features (Fig. 1.6–3). First, the channel is blocked by magnesium (Mg^{2+}) at resting membrane potential. Thus, NMDA receptors are "silent" until activation of the AMPARs has sufficiently depolarized the neuronal membrane to relieve the Mg^{2+} blockade. The NMDA receptor requires the simultaneous binding of two ligands to separate recognition sites on two different subunits in order for the channel to open. On the NR1 subunit, which forms the channel, is a binding site termed the glycine modulatory site (GMS), for which glycine and D-serine are the endogenous ligands. The binding site for the neurotransmitter glutamate is located on the second nonchannel subunit (NR2A-D). In the forebrain, D-serine is the dominant coagonist and is synthesized in the synaptic spine of the postsynaptic neuron and released at the synapse where, as an autocrine agent, it primes the synaptic NMDARs to respond immediately to synaptic glutamate. The NMDAR has been described as a coincidence detector because three events must occur simultaneously for the channel to open. Thus, the NMDAR becomes functional only when a sufficient amount of presynaptic glutamate has been released to saturate the receptor, D-serine (or glycine) occupies the GMS, and the synaptic membrane is sufficiently depolarized AMPAR activation to remove the Mg^{2+} blockade. Typically, for this to occur, multiple, converging glutamatergic afferents must fire simultaneously.

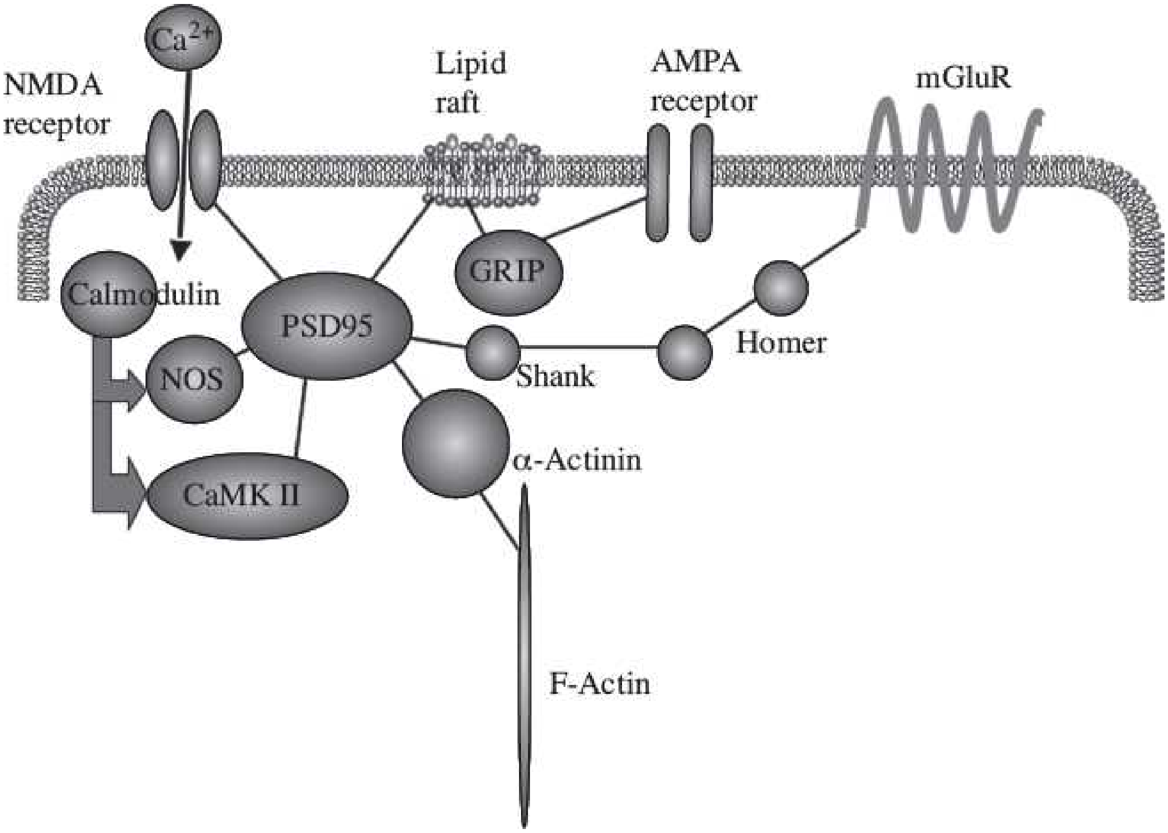

FIGURE 1.6–2. Schematic representation of the postsynaptic density (PSD) of the excitatory synapse. The NMDA receptor is bound to the principal organizing protein, PSD-95. Effector enzymes such as nitric oxide synthase (NOS) and calmodulin-activated protein kinase II (CaMKII) are also bound to PSD-95, keeping them in close proximity to the Ca^{2+} permeable NMDA receptor channel. PSD-95 is connected to the intracellular cytoskeletal protein, F-action by α-actinin. PSD-95 also is attached to neuronal membrane lipid rafts, which indirectly links it to the AMPA receptor through glutamate receptor–interacting protein (GRIP). Finally, postsynaptic group I mGluR receptors are linked to PSD-95 by the scaffolding proteins Shank and Homer. The gene-encoding Shank-3 is a risk gene for autism spectrum disorder.

The NMDAR channel is sufficiently large for Ca^{2+} to readily pass through it. Intracellularly, Ca^{2+} activates several kinases that ultimately affect gene expression in the neuron. For example, the immediate-early gene cFos is a sensitive surrogate for NMDAR activation. The type of NR2 subunit affects the pharmacology and biophysics of the NMDA receptor. For example, NR2B-containing receptors are much more Ca^{2+} permeable than NR2A-containing receptors. NR2A-containing receptors are expressed primarily in corticolimbic regions in the mature brain. NR2B is expressed at high levels in the immature cortex and decreases with maturation. NR2C is expressed primarily in the cerebellum, and NR2D is localized predominately to the cerebellum, the midbrain, and the brainstem.

FIGURE 1.6–3. Schematic representation of the NMDA receptor. The NMDA receptor is a heterotetramer composed of the NR1 subunit that comprises the channel and the NR2 subunit, which contains the ligand binding site for the agonist glutamate. The channel is blocked at the resting membrane potential by Mg^{2+}. The glycine modulatory site on the NR1 subunit must be occupied by the endogenous agonists, D-serine or glycine, for the channel to open. The channel accommodates both Na^+ and Ca^{2+}. A polyamine site positively modulates the receptor. Within the channel is the binding site for dissociative anesthetics, which are use-dependent, noncompetitive inhibitors of the NMDA receptor.

Given their prominent role in learning and in excitotoxicity (see below), it is not surprising that NMDARs are among the most tightly regulated neurotransmitter receptors. As described above, two separate ligands must be bound to two distinct subunits on the NMDAR for it to function. In addition, there are binding sites for Zn^{2+} and H^+ that inhibit ion flux. A polyamine site enhances channel opening. Furthermore, the channel is sensitive to its redox state, which also affects ion currents. Subunit composition affects responses to modulators. For example, the NR2A subunit is much more sensitive to inhibition by Zn^{2+}, whereas the NR2B is differentially more sensitive to the polyamine site antagonist ifenprodil. The influx of Ca^{2+} via the NMDARs activates calmodulin, which then binds to the C-terminus of NR1 and reduces channel opening frequency and duration.

Metabotropic Glutamate Receptors

mGluRs are so designated because their effects are mediated by G-proteins and not by the influx of cations. All mGluRs are activated by glutamate, although their sensitivities vary remarkably. To date, eight mGluRs have been cloned. These genes encode seven membrane-spanning proteins that are members of the superfamily of GPCRs. They are subgrouped into three classes based upon amino acid sequence homology, agonist pharmacology, and signal transduction pathway utilized. Group I mGluRs, which includes mGluR1 and 5, activate PLC, presumably through G_Q. Group II includes mGluR2 and 3. Group III includes mGluR4, 6, 7, and 8. Group II and III mGluRs inhibit adenylyl cyclase through G_i-protein. The abundant neuropeptide N-acetylaspartylglutamate is a specific agonist at mGluR3.

mGluRs located postsynaptically modulate several channels and receptors. All three groups inhibit L-type voltage-dependent calcium channels, and groups I and II inhibit N-type calcium channels. In addition, mGluRs are reported to close voltage-dependent K^+ channels, thereby slowing depolarization and reducing excitability. Presynaptic mGluRs on both GABAergic and glutamatergic terminals inhibit neurotransmitter release, possibly by inhibiting the P/Q-type calcium channel.

Postsynaptic Density

Considerable advances have been made in characterizing the organization and dynamics of glutamate receptors at the postsynaptic density (PSD). The PSD is an osmophilic multiprotein complex that contains scaffolding proteins, cell adhesion molecules, and proteins for intercellular signaling pathways. A major scaffolding protein is PSD-95 (an acronym for *postsynaptic density* protein with a molecular weight of 95 kDa). PSD-95 contains several regions that bind other proteins. There are three PDZ domains (an acronym for PSD-95/disc large/zona occludens-1). The PDZ domains contain approximately 90 amino acids that bind the C-termini of proteins with complementary amino acid sequences. Neuroligin binds to the PDZ and extends into the synaptic cleft to bind to β-neurexin, which is anchored to the presynaptic component of the synapse. This arrangement stabilizes the synapse by connecting pre- and postsynaptic components. Two N-terminal cysteines of PSD-95 bind palmitic acid, which links the protein to lipid rafts in the plasma membrane. The NR2 subunit of the NMDAR binds to the PDZ domain. PSD-95 also binds α-actin, which is bound to filamentous actin, an important component of the cytoskeletal complex in the dendritic spine.

In contrast to NMDARs, AMPARs do not bind directly to PSD-95 but are associated with it indirectly by binding to intermediary proteins that bind to PSD-95. These include glutamate receptor–interacting protein (GRIP), protein interacting with C-kinase1 (PICK1), and synapse-associated protein of 97 kDa (SAP-97). In addition, there are the transmembrane AMPA receptor regulatory proteins (TARPs), which are involved in transporting AMPARs to and intercalating them within the PSD. Whereas the number of NMDARs in mature synapses tends to be relatively constant, the number of AMPARs in the PSDs varies tremendously. In fact, there are some PSDs that contain no AMPARs but do contain NMDARs. They are referred to as “silent synapses” because glutamate has no excitatory effects since the NMDARs are inactivated at the resting membrane potential with a few exceptions. Except for mGluR7, postsynaptic mGluRs are tethered to the periphery of the PSD by binding to two scaffolding proteins, homer and shank, the latter of which binds to PSD-95. Notably, allelic variants of gene-encoding proteins that comprise the PSD, including neurexin, neuroligin, and shank, have been implicated in autism.

The Role of Astrocytes

Specialized endfeet of the astrocyte surround glutamatergic synapses. The astrocyte expresses the two Na^+-dependent glutamate transporters that play the primary role in removing glutamate from the synapse, thereby terminating its action: EAAT1 and EAAT2 (excitatory amino acid transporter 1 and 2). The neuronal glutamate transporter, EAAT3, is expressed in upper motor neurons, whereas EAAT4 is expressed primarily in cerebellar Purkinje cells; and EAAT5 are restricted to the retina. Mice homozygous for null mutations of either EAAT1 or EAAT2 exhibit elevated extracellular glutamate and excitotoxic neurodegeneration. Notably, several studies have described the loss of EAAT2 protein and transport activity in the ventral horn in amyotrophic lateral sclerosis (ALS).

The astrocytes express AMPARs so that they can monitor synaptic glutamate release. GlyT1, which maintains subsaturating concentrations of glycine in the extracellular space, is expressed on the astrocyte plasma membrane. GlyT1 transports three Na^+ out for each molecule of glycine transported into the astrocyte. This stoichiometry results in a robust reversal of the direction of transport when glutamate released in the synapse activates the AMPARs on the astrocyte, thus depolarizing the astrocyte. Glycine release in the synapse by GlyT1 is coordinated with glutamatergic neurotransmission. D-Serine, which is found primarily in the forebrain, is synthesized by serine racemase (SR), which is expressed primarily in pyramidal neurons and, to a lesser extent, GABAergic neurons. D-Serine levels are also determined by D-amino acid oxidase (DAAO), with low D-serine levels in the cerebellum and brainstem where DAAO expression is high, and high D-serine levels are found in corticolimbic brain regions where DAAO expression is quite low. In contrast, the expression of GlyT1 is highest in the cerebellum and brainstem. This distribution suggests that D-serine is the primary coagonist of the NMDARs in the forebrain, whereas glycine is more prominent in the brainstem and cerebellum. Nevertheless, GlyT1 inhibitors have procognitive effects in experimental animals and are being tested clinically for the treatment of cognitive impairment and negative symptoms in schizophrenia.

Plasticity and Glutamatergic Neurotransmission

Hebb proposed that learning and memory involved use-dependent changes in synaptic efficacy. Neurophysiologic studies, originally exploiting the identifiable glutamatergic Schaffer collateral synapse on the hippocampal CA1 pyramidal cell, showed that a brief period of intense stimulation of the Schaffer collateral (100 Hz) resulted in a subsequent persistent increase in the efficacy of synaptic neurotransmission at these synapses. This phenomenon is known as long-term potentiation (LTP) and is quite widespread at glutamatergic synapses. In contrast, a period of stable low-frequency stimulation of the glutamatergic axons results in a persistently reduced efficacy of synaptic neurotransmission, a phenomenon known as long-term depression (LTD). LTP in these hippocampal studies requires the activation of NMDARs, as demonstrated by the fact that it is blocked by NMDAR antagonists such as the dissociative anesthetics ketamine and phencyclidine (PCP). Conditions resulting in blockade of LTP in the hippocampus are associated with impairments in the acquisition of new memories. The nature of these plastic changes has been the focus of intense research. The persistent changes in synaptic efficacy in LTP and LTD result from the insertion (LTP) or removal (LTD) of AMPARs from the PSDs of affected synapses. Thus, in contrast to the NMDARs, the AMPARs are quite dynamic, and their synaptic function is controlled through trafficking in and out of the synapse.

The extinction of conditioned fear has also been shown to be an active process mediated by the activation of NMDARs in the amygdala. Treatment of rats with NMDAR antagonists prevents the extinction of conditioned fear, whereas treatment with the GMS partial agonist D-cycloserine facilitates the extinction of conditioned fear. (D-Cycloserine is an antibiotic used to treat tuberculosis that is a partial agonist at the NMDAR with 50 percent efficacy of glycine). To determine whether the phenomenon generalizes to humans, patients with acrophobia were administered either placebo or a single dose of D-cycloserine along with cognitive-behavioral therapy (CBT). D-Cycloserine plus CBT resulted in a highly significant reduction in acrophobic symptoms that persisted for at least 3 months as compared to placebo plus CBT. Other placebo-controlled clinical trials support the notion that D-cycloserine is a robust enhancer of CBT, suggesting that pharmacologically augmenting neural plasticity may be used to bolster psychological interventions. D-Cycloserine may enhance cognitive remediation in patients with schizophrenia, although the evidence for this is limited to pilot data.

Glutamate-mediated synaptic plasticity is not only functional; it is also structural. Dendritic spines are dynamic appendages. Such dynamics have cleverly been demonstrated in real-time in vitro and in vivo in the brains of mice in which a gene from jellyfish that encodes a green fluorescent protein is inserted into the mouse genome in a manner so that only glutamatergic neurons become fluorescent. Using confocal microscopy, investigators have been able to demonstrate in real time that persistent activation of NMDARs results in spine maturation from long and skinny to fat and stubby and even the elaboration of new spines. This transformation is mediated in part by the influx of calcium through the activated NMDARs. Such rapid structural changes in the synaptic spine reflect the fact that protein synthesis (i.e., translation) has recently been demonstrated to occur within individual dendritic spines.

Fragile X mental retardation protein (FMRP), which is deficient in individuals with fragile X syndrome, is synthesized locally within the spine during times of NMDAR activation and also plays a role in transporting specific mRNAs to the dendritic spine for translation. Notably, mice in which the *FMRP* gene has been inactivated through a null mutation, as well as patients with fragile X syndrome, have fewer dendritic spines, the preponderance of which have an immature morphology. Loss of FMRP exaggerates responses of mGluR5, which stimulates dendritic protein synthesis. Treatment with an mGluR5 antagonist reverses the fragile-X–like phenotype in mice with the FMRP gene inactivated; however, this strategy failed in clinical trials.

Excitotoxicity

In the early 1970s, it was shown that the systemic administration of large amounts of monosodium glutamate to immature animals causes the degeneration of neurons in brain regions where the BBB was deficient such as the arcuate nucleus of the hypothalamus. Subsequent studies showed that the direct injection of ionotropic glutamate receptor agonists such as KA, ibotenic acid, and NMDA caused a pattern of neuronal degeneration that affected neurons with their cell bodies in proximity to the injection site but spared axons passing through the area arising from distant neurons as well as glia. Persistent and overwhelming activation of AMPA/kainate receptors and NMDA receptors causes a tremendous influx of Na^+ and Ca^{2+} and a secondary influx of H_2O. The resulting acute cellular edema causes *necrotic* cell death. At sites more distant from the injection, the persistent elevation of intracellular Ca^{2+} disrupts the mitochondria, which release cytochrome C and activate caspases, resulting in programmed cell death (*apoptosis*).

The neuronal degeneration occurring after ischemic stroke is the result of excitotoxicity. Local hypoxia due to ischemia results in a cessation of

ATP production, causing the collapse of the ATP-driven sodium gradient across the neuronal and astroglial membranes. Consequently, the direction of the sodium-dependent glutamate transporters is reversed, causing a massive release of glutamate. Although several drugs that block the ionotropic glutamate receptors or the downstream events caused by their overstimulation have proved effective in reducing the amount of neuronal damage in animal models of stroke, no such agent has yet proved effective in clinical trials.

Excitotoxicity has also been implicated as the proximate cause of neuronal degeneration in Alzheimer disease. Most evidence points to the toxic consequences of aggregates of β-amyloid, especially β-amyloid$_{1–42}$. The β-amyloid fibrils depolarize neurons, resulting in loss of the Mg^{2+} block and enhanced NMDA receptor sensitivity to glutamate. The fibrils also impair glutamate transport into astrocytes, thereby increasing the extracellular concentration of glutamate. β-Amyloid directly promotes oxidative stress through inflammation that further contributes to neuronal vulnerability to glutamate. Finally, the proliferation of inflammatory (“reactive”) astrocytes further promotes excitotoxicity by releasing the obligatory NMDAR coagonist, D-serine, rendering neurons vulnerable to elevated extracellular glutamate. Thus, several mechanisms contribute to neuronal vulnerability to NMDA-receptor–mediated excitotoxicity in Alzheimer disease. Memantine (Namenda), an FDA-approved treatment for mild to moderate Alzheimer disease, is a weak noncompetitive inhibitor of NMDA receptors. It reduces the tonic sensitivity of NMDA receptors to excitotoxicity but does not interfere with “phasic” neurotransmission, thereby attenuating neuronal degeneration in Alzheimer disease.

Inhibitory Amino Acids: GABA

GABA is the major inhibitory neurotransmitter in the brain, where it is broadly distributed and occurs in millimolar concentrations. In view of its physiologic effects and distributions, it is not surprising that the dysfunction of GABAergic neurotransmission has been implicated in a wide range of neuropsychiatric disorders, including anxiety disorders, schizophrenia, alcohol dependence, and seizure disorders. Chemically, GABA differs from glutamic acid, the major excitatory neurotransmitter, simply by the removal of a single carboxy group from the latter.

GABA is synthesized from glutamic acid by GAD, which catalyzes the removal of the α-carboxyl group. In the CNS, the expression of GAD appears to be restricted to GABAergic neurons, although in the periphery, it is expressed in pancreatic islet cells. Two distinct but related genes encode GAD. GAD65 is localized to nerve terminals, where it is responsible for synthesizing GABA that is concentrated in the synaptic vesicles. Consistent with its role in fast inhibitory neurotransmission, mice homozygous for a null mutation of GAD65 have an elevated risk for seizures. GAD67 appears to be the primary source of neuronal GABA because mice homozygous for a null mutation of GAD67 die at birth, have a cleft pallet, and exhibit major reductions in brain GABA.

GABA is catabolized by GABA transaminase (GABA-T) yielding succinic semialdehyde. Transamination generally occurs when the parent compound, α-ketoglutarate, is present to receive the amino group, thereby regenerating glutamic acid. Succinic semialdehyde is oxidized by succinic semialdehyde dehydrogenase (SSADH) into succinic acid, which reenters the Krebs cycle. GABA-T is a cell surface, membrane-bound enzyme that is oriented toward the extracellular compartment and is expressed by both neurons and glia. As would be anticipated, drugs that inhibit the catabolism of GABA have anticonvulsant properties. One of the mechanisms of action of valproic acid (VPA) is the competitive inhibition of GABA-T. γ-Vinyl-GABA is a suicide substrate inhibitor of GABA-T that is used as an anticonvulsant in Europe but can impair vision by potentiating retinal GABAergic neurotransmission (vigabatrin; Sabril).

The synaptic action of GABA is also terminated by high-affinity transport back into the presynaptic terminal as well as into astrocytes. Four genetically distinct GABA high-affinity transporters have been identified with differing kinetic and pharmacologic characteristics. They all share homology with the other neurotransmitter transporters with the characteristic of 12 membrane-spanning domains. The active transport is driven by the sodium gradient so that upon depolarization, transportation of GABA out of the neuron is favored. GABA transported into astrocytes is catabolized by GABA-T and ultimately converted to glutamic acid and then to glutamine, which is transported back into the presynaptic terminal for GABA synthesis. Tiagabine (Gabitril) is a potent GABA transport inhibitor that is used to treat epilepsy.

Anatomy of GABAergic Systems

In the corticolimbic regions of the brain, GABA is localized to the intrinsic (i.e., local circuit) neurons. In the columnar organization of the cerebral cortex, the GABAergic neurons provide the outer boundaries of the columns with inwardly directed axons. While the GABAergic interneurons comprise a minority of cortical neurons (15 to 25 percent), they exert a profound degree of inhibition of the activity of the glutamatergic pyramidal cells. The remarkable efficacy of inhibition reflects two neuroanatomical features of GABAergic synapses: they are concentrated on the shafts of synaptic spines to counteract glutamatergic depolarization and on the neuronal cell body and proximal axon to restrict the generation of action potentials. In the cerebral cortex, the GABAergic interneurons are the primary site of colocalization of neuropeptides. These include cholecystokinin (CCK), dynorphin, neuropeptide Y (NPY), somatostatin, substance P, and vasoactive intestinal peptide (VIP).

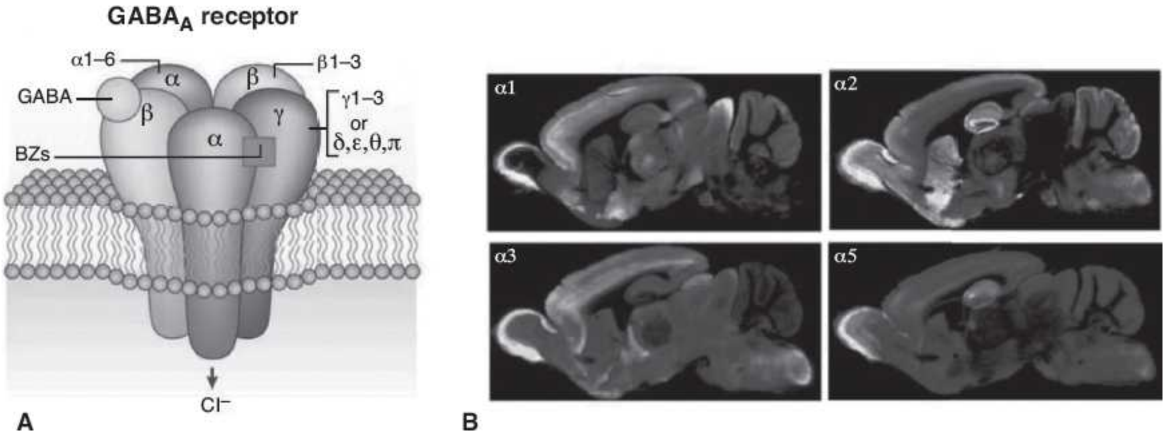

FIGURE 1.6–4. Schematic representation of the GABA$_A$ receptor. **A:** GABA$_A$ receptors are defined by a complex of five subunits, creating a pore through which Cl⁻ ions flow down their concentration gradient to mediate fast synaptic inhibition. The most common subunit assembly is depicted here with 2α, 2β, and 1γ subunits. The receptor is also defined by the presence of GABA and benzodiazepine binding sites, which are formed by α and β or α and γ subunits, respectively. (A, reprinted by permission from Springer Nature: Jacob TC, Moss SJ, Jurd R. GABAA receptor trafficking and its role in the dynamic modulation of neuronal inhibition. *Nat Rev Neurosci* 2008; 9:331–343. Copyright © 2008.) **B:** The four α subunits, which bind classical benzodiazepines (α1, α2, α3, and α5), have distinct expression patterns within the brain, as demonstrated by these autoradiographs of benzodiazepine binding in the rat brain. (B, reproduced by permission of ASPET from Mohler H, Fritschy JM, Rudolph U. A new benzodiazepine pharmacology. *J Pharm and Exp Ther*. 2002;300(1):2–8.)

In the striatum, GABAergic neurons project directly to the substantia nigra pars reticulata, which regulates dopaminergic neuronal activity. In addition, there are striatal GABAergic neurons that project to the globus pallidus to synapse on pallidal–subthalamic GABAergic neurons that regulate the excitatory output from the subthalamic nucleus as well as reciprocal GABAergic projections from the substantia nigra/ventral tegmental area to the striatum. In the cerebellum, the GABAergic Purkinje cells are its main efferent system.

GABA$_A$ Receptors

GABA$_A$ receptors are distributed throughout the brain. The GABA$_A$ receptor complex, when activated, mediates an increase in membrane conductance with an equilibrium potential near the resting membrane potential of −70 mV (Fig. 1.6–4). In the mature neuron, this typically results in an influx of Cl^-, causing membrane hyperpolarization. Hyperpolarization is inhibitory because it increases the threshold for generating an action potential. In immature neurons, which have unusually high levels of intracellular Cl^-, activating the GABA$_A$ receptor can counterintuitively cause depolarization. For this reason, anticonvulsants that act by enhancing GABA$_A$ receptor activity may exacerbate seizures in the neonatal period.

The GABA$_A$ receptor subunits exhibit sequence homology to a larger family of ligand-gated channels, including the nicotinic acetylcholine receptor and the glycine receptor. At least 19 distinct but closely related genes have been identified that encode GABA$_A$ receptor subunits. Each subunit contains four α-helical membrane-spanning domains, the sequences of which are highly conserved among the subunits. The receptor complex is a heteropentamer. The ligand-binding site is formed at the interface between the α- and the β-subunits. The subunit composition affects the biophysical and pharmacologic characteristics of the receptor. Different subunit-containing GABA$_A$ receptor complexes are expressed at different stages of development as well as in different regions of the brain.

The pharmacology of GABA$_A$ receptors is particularly rich. A component of the extracts of the psychoactive mushroom *Amanita muscaria* is muscimol, which is a direct agonist at the GABA$_A$ receptor. The prototypical GABA$_A$ antagonist is bicuculline, which acts by decreasing the frequency and duration of channel opening and has proconvulsant effects. Picrotoxin, another proconvulsant, acts by blocking the chloride channel.

Reminiscent of the NMDA receptor, the $GABA_A$ receptor complex is noteworthy for multiple allosteric modulatory interactions. These include benzodiazepines, barbiturates, general anesthetics, ethanol, and neurosteroids. Benzodiazepines bind to a distinct site in the $GABA_A$ receptor complex and allosterically increase the frequency of channel opening in response to GABA. Therefore, benzodiazepines do not directly activate the receptor, but they enhance the phasic responses to synaptically released GABA. This indirect mechanism of action and the localization of benzodiazepine-sensitive receptors account for the lower risk of respiratory suppression for benzodiazepines as compared to that of barbiturates. The benzodiazepine site is allosterically linked to the binding sites of other modulatory ligands, which can contribute to toxic interactions such as with ethanol. Notably, antagonists and inverse agonists for the benzodiazepine receptor have been developed that demonstrate anxiogenic and procognitive effects.

Barbiturates such as phenobarbital and pentobarbital are noted for their sedative and anticonvulsant activities. Barbiturates allosterically increase the affinities of the binding sites for GABA and benzodiazepines at concentrations that are pharmacologically relevant. Barbiturates also affect channel dynamics by markedly increasing the long open state and reducing the short open state, thereby increasing Cl^- conductance, and inhibition. This direct mechanism of action at the $GABA_A$ receptors accounts for fatal respiratory suppression when taken in excessive amounts.

Chemically modified analogs of progesterone and corticosterone have been shown in behavioral studies to have sedative and anxiolytic effects through their interaction with the $GABA_A$ receptor complex. They share features with barbiturates, although the hydrophobic neurosteroids accumulate in high concentrations within the cell membrane at their recognition site on the $GABA_A$ receptor. They allosterically enhance agonist binding to the receptor and increase the duration of Cl^- channel opening. A variety of behavioral effects associated with steroid administration or fluctuation of endogenous steroids and sex-specific effects of GABAergic drugs have been linked to the action of endogenous neurosteroids. Recently, the FDA approved brexanolone (allopregnanolone; Zulresso) as a treatment for women with postpartum depression.

Regarding $GABA_A$ receptor antagonists, picrotoxin, like the barbiturates, alters channel dynamics but in the opposite direction by reducing long open states and favoring the briefest open state. The proconvulsant pentylenetetrazol also acts by reducing Cl^- channel permeability. Penicillin, which at high concentrations is proconvulsant, binds to the positively charged residues in the channel, thereby occluding it. As a general class, anesthetics including barbiturates, steroids, and volatile anesthetics increase chloride conductance, thereby inhibiting neurotransmissions. Amino acids in the membrane-spanning domain of the GABA receptor subunits confer sensitivity to anesthetics. The precise mechanism whereby ethanol enhances $GABA_A$ receptor function remains unclear due to inconsistent results, suggesting that subunit composition may be important. However, recent studies suggest that ethanol increases the response of the tonic GABA-activated currents, which contain the δ-subunit and exhibit remarkably high affinity for GABA.

Recombinant DNA strategies exploiting site-directed mutagenesis have permitted the identification of sites on the specific subunits that mediate the pharmacologic action of drugs such as the benzodiazepines. Mutational removal of the binding ability for benzodiazepines has established that the α_1-subunit plays a major role in the sedative and amnestic effects of benzodiazepines, the α_2-subunit confers the anxiolytic effects, the α_3-subunit contributes to fear reduction and the α_5-subunit to muscle relaxation. Developing drugs that are subunit selective for benzodiazepines, such as the sedative zolpidem (Ambien), reduce off-target side effects associated with nonspecific benzodiazepines.

$GABA_B$ Receptors

The $GABA_B$ receptors are distinguished pharmacologically from $GABA_A$ receptors by the fact that they are insensitive to the canonical $GABA_A$ receptor antagonist bicuculline and that they are potently activated by baclofen (β-(4-chlorophenyl)-γ-aminobutyric acid; Lioresal), which is inactive at $GABA_A$ receptors. They are members of the G-protein–coupled superfamily of receptors but are highly unusual as they are made of a dimer of two seven transmembrane-spanning subunits. $GABA_B$ receptors are widely distributed throughout the nervous system and are localized both pre- and postsynaptically. The postsynaptic $GABA_B$ receptors cause a long-lasting hyperpolarization by activating potassium channels. The presynaptic $GABA_B$ receptors act as auto- and heteroreceptors to inhibit neurotransmitter release.

All $GABA_B$ receptors in the vertebrate brain are the sole products of the $GABA_B$(1) and $GABA_B$(2) genes (Fig. 1.6–5). Pharmacologic heterogeneity among $GABA_B$ receptors reflects different isoforms resulting from splice variants. The most common variants that are conserved across species are $GABA_B$(1A) and $GABA_B$(1B). They exhibit different regional distributions in the brain where, for example, $GABA_B$(1A) transcripts are confined to the granule cell layer, whereas $GABA_B$(1B) transcripts are expressed primarily in Purkinje cells. All $GABA_B$ agonists and competitive antagonists bind to the extracellular domain of the $GABA_B$(1) subunit. The $GABA_B$(2) subunit also has a large extracellular domain, which may be the site for allosteric modulation of the $GABA_B$ receptor. Interestingly, there is a binding site for Ca^{2+} in the ligand-binding pocket of the $GABA_B$(1) subunit that increases the affinity for GABA. This Ca^{2+} binding site is typically saturated at physiologic concentrations of Ca^{2+}.

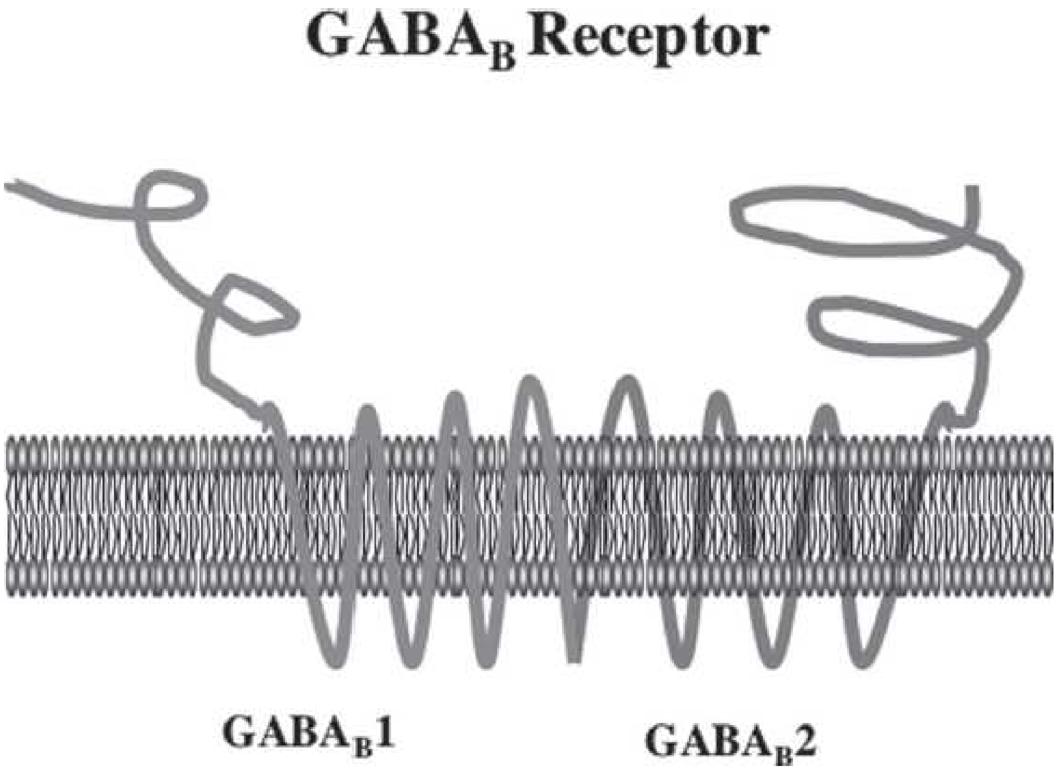

FIGURE 1.6–5. Schematic representation of the GABA$_B$ receptor. This G-protein–coupled receptor (GPCR) is a heterodimer of two seven-membrane-spanning GPCRs. The extensive extracellular domains have binding sites for GABA and allosteric modulators.

γ-Hydroxybutyrate (GHB), which is approved for the treatment of narcolepsy, has been misused as a “date rape” drug because it rapidly induces deep sleep. Although high-affinity binding sites for GHB have been described in the brain, the sedative and hypnotic effects of exogenous GHB can be prevented by GABA$_B$ receptor antagonists. Furthermore, administration of GHB to GABA$_B$−/− mice resulted in no behavioral effects of GHB, indicating that GABA$_B$ receptors are its likely site of action and not the so-called GHB receptors.

Glycine as a Neurotransmitter

Glycine is an inhibitory neurotransmitter primarily in the brainstem and spinal cord, although the expression of glycine receptor subunits in the thalamus, cortex, and hippocampus suggests a broader role. Glycine is a nonessential amino acid that is synthesized in the brain from L-serine by serine hydroxymethyltransferase. Glycine is concentrated within synaptic vesicles by H$^+$-dependent vesicular inhibitory amino acid transporter

(VIAAT or VGAT), which also transports GABA. Termination of the synaptic action of glycine is through reuptake into the presynaptic terminal by the glycine transporter II (GlyT2), which is quite distinct from the GlyT1 that is expressed in astrocytes and modulates NMDA receptor function.

The inhibitory effects of glycine are mediated by a ligand-gated chloride channel, which can also respond to β-alanine, taurine, L-alanine, L-serine, and proline but not to GABA. The canonical antagonist for the glycine receptor is the plant alkaloid strychnine. The receptor was first identified through the specific binding of [^{3}H]strychnine to synaptic membranes. [^{3}H]Glycine itself binds to two sites: One that is displaceable by strychnine and represents the glycine A receptor, and a second that is insensitive to strychnine and is designated the glycine B receptor, representing the GMS on the NMDA receptor.

The glycine A receptor is a macromolecular complex of approximately 250 kDa that is comprised of five subunits surrounding a central pore. There are two subunits with a high degree of homology: The 48-kDa α-subunit and the 58-kDa β-subunit. The subunits display a structural similarity to other members of this ion channel family with four hydrophobic domains that span the lipid bilayer in α-helices. The binding site for both glycine and strychnine is located on the α-subunit. There are four genes that encode the α-subunits, but only one gene encodes for the β-subunit. Interestingly, the β-subunit is expressed fairly abundantly in rostral brain regions that exhibit no [^{3}H]strychnine binding or α-subunit expression.

Hereditary hyperekplexia is a disorder due to mutations in genes encoding components of the glycinergic synapse. It is characterized by stiffness and an excessive startle reflex in infancy that subsides with maturation. Mutations causing hyperekplexia have been described in the α-subunit (GLRA1) and in the β-subunit (GLRB) of the glycine receptor but also in GlyT2 (SLC6A5). Treatment with oral clonazepam is usually an effective therapy.

Neuropsychiatric Implications of Amino Acid Transmitters

Schizophrenia Evidence accumulating from postmortem, pharmacologic, and genetic studies is shifting the focus of the pathophysiology of schizophrenia from dopamine to glutamate and GABA. Indeed, after the use of dopamine D_2 receptor antagonists of varying structures and side-effect profiles as the primary treatment of schizophrenia for the last 60 years, over two-thirds of the treated patients still remain substantially disabled. Postmortem studies conducted over 40 years ago indicated a reduction in the activity of GAD in the cerebral cortex in patients with schizophrenia as compared to suitable controls. With the advent of immunocytochemistry and gene expression techniques, it has been possible to more precisely define the GABAergic deficit in schizophrenia. The parvalbumin-positive GABAergic interneurons in the intermediate layers of the cortex bear the brunt of the pathology, which includes reduced expression of GAD67, parvalbumin, and the GABA transporter (GAT). The finding that $GABA_A$ receptors are upregulated, as measured by autoradiography or with antibodies, supports the theory that these changes reflect the hypofunction of the presynaptic GABAergic neurons. These particular GABAergic interneurons, which include the chandelier cells, play an important role in negative feedback inhibition to the pyramidal cells in the cortex.

The theory that hypofunction of NMDA receptors is an etiologic factor in schizophrenia initially arose from the observation that PCP and related dissociative anesthetics that block NMDA receptors produce a syndrome that can be indistinguishable from schizophrenia. Dissociative anesthetics are so named because they prevent the acquisition of new memories without diminishing the apparent level of consciousness. In fact, under laboratory conditions, infusion of low doses of ketamine, another dissociative anesthetic, can produce the positive symptoms, negative symptoms, and specific cognitive deficits associated with schizophrenia in clear consciousness. Subsequent studies indicated that low-dose ketamine can also cause enhanced amphetamine-induced subcortical dopamine release, as is observed in schizophrenia, as well as abnormal cortical event-related potentials (ERPs) and disruption of prepulse inhibition in experimental animals.

Early-gene studies in schizophrenia were limited by the biased selection of “candidate” genes and small numbers of subjects, resulting in contradictory results. In 2014, a large GWAS comparing nearly 40,000 subjects with schizophrenia to a hundred thousand controls identified 108 sites (single-nucleotide polymorphism [SNP]) on the genome, which attained the stringent level of genome-wide significance (5×10^{-8}) required by the multiple comparisons inherent to GWAS (Fig. 1.6–6). Recently, this was expanded to 70,000 schizophrenics and 236,000 controls. A clear pattern has emerged. Most of the risk-associated SNPs do not localize to coding regions of the genome but presumably act by altering gene expression or RNA splicing. Notably, none contributed more than 5 percent to the ascribable risk for schizophrenia, indicating that schizophrenia was a disorder of complex genetics like diabetes with multiple risk genes of modest effects interacting with the environment to produce the phenotype.

Three major categories of risk genes were identified: major histocompatibility complex (MHC) genes, genes related to neurotransmission, and genes involved in development. Nearly a dozen risk genes are within two degrees of separation from the NMDAR, including *SRR* (the gene-encoding serine racemase, SR), whereas a dozen more are involved in glutamate signaling such as voltage-dependent Ca^{2+} channels. Genetic inactivation of SR in mice results in a phenotype that shares many features with the neurochemical alterations, neuronal structural deficits such as loss of synaptic spines, electrophysiologic abnormalities such as impaired EEG ERPs and cognitive features of schizophrenia as well as increased striatal dopamine release consistent with psychosis. Although the GWAS in bipolar disorder are not as well powered as those in schizophrenia, risk genes shared between schizophrenia and bipolar disorder have been identified that implicate glutamatergic neurotransmission, including the voltage-gated calcium channel CACNA1C, and NAMDAR subunit, GRIN2A, in the pathophysiology of bipolar disorder.

Several clinical trials have been carried out with agonists at the GMS on the NMDA receptor in patients receiving concurrent treatment with antipsychotic medications. The hypothesis being tested was that enhancing NMDA receptor function would reduce negative symptoms and improve cognition, aspects of the disorder unaffected by antipsychotic drugs. A meta-analysis of the results of these placebo-controlled trials of agonists at the NMDA receptor GMS revealed highly significant reductions in depression, negative symptoms, cognitive deficits, and even positive symptoms. However, other meta-analyses that used different selection criteria have reported less compelling results, indicating that these weak agonists at the GMS are unlikely to be clinically relevant but rather contribute to “proof of principle.”

FIGURE 1.6–6. Genetic risk for schizophrenia converges on the glutamatergic synapse. Genome-wide association studies (GWAS) of over nearly two hundred thousand subjects with schizophrenia and controls have identified over a hundred single nucleotide polymorphisms that exhibit genome-wide significant association (5×10^{-8}) with the risk for schizophrenia. Associated risk genes indicate a prominent role for the glutamatergic synapse in schizophrenia pathology. The selected schizophrenia risk genes are shown here demonstrate the relevance to all aspects of the glutamatergic synapse function to schizophrenia. At the presynaptic terminal, genes including *SNCA* (*synuclein alpha*) and *SNAP91* (*synaptosome associated protein 91*) regulate synaptic vesicle trafficking. Trans-synaptic cell adhesion molecules such as *PTPRF* (*Protein Tyrosine Phosphatase Receptor Type F*) and *LRRC4B* (*Leucine-Rich Repeat-Containing 4B*) regulate synaptic signaling, establishment, and remodeling. Multiple nonreceptor ion channel subunit genes are associated with schizophrenia, including voltage-dependent calcium channel subunits *CACNA1C*, *CACNA1D*, and *CACNA1G* and chloride ion channel subunit *CLCN3*. Similarly, subunits of glutamate receptors are themselves encoded by schizophrenia risk genes, including NMDA receptor

subunit *GRIN2A*, AMPA receptor subunits *GRIA1* and *GRIA3*, and metabotropic glutamate receptors *GRM1* and *GRM3*. The serine racemase enzyme encoded by *SRR* converts L-serine to D-serine, the primary coagonist of NMDA receptors. Complement component C4, encoded by the *C4A* and *C4B* genes within the major histocompatibility complex locus, contributes to excessive pruning of excitatory synapses in late adolescence and the decreased density of dendritic spines observed in schizophrenia. Finally, multiple nuclear factors, including the transcription factor *MEF2C*, regulate gene expression–modulated glutamatergic neurotransmission via the NMDA receptor. Recent findings have provided a link between the GABAergic neuropathology and NMDAR hypofunction in schizophrenia. Chronic treatment of rats with NMDAR antagonists causes a downregulation of GAD67, parvalbumin, and GAT. The most sensitive subpopulation of GABAergic neurons is the rapidly firing interneurons that provide the perisomatic and axon hillock innervation of the pyramidal cells. Their NMDAR appear to be much more sensitive to antagonists than those less active GABAergic neurons and pyramidal cells because a critical feature of NMDAR function is membrane depolarization. Except for the genes encoding *GABBR1*, *GABBR2,* and *CALB2*, current GWAS results have not found other genes related to GABAergic function as significant risk genes, suggesting that cortical GABAergic deficits in schizophrenia may be a downstream consequence of some more proximal genetic defects affecting GABAergic neuronal function such as reduced NMDAR function.

The subtly reduced GABAergic inhibition results in a disinhibition of the glutamatergic pyramidal output. This degradation of the cortical inhibitory feedback likely accounts for the cognitive deficits and negative symptoms in schizophrenia, and the disinhibited pyramidal neuron output also results in elevated subcortical dopamine release causing psychosis. These findings that mimic the schizophrenia phenotype are replicated by silencing the risk gene for schizophrenia, *SRR*, which eliminates D-serine, the dominant NMDAR coagonist in the forebrain. Thus, psychosis appears to be a downstream consequence of the disruption in critical glutamatergic–GABAergic synaptic function in the cerebral cortex.

Anxiety and Depression

GABAergic dysfunction has been associated with anxiety disorders, especially panic disorder, as well as with major depressive disorder (MDD). Clinically, there is considerable comorbidity between anxiety and affective disorders. MRS reveals significant reductions in GABA in the prefrontal cortex, cingulate cortex, and occipital cortex in MDD. The reduced levels of GABA in the occipital cortex in episodes of MDD normalize with effective treatment with selective serotonin reuptake inhibitor (SSRI) or with electroconvulsive therapy (ECT). Postmortem studies have revealed upregulation of the $GABA_A$ receptor α_1- and β_3-subunits in the cerebral cortices of depressed patients who committed suicide, consistent with a reduction in GABAergic neurotransmission. Decreased levels of the $GABA_A$ receptor modulators, three α-reduced neuroactive steroids, have been found both in plasma and in CSF in MDD. Effective treatment with SSRI increases the neurosteroid levels. MRS has disclosed significant reductions in GABA levels in the anterior cingulate and in the basal ganglia of medicated patients with panic disorder. PET scanning reveals a highly selective reduction in benzodiazepine receptor sites bilaterally in the insular cortex in panic disorder. A genome-wide screen has shown significant linkage at 15q in a region containing $GABA_A$ receptor subunit genes and panic disorder.

Glutamatergic dysfunction has also been implicated in depression. NMDAR antagonists have antidepressant effects in several animal models of depression, including forced swim, tail suspension, and learned helplessness. A single injection of ketamine provides protection from the induction of behavioral despair in rats for up to 10 days. Chronic treatment with antidepressants alters the expression of NMDAR subunits and decreases GMS binding. Several placebo-controlled clinical trials have shown that a single dose of ketamine can produce a rapid, substantial, and persistent reduction in symptoms in patients with MDD, especially those who have not responded to SSRI/SNRI treatment. Furthermore, ketamine administration causes a rapid and persistent reduction in suicidal thoughts. In 2019, Jansen received FDA approval for the use of the S-isomer of ketamine (Esketamine) administered by nasal insufflation for treatment of depression and suicidal ideation. There is debate about the precise mechanism of rapid antidepressant action of ketamine, but most converge on its transient blockade of NMDARs resulting in a rapid increase in brain-derived neurotrophic factor (BDNF) release and strengthening of glutamatergic neurotransmission, especially in reward pathways.

Alcoholism

Ethanol at concentrations associated with intoxication has a dual action of enhancing GABAergic receptor function and attenuating NMDAR function. The GABA receptor effects may be associated with the anxiolytic effects of ethanol. Persistent abuse and dependency on ethanol result in a downregulation of $\mathrm{GABA_A}$ receptors and an upregulation of NMDARs such that acute discontinuation of ethanol results in a hyperexcitable state characterized by delirium tremens. Furthermore, supersensitive NMDARs in the context of thiamine deficiency may contribute to the excitotoxic neuron degeneration of Wernicke–Korsakoff syndrome.

Acamprosate (Campral) is a derivative of homotaurine that was developed as an agent to reduce alcohol consumption, craving, and relapse in alcohol use disorder (AUD). It exhibits moderate efficacy in clinical trials. Because of taurine’s resemblance to GABA, it was thought that acamprosate acted via $\mathrm{GABA_A}$ receptors, but electrophysiologic studies found little evidence to support this hypothesis. Subsequent studies demonstrated that it inhibited NMDAR responses in cortical slices and recombinant NMDARs. The precise mechanism whereby acamprosate alters NMDAR function, however, remains unclear. Recently, acamprosate has been combined with the opiate receptor antagonist, naltrexone (Vivitrol), to better prevent relapse in AUD.

Fetal alcohol syndrome (FAS) is the most common preventable cause of intellectual disability. Convincing evidence has been developed that the microcephaly associated with fetal alcohol exposure results from its inhibition of NMDAR function, resulting in widespread neuronal apoptosis in the immature cortex because NMDAR activation is essential for immature neuronal survival and differentiation.

CONCLUSION

Over the last 70 years, very few FDA-approved psychiatric drugs that deviated from the fundamental mechanisms of reducing dopamine function for psychosis, inhibiting biogenic amine uptake for depression and anxiety disorders, and enhancing $\mathrm{GABA_A}$ receptor function for anxiolysis. However, recently some novel effective treatments have been developed that work through altering amino acid neurotransmitter function, including acamprosate for AUD, esketamine, an NMDAR antagonist, for treatment-resistant depression, and brexanolone a $GABA_A$ receptor allosteric modulator, for postpartum depression.

The expansion of genetic studies to permit sufficiently powered GWAS are now disclosing risk genes that involve pathways for psychiatric disorders linked to glutamatergic and GABAergic neurotransmission. The expanding GWAS findings in serious mental illness will provide targets for rational drug development, deviating from the historical reliance on serendipity, an inefficient method for treatment development. These advances will present real challenges for students and psychiatric clinicians as more and more drugs that address symptom domains linked to risk gene pathways are introduced and erode the categorical approach to diagnosis and treatment. Given their preeminent role in brain neurotransmission, glutamate and GABA pathways will likely play a prominent role in these developments.

1.7 Biogenic Amine Neurotransmitters

JOHN D. ELSWORTH, PH.D.

The biogenic amine neurotransmitters comprise the catecholamines (dopamine, norepinephrine, and epinephrine) and serotonin (5-hydroxytryptamine, 5HT), histamine, and acetylcholine. The importance of these messengers to central nervous system (CNS) function is reflected in the critical roles these systems play in cognition, memory, motivation, motor function, and arousal, and their relevance to psychiatry is demonstrated by their involvement in the pathophysiology and pharmacologic treatment of multiple disorders.

These neurotransmitters have an unusual and functionally significant organization in the CNS. Their cell bodies are restricted to a relatively small number of nuclei in the midbrain, brain stem, basal forebrain, and hypothalamus, yet their axons project extensively, with some biogenic amine transmitter systems displaying a more complex topographical arrangement than others. This widely disbursed influence permits each of these neurotransmitters to modulate activity in diverse circuits throughout the CNS, sometimes in a coordinated fashion. This anatomical organization poses a major challenge to deciphering the precise molecular, cellular, and systems-level contributions these neurotransmitters exert in neuropsychiatric disorders. Advances in genomics have revealed insights into the complexity of these neurotransmitter systems, exemplified by the identification of a large number of genes that regulate monoaminergic neurotransmission, such as the enzymes, receptors, and transporters that mediate the synthesis, cellular actions, and cellular reuptake of these neurotransmitters, respectively. Human genetics studies have provided evidence of tantalizing links between allelic variants in specific monoamine-related genes and psychiatric disorders and personality traits, while the ability to modify gene function and cellular activity in experimental animals has clarified the roles of specific genes and neural pathways in mediating behavioral processes.

In this chapter, each of the biogenic amine transmitters is considered separately with the details of its “life cycle,” specifically the details of enzymes and transporters devoted to the synthesis, degradation, and transporters of the transmitter. These descriptions also incorporate transmitter-specific receptors since, ultimately, the effects of biogenic amine transmitters on CNS function and behavior depend on their interactions with receptor molecules. The binding of biogenic amines to these plasma membrane proteins initiates a series of intracellular events that modulate neuronal excitability. Unlike transporters, multiple receptor subtypes exist for each biogenic amine transmitter. Neurotransmitter receptors produce intracellular effects by one of two basic mechanisms: (1) by interactions with G proteins that couple receptors (GPCRs) to intracellular effector systems and (2) by providing channels through which ions flow when transmitters bind (ligand-gated ion channels). The neurotransmitter receptors covered in this chapter, with the exception of the serotonin 5-HT$_3$ receptor subtype and the cholinergic nicotinic receptors, all belong to the superfamily of GPCRs. However, within each neurotransmitter receptor group, the subtypes are heterogeneous with regard to the G proteins with which they interact and to the second messenger effects that they induce. Receptors are also diverse in their regional patterns of expression within the brain, their neurotransmitter binding affinities, and their synaptic localization. Whereas many receptor subtypes are located exclusively in postsynaptic membranes, others are located presynaptically, and some are both pre- and postsynaptically. Populations of receptors on the presynaptic terminal that respond to a transmitter released by that neuron are known as “*autoreceptors*,” which often act to inhibit neurotransmitter release in order to regulate the concentration of transmitter in the synapse (“local feedback inhibition”). When a receptor for a particular transmitter is located on terminals of a neuron expressing a different transmitter, it is termed a “*heteroreceptor,*” and its activation can either increase or decrease transmitter release.

Much effort has been focused on determining the location and function of individual neurotransmitter receptor subtypes. Limited availability of selective agonist and antagonist drugs hampers this effort, but recent advances in gene manipulation and targeted gene editing are advancing the fields of neuroscience and pharmacology considerably. Such studies in animals provide clues to receptor function and to the contributions of each receptor to the actions of nonspecific drugs. It is anticipated that the near future will witness the development of receptor subtype–selective compounds that achieve therapeutic effects by altering biogenic amine transmission in a more refined manner.

DOPAMINE AND NOREPINEPHRINE

Dopamine Anatomy and Functions

Several distinct populations of dopaminergic neurons have been identified in the brain and are classified as groups A8–A16. The majority of dopaminergic innervation in the brain is provided by long projection neurons arising from two clusters of cell bodies in the midbrain (mesencephalon), the substantia nigra (A9), and the ventral tegmental area (VTA, A10). Neurons from the substantia nigra provide a dense input to the dorsal striatum (caudate nucleus and putamen), while projections from the VTA principally target limbic regions (e.g., nucleus accumbens and septum) in addition to cortical regions (e.g., prefrontal cortex and cingulate cortex). It should also be noted, though, that it is not possible to completely segregate the motor, motivational, and cognitive behaviors that are often attributed to the striatal, limbic, and cortical dopamine systems, respectively.

Dysfunction in dorsal striatal dopamine transmission is strongly associated with movement disorders such as Parkinson disease or tardive dyskinesia. The hallmark signs of Parkinson disease (hypokinesia, rigidity, and tremor) originate from a loss of striatal dopaminergic innervation. Tardive dyskinesia (repetitive, involuntary movements) can occur following high-dose or long-term exposure to certain antipsychotic drugs that block dopamine receptors. Nigrostriatal dopamine neurons do not merely allow motor behavior to occur. They also play an important role in the selection and initiation of actions and in establishing motor skills and habits.

A unique feature of nigrostriatal dopamine neurons is the complex arborization of their terminals. This is illustrated by the estimate that over 1 million striatal synapses are associated with each human nigrostriatal dopamine neuron, which at least two orders of magnitude greater than for other types of neuron. This large architecture, together with the unmyelinated nature of its axons, puts the nigrostriatal dopamine neuron under a phenomenal energy demand and probably is a critical factor in their particular susceptibility to a variety of biochemical, environmental, and pharmacologic insults.

Dopamine neurons arising in the VTA and terminating in the frontal cortex play an important role in executive function, a set of mental functions such as directing attention, working memory, maintaining task goals, decision making, flexible thinking, and self-control. Dopamine neurons innervating limbic regions such as the nucleus accumbens are strongly implicated in goal-oriented (motivated) behaviors, in addition to reward, attention, and pharmacologically induced locomotion. Enhancement of dopamine transmission in the mesolimbic system has been linked with the reinforcing and sensitizing effects of repeated exposure to psychostimulant drugs of abuse and with stress. However, blunting of dopamine release in ventral striatal dopamine has been associated with established addictions and may contribute to neuroadaptive changes that provoke craving during abstinence. Tourette syndrome and attention deficit hyperactivity disorder (ADHD) have been linked to a dysfunction of dopaminergic neurotransmission in limbic and cortical regions, based mainly on the success of dopaminergic drugs in the treatment of their symptoms.

The oldest credible neurochemical hypothesis of schizophrenia posited that the disease is related to excessive dopamine activity in striatal and limbic regions. Subsequently, it was shown that psychosis symptoms of schizophrenia were associated with increased dorsal/associative striatum dopamine release, while negative symptoms and cognitive impairments were associated with reductions in cortical and ventral/limbic striatal dopamine release. There is solid evidence that dopamine is involved in the pathophysiology of schizophrenia, but not necessarily its root cause. Rather, dopamine systems probably act as the common final pathway for a wide variety of predisposing factors, either environmental, genetic, or both, that lead to symptoms of the disease.

Anterior to the mesencephalic substantia nigra and VTA are several other relatively small groups of dopaminergic cell bodies. The most prominent of these are the tuberoinfundibular dopamine neurons, which are located in the arcuate nucleus of the hypothalamus and project to the median eminence. Dopamine released from these neurons enters the circulation and is transported to the anterior pituitary, where it inhibits the release of prolactin from the anterior lobe of the pituitary. Antipsychotic drugs that block dopamine receptors in the pituitary induce an increase in blood prolactin levels.

Electrophysiologic studies have shown that dopamine cells fire in two different modes, either single spiking or burst firing, presumably as a result of a change in the balance between excitatory and inhibitory inputs. As cells are able to switch between these levels, the transition in activity may be a mechanism for altering the impact of dopamine neurotransmission on receptive cells. Bursting activity elicits more terminal dopamine release per action potential than pacemaker activity, and interestingly stimulation of mesocortical neurons in a burst pattern produces a greater release than tonic stimulation of both dopamine and a colocalized peptide, neurotensin. The different rates of firing of dopamine neurons probably code different responses in the brain. At the fastest scale, with burst firing, dopamine neurons can signal a reward or indicate to what extent a reward occurs differently than predicted. At the slowest time scale, the pacemaker activity of dopamine neurons has been linked to a tonic-enabling function on a variety of motor, cognitive, and motivational processes, which are deficient in Parkinson disease and which can be restored by dopamine replacement therapy. Recent data indicate that phasic and tonic modes of dopamine neurotransmission can operate as a continuum, with the postburst elevation of extracellular dopamine being sustained to engage tonic functions of dopamine; such an explanation is consistent with the need for both types of dopamine signaling in the motivational and cognitive functions.

In addition to the dopamine systems in the brain and pituitary, dopamine has restricted yet critical roles in the periphery. The best-defined action for peripheral dopamine neurons is in renal regulation of sodium homeostasis, and impairment of this control may underlie the development of hypertension in some cases. Another important function of dopamine outside the brain is in the retina, where dopamine-containing amacrine cells modulate high acuity, light-adapted vision, and photoreceptor coupling.

Norepinephrine Anatomy and Functions

The different populations of noradrenergic neurons in the brain have been designated A1–A7. The widespread noradrenergic innervation in the brain mainly derives from a small cluster of neurons located in the locus coeruleus (LC, part of the pons, A6) in addition to a more diffuse grouping in the lateral tegmental area (part of the midbrain). These two populations provide input to virtually all brain regions, with LC neurons primarily targeting the forebrain, thalamus, cerebellum, and spinal cord, and with lateral tegmental neurons principally sending fibers to the hypothalamus and basal forebrain. An unusual feature of noradrenergic innervation is that a single neuron typically innervates several brain regions. LC noradrenergic neurons exhibit different activity modes: tonic firing alternating with short periods of burst firing. Increased tonic activity has been associated with behavioral flexibility, whereas the phasic mode is linked with arousing stimuli. There is good evidence for an important role of LC noradrenergic neurons in arousal, vigilance, attention, working memory, and regulation of the sympathetic nervous system.

Epinephrine Anatomy and Functions

In the sympathetic nervous system and the adrenal medulla, epinephrine shares with norepinephrine the role of the final neurotransmitter, and the proportion of this overlap is species dependent and hormonally modified. The relatively few epinephrine-containing cells in the brain exist mostly in the medulla. These neurons predominate in the C1, C2, and C3 regions of the medulla and send axons to a variety of brainstem and forebrain structures, including the LC, dorsal raphe, nucleus accumbens, and provide innervation to subregions of the hypothalamus.

Life Cycle of Dopamine, Norepinephrine, and Epinephrine

Synthesis. These three catecholamine neurotransmitters share a common synthetic pathway (Fig. 1.7–1). Bloodborne tyrosine, derived from dietary proteins and from phenylalanine metabolism, enters the brain by the large neutral amino acid (LNAA) transport system. Tyrosine in brain extracellular fluid is taken up into catecholamine neurons by a high-affinity amino acid transporter. In the first reaction in the cytosol, tyrosine is converted to L-dopa by the enzyme tyrosine hydroxylase. Because this step is rate limiting, it sets the pace for the conversion of tyrosine to dopamine and makes this reaction the most susceptible to physiologic regulation and pharmacologic manipulation. Tyrosine hydroxylase requires tetrahydrobiopterin as a cofactor, and the synthesis of tetrahydrobiopterin is itself dependent on the activity of another enzyme GTP-cyclohydrolase-1. The next reaction is in catecholamine synthesis, the decarboxylation of L-dopa by aromatic amino acid decarboxylase

(AADC) in the cytosol to form dopamine. AADC decarboxylates L-dopa so avidly that the level of this amino acid in the brain is very low under normal conditions. L-dopa is the principal drug used to treat Parkinson disease as it restores the deficient striatal dopamine level that characterizes the disorder. Supplying exogenous L-dopa to the neuron ensures efficient conversion to dopamine because it relies only on AADC and bypasses tyrosine hydroxylase, the rate-limiting step in dopamine biosynthesis. An inhibitor of AADC that does not cross the blood–brain barrier (BBB) (e.g., carbidopa or benserazide) is routinely administered with levodopa to patients with Parkinson disease to inhibit the peripheral decarboxylation of L-dopa to dopamine, which reduces peripheral side effects resulting from abnormally high circulating levels of dopamine. One prominent side effect of excessive circulating dopamine is emesis resulting from the activation of dopamine receptors in the area postrema, an area outside the BBB. In fact, D_2 antagonists (e.g., promethazine [Phenergan]) are a widely used class of antiemetic agents. However, because dopamine antagonists are prone to induce parkinsonian-like side effects, alternatives such as $5HT_3$ antagonists (e.g., ondansetron [Zofran]) and neurokinin-1 receptor antagonists (e.g., aprepitant [Emend]) are increasingly used for controlling the emergence of nausea and vomiting that can occur after chemotherapy and surgery.

In norepinephrine neurons, as well as in chromaffin cells of the adrenal medulla, an additional enzyme, dopamine-β-hydroxylase (DBH), is present that enables the conversion of dopamine to norepinephrine. This enzyme is concentrated inside the storage vesicles, so unlike other reactions, this step of norepinephrine synthesis does not occur in the cytoplasm. Disulfiram (Antabuse), a drug used to treat alcohol addiction, is an inhibitor of DBH. However, the principal relevant property of disulfiram in treating alcoholism is to block acetaldehyde dehydrogenase, the enzyme that metabolizes acetaldehyde formed from ethanol, and this results in elevated acetaldehyde levels that induces moderate to severe adverse effects after consumption of ethanol.

FIGURE 1.7–1. Biosynthesis of dopamine, norepinephrine, and epinephrine. The catecholamine neurotransmitters are produced by a multistep synthesis that starts with the dietary amino acid, tyrosine. Dopamine neurons contain

the enzymes TH and AADC, whereas norepinephrine neurons also express DBH. PNMT is an additional enzyme that is present only in epinephrine neurons. AADC, aromatic amino acid decarboxylase; DBH, dopamine-β-hydroxylase; PNMT, phenol-N-methyltransferase.

In central epinephrine neurons and those in the adrenal medulla and heart, norepinephrine is N-methylated by the enzyme phenylethanolamine-N-methyltransferase (PNMT) to form epinephrine. As PNMT is located in the cytoplasm, norepinephrine has to exit its storage site in vesicles to be converted to epinephrine before being transported back into vesicles. This reaction with PNMT presumably takes place during spontaneous leakage of norepinephrine from vesicles in the cytoplasm or after norepinephrine has been released into the synapse and taken back up into the cytoplasm.

Phenylketonuria (PKU) is a rare genetic disease caused by a mutation in the phenylalanine hydroxylase gene, resulting in the production of a nonfunctional enzyme, hampering the metabolism of circulating phenylalanine, which can lead to severe mental retardation unless steps are taken to limit dietary intake of phenylalanine.

Vesicular Transporter. Vesicles that are present in the presynaptic terminals are specialized for the uptake and storage of catecholamines, thus protecting the transmitter from degradation by the enzyme monoamine oxidase (MAO) found in mitochondria. The accumulation and concentration of catecholamine transmitters inside the vesicles is accomplished by the vesicular monoamine transporter (VMAT), and this sequestration is disrupted by amphetamine-like drugs, leading to the mobilization of the transmitter from vesicular storage into the cytoplasm, which increases the concentration available for release to the extracellular compartment. There are two forms of VMAT, with VMAT-2 being primarily located in neuronal cells of the CNS, peripheral nervous system, and enteric nervous system and VMAT-1 being expressed in extraneuronal tissues, such as chromaffin cells of the adrenal medulla.

FIGURE 1.7–2. Schematic model of a dopaminergic synapse with sites of drug action. **Site 1:** Tyrosine hydroxylase reaction blocked by the competitive inhibitor, α-methyltyrosine. Administration of L-dopa augments dopamine levels and is the mainstay treatment of Parkinson disease. Carbidopa is an inhibitor of AADC that does not cross the blood–brain barrier, and is used in conjunction with L-dopa in the treatment of Parkinson disease to reduce the peripheral side effects of L-dopa. **Site 2:** VMAT transports cytoplasmic dopamine into storage vesicles, decreasing its cytoplasmic concentration and preventing metabolism by monoamine oxidase. Reserpine inhibits VMAT and depletes dopamine stores. Tetrabenazine also interferes with the uptake–storage mechanism and has been used for treatment of hyperkinetic movement disorders. **Sites 3 and 4:** Once released, dopamine can interact with postsynaptic D1-like receptors (site 3) and D2-like receptors (site 4). Bromocriptine (Parlodel) and apomorphine (Apokyn) are D2 agonists used in the treatment of Parkinson disease. Pramipexole (Mirapex) is a D3 agonist used in the treatment of Parkinson disease and restless legs syndrome. Aripiprazole (Abilify) is a partial D2 agonist used as an antidepressant. All antipsychotic drugs block D2 receptors to some degree. **Site 5:** Interaction of

dopamine with autoreceptors regulates synthesis and release of dopamine. Low doses of apomorphine have been used experimentally as an autoreceptor agonist. **Site 6:** The plasma membrane transporter recaptures synaptic dopamine. The drug of abuse, cocaine, inhibits the dopamine transporter, and amphetamine increases dopamine release via the transporter. **Site 7:** MAO present outside the presynaptic terminal can metabolize dopamine that has been released. Selegiline (Eldepryl) is an MAO-B inhibitor used in the treatment of Parkinson disease. **Site 8:** Dopamine is a substrate for COMT, an enzyme that is inhibited by tolcapone and entacapone, which are used in treatment of Parkinson disease. AADC, aromatic amino acid decarboxylase; AC, adenylate cyclase; cAMP, cyclic AMP; COMT, catechol-O-methyltransferase; D1–5, dopamine receptor subtypes; DOPAC, dihydroxyphenylacetic acid; G, G protein; HVA, homovanillic acid; MAO, monoamine oxidase; VMAT, vesicular monoamine transporter. (Modified from Nestler E, Hyman S, Holtzman D, Malenka R. *Molecular Neuropharmacology*. McGraw-Hill Companies, Inc; 2015.)

Dopamine Plasma Membrane Transporter. A high-affinity dopamine transporter (DAT) serves to recapture released dopamine and limits the concentration and actions of dopamine in the synapse (Fig. 1.7–2). Importantly, dopamine neurons in the striatum and nucleus accumbens are equipped with a high density of DATs and so are especially susceptible to drugs that target this site and inhibit its actions. For example, blockade of dopamine reuptake by cocaine in the nucleus accumbens prolongs and intensifies dopamine's actions in this region and is key to the euphoric effects of the drug. Similarly, amphetamine and methamphetamine amplify dopamine signaling in the nucleus accumbens by blocking dopamine reuptake and increasing the release of dopamine. The VTA-nucleus accumbens pathway is part of the brain's reward pathway that is activated by all types of reinforcing stimuli such as food, sex, and many drugs of abuse. While drugs that rapidly increase synaptic dopamine concentration can be addictive, some of these agents (e.g., methylphenidate, amphetamine) are used at lower doses to treat ADHD and may achieve their beneficial effects by actions on the dopamine and norepinephrine transporters (NETs) and subsequent interaction of the transmitter with their autoreceptors, which are generally sensitive to a lower concentration of agonists than is necessary to activate postsynaptic receptors. Lisdexamfetamine (Vyvanse) is a long-acting oral prodrug that is hydrolyzed in blood to active D-amphetamine, and it has been approved for treating ADHD. The DAT also provides access to dopamine neurons for parkinsonian neurotoxins, 6-hydroxydopamine, and 1-methyl-4-phenyl-

1,2,3,6-tetrahydropyridine (MPTP) because they are substrates for the transporter.

FIGURE 1.7–3. Schematic model of a central norepinephrine synapse with sites of drug action. **Site 1:** Tyrosine is transported into the presynaptic terminal by an active uptake mechanism and converted to NE by a series of enzymatic steps. The competitive inhibitor, α-methyltyrosine blocks the tyrosine hydroxylase reaction. DBH reaction is prevented by disulfiram. **Site 2:** Norepinephrine is taken up from the cytoplasm and transported into storage vesicles by the VMAT-2. Reserpine inhibits VMAT and depletes norepinephrine stores; the drug was once widely prescribed for its antihypertensive actions. Tetrabenazine also interferes with the uptake–storage mechanism and has been used for treatment of hyperkinetic movement disorders. **Sites 3, 4, and 5:** After release, norepinephrine can interact with two categories of G-protein–coupled adrenergic receptors, α1 and α2 (**sites 3 and 4**) and β (**site 5**). The majority of adrenergic receptors are localized postsynaptically where they mediate the cellular responses of the postsynaptic neuron. Propranolol (Inderal) is an antagonist of β-adrenergic receptor, and is used to treat performance anxiety and hypertension. α1-Receptor (**site 3**) is inhibited prazosin (Minipress), used as an antihypertensive, but which also has anxiolytic effects used in the treatment

PTSD. **Site 6:** α2-Autoreceptors localized in the nerve terminals modulate the synthesis and release of norepinephrine, while cell body and dendritic α2-autoreceptors modulate impulse flow. Low doses of clonidine (Catapres) and guanfacine (Intuniv) are agonists at these sites. α2-Agonists are used to treat opioid withdrawal, Tourette syndrome, and hypertension. Yohimbine is an antagonist at this receptor site. **Site 7:** The synaptic action of norepinephrine is terminated by reuptake into the presynaptic terminal by norepinephrine plasma membrane transporter. The tricyclic antidepressants, such as desipramine (Norpramin), are inhibitors of this uptake mechanism. Some newer antidepressants are more selective for NET, such as atomoxetine (Strattera), and by SNRIs such as duloxetine (Cymbalta). **Site 8:** Norepinephrine is metabolized by MAO and it is a preferential substrate for MAO-A. Inhibitors of MAO-A block metabolism of norepinephrine, and this action may contribute to their antidepressant property. Examples of irreversible nonselective inhibitors are isocarboxazid, phenelzine, and tranylcypromine. Moclobemide inhibits MAO-A reversibly. **Site 9:** Norepinephrine is also metabolized by COMT, which is inhibited by tolcapone (Tasmar) and entacapone (Comtan), drugs that are used in treatment of Parkinson disease. The combined actions of MAO and COMT produces MHPG, a major brain norepinephrine metabolite. α and β*,* subtypes of norepinephrine receptor; AADC, aromatic amino acid decarboxylase; AC, adenylate cyclase; cAMP, cyclic AMP; COMT, catechol-O-methyltransferase; DAG, diacylglycerol; DBH, dopamine β-hydroxylase; DHPG, 3,4-dihydroxyphenylglycol; G, G protein; IP3, inositol triphosphate; MAO, monoamine oxidase; MHPG, 3-methoxy-4-hydroxyphenylglycol; SNRI, serotonin–norepinephrine reuptake inhibitor; VMAT, vesicular monoamine transporter. (Modified from Nestler E, Hyman S, Holtzman D, Malenka R. *Molecular Neuropharmacology*. McGraw-Hill Companies, Inc; 2015.)

Norepinephrine Plasma Membrane Transporter. The NET is located on all noradrenergic neurons and efficiently recaptures most of the transmitter that is released into the synapse (Fig. 1.7–3). In addition to the impact of the psychostimulants (e.g., cocaine and amphetamines) on DAT, these drugs also interact with NET and intensify the synaptic actions of NE. The mechanism of certain antidepressant drugs includes blockade of NET, and these include the tricyclic antidepressants (TCAs) and the more specific serotonin–norepinephrine reuptake inhibitors (SNRIs) such as duloxetine (Cymbalta) and venlafaxine (Effexor), norepinephrine–dopamine reuptake inhibitors (NDRIs) such as bupropion (Wellbutrin), and the selective norepinephrine reuptake inhibitors (NRIs), such as maprotiline and atomoxetine (Strattera), which is also used in the treatment of ADHD.

Some of the original studies on dopamine uptake revealed that dopamine is a good substrate for the NET. However, not until relatively recently has the importance of this been appreciated. In regions, such as the striatum and nucleus accumbens, where dopamine neurons express a high density of DAT, there is a relatively sparse norepinephrine innervation, and dopamine uptake depends primarily on DAT. In contrast, in regions such as the prefrontal cortex, where dopamine neurons express low levels of DAT, and there is a rich norepinephrine innervation, dopamine uptake depends strongly on NET. In fact, it has been suggested that dopamine can be co-released with norepinephrine by noradrenergic neurons as a result of nonspecific uptake of dopamine by the NET and/or because dopamine is a precursor in the biosynthesis of norepinephrine.

Epinephrine Plasma Membrane Transporter. There is no evidence for a specific transporter for epinephrine, and no drug that selectively blocks epinephrine reuptake has been described. All of the pharmacologic agents that block the NET selectively are also effective inhibitors of epinephrine uptake. Thus, it appears unlikely that a selective transporter for epinephrine exists.

Metabolism. The major mammalian enzymes of importance in the metabolic degradation of catecholamines are MAO and catechol O-methyltransferase (COMT), and either of these enzymes can catalyze the first step in catecholamine metabolism. MAO converts its substrates to their corresponding aldehydes, and these aldehyde intermediates are rapidly metabolized either by the aldehyde dehydrogenase or aldehyde reductase. Thus, multiple metabolites of catecholamines are formed. In the primate brain, the major end metabolites for dopamine are homovanillic acid (HVA), whereas, in the rodent brain, 3,4-dihydroxyphenylacetic acid (DOPAC) and DOPAC sulfate predominate. For norepinephrine, 3-methoxy-4-hydroxyphenylglycol (MHPG) is the main end metabolite in the primate brain, but in the rodent brain, both 3,4-dihydroxyphenylglycol (DHPG) and MHPG exist in high concentrations, and both metabolites are mainly sulfate conjugated. In the periphery, the major metabolite of dopamine is HVA, and for norepinephrine, it is vanillylmandelic acid (VMA), with a significant proportion of both compounds being conjugated to either sulfate or to glucuronide.

It is well documented in animals that short-term fluctuations in the levels of dopamine metabolites, DOPAC, and HVA, in the striatum, nucleus accumbens, and prefrontal cortex provide a useful index of alterations in impulse flow in the nigrostriatal, mesolimbic, and mesocortical dopamine pathways, respectively. Changes in dopamine metabolite concentration in CSF have also been associated with alterations in central dopaminergic activity or integrity of central dopamine systems. Similarly, shifts in the concentration of MPHG or DHPG have been correlated with changes in norepinephrine function.

MAO. This enzyme is located on the outer membrane of mitochondria. Separate genes encode two isoforms of MAO (types A and B), which can be distinguished by substrate specificity and sensitivity to selective inhibitors. In the brain, MAO-A is preferentially located in dopaminergic and noradrenergic neurons, while MAO-B is the major form present in serotonergic neurons and glia. Dopamine and norepinephrine are effective substrates for both forms, whereas serotonin is a preferential substrate for MAO-A. The predominance of MAO-B in serotoninergic neurons appears counterintuitive as this transmitter is a better substrate for MAO-A; it is possible that MAO-B in serotoninergic neurons serves to regulate phenylethylamine levels a “trace amine” that is a selective MAO-B substrate and can affect serotonin uptake and efflux. The prototypical inhibitors of the two forms are clorgyline for MAO-A and selegiline (formerly known as deprenyl) for MAO-B. Selegiline (Eldepryl) or rasagiline (Azilect) are irreversible MAO-B inhibitors, and Safinamide (Xadago) is a reversible MAO-B inhibitor that is used in the treatment of Parkinson disease, usually in combination with L-dopa to prolong or enhance the effect of dopamine formed from L-dopa.

COMT. There are two isoforms of COMT, a membrane-bound form, and a soluble form. Membrane-bound COMT is the major form found in the CNS, has a higher affinity for catecholamines, and is located principally in neurons. The soluble form has a lower affinity for catecholamines and is the major form expressed in the periphery but is present also in CNS glia. Two COMT inhibitors, tolcapone and entacapone, are used as adjuncts to L-dopa in the treatment of Parkinson disease to slow L-dopa metabolism and thereby prolong its effects and reduce L-dopa requirements.

Accumulating evidence from clinical and preclinical studies shows that COMT plays a more significant role in dopamine metabolism in the prefrontal cortex than in other regions such as the striatum, likely because of the paucity of DAT in the prefrontal cortex. Another interesting facet of the role of COMT in the frontal cortex is the finding that the COMT gene contains a polymorphism (Val158Met) that affects the in vivo activity of the enzyme. Met158 homozygotes have approximately one-third less COMT enzyme activity in the prefrontal cortex than Val158 homozygotes, and this aligns with an altered rate of dopamine metabolism by the alleles. COMT Val158Met polymorphism has been associated with different phenotypes, such as reward responsiveness and reward-seeking, cognitive abilities, and stress processing. However, it should be noted that an inverted "U"–shaped curve describes the relationship between dopaminergic transmission in the prefrontal cortex and behavior-like cognition, with both sub- and supraoptimal dopamine activity impairing performance.

Dopamine Receptors

The physiologic actions of dopamine are mediated by five distinct but closely related GPCRs. On the basis of their structure, pharmacology, and primary effector mechanisms, they are grouped as D_1-like (D_1 and D_5) and D_2-like (D_2, D_3, D_4) dopamine receptors (Fig. 1.7–2). The D_1-like dopamine receptors activate the Gs family of G proteins, increase adenylate cyclase activity, and are found postsynaptically on dopamine-receptive cells. The D_2-like dopamine receptors (D_2, D_3, and D_4) couple to the Gi family, inhibit adenylate cyclase activity and are expressed both postsynaptically on dopamine-receptive cells and presynaptically on dopaminergic neurons.

In the brain, D_1 dopamine receptors are expressed in particularly high density in the nigrostriatal, mesolimbic, and mesocortical dopamine systems, such as the striatum, nucleus accumbens, and frontal cortex. In contrast, D_2 receptors are more evenly distributed in the brain, with the highest levels in the striatum and nucleus accumbens. Dopamine transmission through D_1 and D_2 receptors in the striatum and prefrontal cortex plays an essential role in many aspects of motor control, reward systems, and cognition. The alternative splicing of the D_2 gene results in the generation of two major variants, termed D_{2S} (D_2-short) and D_{2L} (D_2-long). There is some evidence that D_{2S} is mostly expressed presynaptically and is involved in autoreceptor functions, with D_{2L} being predominantly a postsynaptic isoform. The D_3 dopamine receptor has a more limited pattern of distribution, with the highest level of expression being observed in the limbic areas, such as in the shell subdivision of the nucleus accumbens. Some data suggest that D_3 receptors can operate as autoreceptors to complement the D_2 autoreceptor role in regulating the neuronal firing rate, synthesis, and release of dopamine. Among the dopamine receptors, the D_4 subtype has the lowest level of expression in the brain, with distribution in the frontal cortex, amygdala, hippocampus, and hypothalamus. D_5 dopamine receptors are expressed at low levels in multiple brain regions, including the frontal cortex, hypothalamus, and hippocampus. D_1, D_2, and D_4 dopamine receptors are also present in the retina. The important role of dopamine in regulating the hypothalamic–pituitary axis accounts for the high expression of D_2 dopamine receptors in the pituitary gland. In the periphery, all subtypes of dopamine receptors have been observed in varying proportions in the kidney, adrenal glands, sympathetic ganglia, gastrointestinal (GI) tract, blood vessels, and heart.

Some of the older, so-called “*typical*” antipsychotic drugs, such as chlorpromazine, block both D_1 and D_2 receptors, while others, like haloperidol, are selective for D_2 receptors. Typical antipsychotic drugs are prone to induce extrapyramidal side effects, which include Parkinsonism, dystonia, and choreiform movements (tardive dyskinesia). “A*typical*” antipsychotics were originally defined by their diminished risk of extrapyramidal side effects compared with typicals, and mechanistically this has been traditionally linked with blockade of D_2 dopamine receptors and $5HT_{2A}$ serotonin receptors with little or no impact on D_1 receptors. Atypical antipsychotics are thought to be more effective in reducing cognitive and negative symptoms of schizophrenia than the typical antipsychotics, although it is not clear to what extent the interaction with serotonin receptors improves the antipsychotic effect or reduces some of the unwanted effects of dopamine receptor blockade. As the full beneficial effects of antipsychotic drugs can take weeks to develop, it is apparent that the therapeutic mechanism involves more than mere blockade of the D_2 receptor site. An additional side effect of antipsychotic drugs is elevated serum prolactin, resulting from a disturbance of dopamine-mediated regulation of prolactin secretion. The consequences of hyperprolactinemia include menstrual disturbances, galactorrhea, sexual dysfunction, gynecomastia, infertility, decreased bone mineral density, and possibly breast cancer. Atypical antipsychotics with an especially high affinity for D_2 receptors, such as risperidone (Risperdal), are more prone to induce hyperprolactinemia, whereas this side effect is rare with those drugs that bind to D_2 less avidly, such as aripiprazole (Abilify), clozapine (Clozaril), olanzapine (Zyprexa), quetiapine (Seroquel), and ziprasidone (Geodon). Although clozapine was discovered in 1959 and first used as an antipsychotic in the 1970s, it still has an important role in combatting treatment-resistant schizophrenia with a low likelihood of extrapyramidal side effects. Current thinking is that clozapine's combined actions at several receptors may be responsible for its therapeutic properties. However, even with careful monitoring, approximately 0.4% of patients treated with clozapine develop serious agranulocytosis. Of the newer antipsychotic drugs, olanzapine has the closest receptor profile to clozapine. Weight gain and induction of metabolic syndrome are central challenges to the use of several atypical drugs, especially with olanzapine, and coadministration of medications such as metformin or samidorphan have been utilized to combat these side effects

D_2-like agonists have an important role in the symptomatic treatment of Parkinson disease. Such drugs include apomorphine, a D_2 agonist, and also pramipexole (Mirapex) and ropinirole (Requip), which are D_2-like agonists with the greatest affinity for the D_3 receptor. Nonselective dopamine agonists (e.g., rotigotine) have also been used to treat symptoms of Parkinson disease, in addition to restless legs syndrome.

Historically, GPCRs were believed to function as monomeric units; however, it is now apparent in some instances, specific biogenic amine receptors may directly interact with other members of the same receptor family or even with structurally divergent families of receptors to form heteromers (e.g., D1-D2, D2-5HT2, D2-cannabinoid receptor-1) which have unique functional properties. Pharmacologic targeting of heteromers offers a novel strategy for the therapeutic manipulation of cell signaling.

Adrenergic Receptors

For many years, receptors for norepinephrine and epinephrine (adrenergic receptors) were divided into just three distinct classes, α_1, α_2, and β. A postsynaptic location is typical for α_1- and β-receptors, whereas α_2-receptors exist both pre- and postsynaptically. Currently, three α_1

subtypes (α_{1A}, α_{1B}, α_{1D}), four α_2-receptor subtypes ($\alpha_{2A–D}$), and three β-receptor subtypes ($\beta_{1–3}$) are recognized (Fig. 1.7–3). All β-receptors are Gs-coupled, whereas most α_1-receptors are Gq-coupled, and α_2-receptors are typically Gi-coupled. As norepinephrine is the transmitter used by most postganglionic neurons of the autonomic nervous system (ANS), agonists and antagonists at various adrenergic receptors exert profound effects on the functioning of many peripheral organs by mimicking or blocking the sympathetic innervation respectively. Agonists are referred to as "*sympathomimetics*" and antagonists as "*sympatholytics.*" In the brain, the LC noradrenergic system exerts a widespread influence on neuronal circuits that are essential substrates of arousal and cognition, and several affective disorders have been posited to involve a dysregulation of noradrenergic neurotransmission. In addition, by sending direct projections to the sympathetic preganglionic neurons in the spinal cord and parasympathetic preganglionic neurons in the brainstem and spinal cord, the noradrenergic LC plays a central role in regulating autonomic activity.

The predominant peripheral effect of α_1-adrenergic agonists is the constriction of arterial smooth muscle, which in turn causes an increase in blood pressure, and drugs such as phenylephrine and methoxamine are used occasionally in the clinic to increase blood pressure during a hypotensive crisis. α_1-Adrenergic agonists are also widely used as nasal decongestants, and their decongestant activity is mediated by constriction of blood flow to the nasal mucosa and by a reduction in airway secretions. Antagonists of α_1-adrenergic receptors inhibit smooth muscle contraction and reduce arteriolar resistance by dilating arteries. Their major uses are as an adjuvant treatment for hypertension and for treating symptomatic benign prostatic hypertrophy. α_1-Antagonists such as prazosin (Minipress) have also been shown to be useful in treating some of the symptoms of post-traumatic stress disorder (PTSD).

α_2-Adrenergic agonists, like clonidine (Catapres) and guanfacine (Intuniv), have been used to combat hypertension and the mechanism appears to be a reduction in sympathetic tone elicited by activation of α_2-receptors in the anterior hypothalamus. α_2-Adrenergic agonists also have a role in the treatment of certain CNS disorders, especially those involving prefrontal cortex dysfunction. Damage to the catecholaminergic innervation of the prefrontal cortex impairs performance in tests of executive function, and although dopamine has a prominent role in mediating the effects of these lesions, substantial evidence indicates that norepinephrine also exerts a potent modulatory influence on prefrontal cortex functions. Early pharmacologic studies on the role of α_2-receptors in prefrontal cortex function focused on clonidine, although this drug produces mixed effects, presumably due to competing pre- versus postsynaptic effects and limitations from the sedative and hypotensive side effects. A superior profile has been observed with the more selective α_{2A}-agonist, guanfacine, which can improve working memory in animals and in some human populations, possibly by binding to postsynaptic α_{2A}-receptors and increasing noradrenergic tone. Guanfacine is now being used to treat a variety of disorders with prominent prefrontal cortex dysfunction, including Tourette syndrome and ADHD. Clonidine is also employed to manage the acute phase of opioid withdrawal, an effect achieved by normalizing the hyperactivity of noradrenergic LC neurons.

β-Adrenergic agonists have profound effects on the cardiac and pulmonary systems and are one of the primary agents used to treat asthma and other chronic obstructive pulmonary diseases. Antagonists of β-adrenergic receptors are mainstays in the treatment of ischemic heart disease and hypertension. β-Adrenergic antagonists, such as propranolol, are also effective in reducing signs of increased sympathetic activity in individuals with social anxiety (stage fright), such as hand tremor, sweating, and rapid heartbeat. Preclinical studies have demonstrated that propranolol reduces the reconsolidation of fear memories, although its effectiveness in the treatment of PTSD has not been resolved.

SEROTONIN

Anatomy and Functions

Mammals employ serotonin (5HT) as a neurotransmitter within both the CNS and peripheral nervous systems. Serotonin is also produced in many cells that are not neurons, such as mast cells and enterochromaffin cells, and bloodborne serotonin is taken up and concentrated in platelets. More than 80% of the serotonin in the body occurs in the GI system, where it modulates motility and digestive functions. In the brain, only one in a million neurons produces serotonin, yet this evolutionary ancient signaling molecule influences virtually all aspects of CNS function due to the extensive innervation pattern of the neurons. Due to this widespread distribution in the brain, serotonin has been implicated in a vast array of physiologic and pathologic processes.

The populations of serotonergic cell bodies, classified as groups B1–B9, are clustered in multiple midline raphe nuclei of the brainstem. The caudal raphe nuclei send descending projections into the medulla, cerebellum, and spinal cord, which are involved in motor activity, pain control, and regulation of autonomic processes. The more rostrally located dorsal and median raphe nuclei send ascending axonal projections to the rest of the brain. The median raphe provides most of the serotonergic fibers that innervate the limbic system, while the dorsal raphe nucleus provides most of the serotonergic fibers that innervate the cerebral cortex, thalamus, and striatum, in addition to the dopaminergic neurons residing in the substantia nigra and VTA. These rostral serotonergic systems have a modulatory role in many functions, including mood, anxiety, aggression, cognition, feeding, the sleep–wake cycle, and sexual behavior. The link between serotonin and depression is particularly compelling, and the clinical efficacy of antidepressant drugs is strongly associated with an enhancement of serotonergic function.

Interestingly, the projections from the dorsal and median raphe can be distinguished morphologically. Dorsal raphe serotonergic fibers are very fine, with small vesicle-coated swellings called varicosities that are fusiform or granular in appearance, while median raphe fibers are thicker with large spherical or beaded varicosities. The two systems coexist in most areas of the brain, although the ratio varies considerably. The striatum, thalamus, and dopaminergic cell bodies in the midbrain receive innervation predominantly by the neurons originating in the dorsal raphe, while the hippocampus, septum, and hypothalamus receive a particularly high proportion of fibers arising in the median raphe. In the cerebral cortex, there is extensive overlap between dorsal and median raphe projections. The two types of fibers exhibit differential sensitivity to the neurotoxic effects of the amphetamine analog 3,4-methylenedioxy-methamphetamine (MDMA, “ecstasy”), which causes long-lasting or permanent damage to the fine axons of the dorsal raphe while sparing the thick beaded axons of the median raphe.

Life Cycle

Synthesis. In the brain, the first step in serotonin synthesis is the active uptake of the dietary amino acid tryptophan across the BBB and then into neurons (Fig. 1.7–4). Brain tryptophan is utilized in all brain cells for protein synthesis, in addition to serving as a substrate for transmitter synthesis in serotonin neurons. The carrier processes that transport tryptophan from plasma into the brain and from the extracellular fluid into neurons are open to competition from LNAAs, including other aromatic amino acids (e.g., tyrosine and phenylalanine), branched-chain amino acids (e.g., leucine, isoleucine, and valine), and others (e.g., methionine and histidine). The competitive nature of the LNAA carrier means that brain levels of tryptophan will be determined not only by the plasma concentration of tryptophan but also by the plasma concentration of competing neutral amino acids. The rate-limiting enzyme for the synthesis of serotonin in the brain, tryptophan hydroxylase, is not saturated under normal physiologic conditions. Therefore, any decrease or increase in brain tryptophan levels results in a reduction or stimulation of serotonin synthesis, respectively. Thus, dietary protein and carbohydrate content can specifically influence brain tryptophan and serotonin levels by effects on plasma amino acid patterns. Because plasma tryptophan has a daily rhythmic variation in its concentration, this concentration variation can also influence the rate and synthesis of brain serotonin. However, it is unclear to what extent pre- and postsynaptic homeostatic mechanisms prevent tryptophan-induced alterations in serotonin synthesis from being translated into changes in neurotransmission.

FIGURE 1.7–4. Biosynthesis of serotonin and melatonin. Serotonin (5-hydroxytryyptamine, 5HT) and melatonin are produced by a multistep synthesis that starts with the dietary amino acid, tryptophan. Cells in the

pineal gland are the major site of melatonin synthesis, and they contain the enzymes AANAT and ASMT that are necessary to convert serotonin to melatonin. AADC, aromatic amino acid decarboxylase; AANAT, aralkylamine *N*-acetyltransferase (also known as serotonin acetylase); ASMT, acetylserotonin O-methyltransferase (also known as hydroxyindole O-methyltransferase); TPH, tryptophan hydroxylase.

Tryptophan hydroxylase catalyzes the formation of 5-hydroxytryptophan from tryptophan, and this step in the synthesis of serotonin can be specifically blocked by p-chlorophenylalanine, which competes directly with tryptophan and binds irreversibly to the enzyme. Once synthesized from tryptophan, 5-hydroxytryptophan is almost immediately decarboxylated to yield serotonin. The enzyme responsible for this conversion is AADC and is identical to the enzyme that decarboxylates L-dopa in dopamine and norepinephrine neurons. AADC is widespread in distribution; it is found in the peripheral and CNS associated with catecholamine- and serotonin-containing neurons and in the adrenal and pineal glands. It is also found in the kidney, liver, and various other tissues in which little or no monoamine transmitter is normally produced. It is possible to increase serotonin formation experimentally by administering 5-hydroxytryptophan and bypassing the rate-limiting tryptophan hydroxylase step. Thus, unlike tryptophan administration, which can result in a selective increase in serotonin in serotonin-containing neurons, 5-hydroxytryptophan administration will result in the nonspecific formation of serotonin at all sites containing AADC, including the catecholamine-containing neurons.

In the pineal gland, serotonin can be further metabolized by acetylation and O-methylation to form melatonin. Tryptophan is a precursor to serotonin and melatonin, yet ingestion of large quantities of tryptophan will not amplify the production of melatonin in the pineal because of the restricted availability and activity of enzymes necessary to complete this conversion. Melatonin has a major role in the regulation of cyclic bodily activities. The suprachiasmatic nucleus of the anterior hypothalamus is the master clock controlling circadian rhythms in mammals, and it controls melatonin secretion from the pineal by an indirect pathway in response to the environmental light/dark cycle. Peak melatonin secretion occurs during darkness. Melatonin signals both the time of the day (“clock” function) and the season of the year (“calendar” function) to many tissues of the body. Melatonin is available for over-the-counter use as a hypnotic agent to induce sleep but has limited effectiveness in healthy subjects at night when endogenous production of melatonin is high. Administration of melatonin may be of use to treat jet lag or to help shift workers adjust to new work hours. Melatonin agonists have been developed and recently marketed, such as ramelteon (Rozerem).

Transporters. After the synthesis of serotonin in the cytoplasm, it is actively sequestered and concentrated in synaptic vesicles to await release (Fig. 1.7–5). The uptake of serotonin into vesicles is accomplished by VMAT-2 in the brain and is inhibited by drugs such as reserpine and tetrabenazine. Once released into the synapse, serotonin can interact with pre- and postsynaptic serotonin receptors. The synaptic effects of serotonin are limited by reuptake into the presynaptic terminal and by enzymatic conversion of serotonin to inactive metabolites. Reuptake serves as the major mechanism for the termination of the action of synaptic serotonin. The primary targets for the TCAs such as amitriptyline (Elavil), clomipramine (Anafranil), desipramine (Norpramin), imipramine (Tofranil), and nortriptyline (Pamelor) is blockade of serotonin and NETs, which prolongs the action of the transmitters in the synapse, although this class of drug possesses several other pharmacologic actions. Newer selective serotonin reuptake inhibitors (SSRIs) are now the most widely prescribed antidepressants and antianxiety medications, such as citalopram (Celexa), escitalopram (Lexapro), fluoxetine (Prozac), fluvoxamine (Luvox), sertraline (Zoloft), and paroxetine (Paxil). More recently, SNRIs, such as duloxetine (Cymbalta), venlafaxine (Effexor), and desvenlafaxine (Pristiq), have been introduced for the treatment of depressive disorders. SSRIs are also acknowledged as the first-line pharmacologic treatment of choice for obsessive-compulsive disorder (OCD). A polymorphism occurs in the promoter region of the serotonin transporter gene that affects the function of the protein, and this finding has provoked considerable controversy over the possible consequences of a particular variant (short allele of 5-HTTLPR). It now appears that there is a small but significant effect of this polymorphism on susceptibility for bipolar depression (BPD) and a reduced remission rate following antidepressant treatment.

Psychomotor stimulants like amphetamine enter monoamine nerve terminals via DAT, NET and the serotonin transporter (SERT) and stimulate the release of all three monoamines into the synapse by rapid reverse transport. Halogenated amphetamine derivatives (e.g., fenfluramine) are selective for SERT compared with DAT and NET. There is some evidence that the appetite-suppressing action of fenfluramine is mediated by the release of serotonin and activation of $5HT_{2C}$ receptors in the medial hypothalamus. Fenfluramine alone or in combination with phentermine (called “fen-phen”) was formerly prescribed as an appetite suppressant. However, fenfluramine was withdrawn from the market when it was found to be associated with a high incidence of pulmonary hypertension and valvular heart disease. This toxic effect is believed to be related either to the peripheral release of serotonin from platelets or, more likely, as a result of activation of cardiac $5HT_{2B}$ receptors by norfenfluramine, the main metabolite of fenfluramine.

Metabolism. Serotonin is enzymatically degraded by MAO, and the product of this reaction, 5-hydroxyindoleacetaldehyde, is oxidized to 5-hydroxyindoleacetic acid (5-HIAA). Some research has shown that people with a particular loss-of-function variant of the MAO-A gene are predisposed to violence and other antisocial behaviors, but this research is quite controversial. Inhibitors of MAO were the first drugs to be marketed as antidepressants, and these monoamine oxidase inhibitors (MAOIs) were not selective for the A or B isoforms and inhibited the enzyme irreversibly, such as tranylcypromine (Parnate) and phenelzine (Nardil). However, the propensity of tyramine-rich foods (such as cheese) to provoke dangerous hypertensive reactions in patients taking these MAOIs was soon recognized and forced their use to be severely curtailed. As the intestinal mucosa contains MAO-A predominantly, it is an important site for metabolizing ingested MAO substrates like tyramine. When intestinal MAO-A is inhibited, dangerous amounts of tyramine can enter the circulation and release norepinephrine from sympathetic neurons and epinephrine from the adrenal medulla, where the metabolism of these transmitters is blunted because of MAO-A inhibition, leading to a pressor response. Selective MAO-B inhibitors were shown to be safer with regard to this “cheese reaction” but unfortunately lacked antidepressant efficacy. Nevertheless, the selective MAO-B inhibitor, selegiline, is marketed as an antidepressant but has to be used at high enough doses to inhibit MAO-A. The delivery of selegiline transdermally (Emsam) is designed to reduce the risk of tyramine-provoked reactions by minimizing inhibition of GI and hepatic MAO-A activity while allowing inhibition of central MAO-A and

MAO-B. Reversible inhibitors of MAO-A (RIMA) (e.g., moclobemide) are efficacious in depressive disorders and appear relatively safe with respect to tyramine sensitivity.

FIGURE 1.7–5. Schematic model of a serotonin synapse with sites of drug action. **Site 1:** Tryptophan is taken up into the neuron by an active transport mechanism and converted to 5-OH-tryptophan by the rate-limiting enzyme tryptophan hydroxylase; this enzyme can be effectively inhibited by p-chlorophenylalanine. AADC converts 5-OH-tryptophan to serotonin. **Site 2:** Serotonin is taken up and stored in vesicles by VMAT-2. Reserpine and tetrabenazine interfere with the uptake–storage mechanism of the amine granules, causing a marked depletion of serotonin. **Sites 3, 4, and 5:** Once released, serotonin can interact with as many as 14 different receptors. A number of G-protein–coupled serotonin receptors are located postsynaptically. Lurasidone (Latuda), a novel antipsychotic drug with possible procognitive properties, has high affinity for the 5HT7 receptor (**site 3**). The anxiolytics, buspirone (Buspar) and gepirone (Ariza), are 5HT1A receptors (**site 4**). Many antipsychotic drugs inhibit 5HT2A receptors (**site 5**). The hallucinogenic effects of drugs such as LSD, mescaline, and psilocybin are mediated by agonist interactions at the 5HT2A receptor. **Site 6:** In contrast to the other serotonin receptors, the 5HT3 receptor is a ligand-gated ion channel. Ondansetron is a 5HT3 antagonist that is an effective antiemetic and lacks parkinsonian side effects inherent in D2 antagonists like metoclopramide (Reglan) or prochlorperazine (Compazine). **Site 7:** Serotonin autoreceptors

(5-HT1B rodent and 5-HT1D human) modulate the stimulus-induced release of serotonin and are located on the presynaptic terminals. 5HT1A autoreceptors are located on the serotonin cell bodies and dendrites where they modulate impulse flow. Antimigraine triptan drugs, such as sumatriptan (Imitrex), are 5HT1D/1B agonists. **Site 8:** Termination of the synaptic actions of serotonin is accomplished by its reuptake into the neuron by the serotonin transporter. SSRIs and SNRIs are classes of antidepressant that inhibit the serotonin transporter and increase the synaptic actions of serotonin. The halogenated amphetamine, fenfluramine, causes release of serotonin by rapid reverse transport. **Site 9:** Synaptic actions of serotonin are also attenuated by its metabolism. Inhibitors of MAO-A block metabolism of serotonin and are used as antidepressants. Examples of irreversible inhibitors are isocarboxazid (Marplan), phenelzine (Nardil), and tranylcypromine (Parnate), whereas moclobemide inhibits MAO-A reversibly. 5HIAA, 5-hydroxyindoleacetic acid; 5HT1–7, subtypes of serotonin receptor; 5-OH-tryptophan, 5-hydroxytryptophan; AADC, aromatic amino acid decarboxylase; AC, adenylate cyclase; cAMP, cyclic AMP; DAG, diacylglycerol; G, G protein; IP3, inositol triphosphate; MAO, monoamine oxidase; SSRI, selective serotonin reuptake inhibitor; VMAT, vesicular monoamine transporter. (Modified from Nestler E, Hyman S, Holtzman D, Malenka R. *Molecular Neuropharmacology*. McGraw-Hill Companies, Inc; 2015.)

Receptors

Seven distinct families of 5HT receptors have been identified (5HT$_1$ to 5HT$_7$), and subpopulations have been described for several of these (Fig. 1.7–5). All of them except the ionotropic 5HT$_3$ receptor are G protein coupled. For serotonin GPCRs, three main types of primary coupling to G proteins have been described. The 5HT$_1$ and 5HT$_5$ receptors activate Gi/Go proteins, the 5HT$_2$ receptors activate Gq/11, and the 5HT$_4$, 5HT$_6$, and 5HT$_7$ activate Gs receptors.

5HT$_1$ Receptors. 5HT$_1$ family comprises five different gene products: 5HT$_{1A}$, 5HT$_{1B}$, 5HT$_{1D}$, 5HT$_{1E}$, and 5HT$_{1F}$ receptors. The 5HT$_{1A}$ receptor is the most widely distributed, and they are expressed on the soma and dendrites of all serotonin neurons, where they serve as autoreceptors to regulate cell excitability and the synthesis and release of 5HT. 5HT$_{1A}$ receptors are also located postsynaptically and on astrocytes and other glia. Partial 5HT$_{1A}$ agonists, such as buspirone (Buspar), are clinically useful anxiolytic drugs, and they augment the efficacy of antidepressants in the treatment of depression.

$5HT_{1B}$ and $5HT_{1D}$ receptors resemble each other in structure and distribution. They are predominantly located on the presynaptic terminals of serotonin neurons, where they function as autoreceptors to control local synthesis and release of 5HT. $5HT_{1B}$ receptors are also present on axon terminals of nonserotonergic neurons, where they act as heteroreceptors to control the presynaptic function of other transmitters. The serotonergic system has long been linked to migraine, and $5HT_{1B/D}$ agonists, such as sumatriptan (Imitrex) and other triptan drugs, are effective treatments for these types of headaches. The mechanism is not clear, however, and may be due either to vasoconstriction induced by activation of $5HT_{1B}$ and $5HT_{1D}$ receptors on cranial blood vessels or to modulation of activity in trigeminal afferents that carry pain information from the meninges. With the development of PET ligands for $5HT_{1B}$, these receptors have been implicated in the biology of psychiatric disorders, including PTSD and major depression. The antagonist of $5HT_{1B}$ and β-adrenergic receptors, pindolol, has been reported to augment the efficacy of antidepressant medications by promoting 5HT release, but this is not yet firmly established.

$5HT_{1E}$ is a highly expressed receptor in the human brain and is particularly enriched in the hippocampus and frontal cortex, making it a possible drug target for memory disorders, such as Alzheimer disease or temporal lobe epilepsy. Interestingly, this receptor subtype is absent in rats and mice. Research into the functions of the $5HT_{1E}$ receptor has been hampered by the lack of selective pharmacologic tools and specific antibodies.

Expression of $5HT_{1F}$ has been reported in various brain regions, in addition to the trigeminal ganglia and cerebral blood vessels. Triptans, which are used to treat migraine, have an appreciable affinity for $5HT_{1F}$ receptors, and the development of $5HT_{1F}$ agonists may provide promising new treatments for migraine.

$5HT_2$ Receptors. The $5HT_2$ family has three members, $5HT_{2A}$, $5HT_{2B}$, and $5HT_{2C}$, which share similarities in amino acid sequence and signaling properties. They all are coupled to phospholipase C (PLC) by Gq/11.

$5HT_{2A}$ is expressed widely throughout the brain, with especially high abundance in the cortex, where it is present in both interneurons and pyramidal neurons. The disturbance in sensory perception induced by hallucinogenic (psychedelic) drugs (e.g., D-lysergic acid diethylamide [LSD], mescaline, psilocybin, and 2,5-dimethoxy-4-methylamphetamine) is mediated by full or partial agonism at the $5HT_{2A}$ receptor. Second-generation antipsychotic drugs are characterized by their relatively higher potency as antagonists at the $5HT_{2A}$ site compared to D_2 receptors. There is some evidence that downregulation of $5HT_{2A}$ receptors and/or $5HT_{2C}$ receptors may be an adaptive mechanism contributing to the antidepressant effect of SSRIs, and in fact, blockade of $5HT_{2A}$ or $5HT_{2C}$ receptors enhances antidepressant-like effects of SSRIs in animal models. In agreement with this hypothesis is evidence of the effectiveness of atypical antipsychotic drugs given with SSRIs in treatment-resistant depression. Pimavanserin (Nuplazid) exhibits inverse agonist and antagonist activity at the $5HT_{2A}$ receptor and has been approved for the treatment of hallucinations and delusions associated with psychosis in patients suffering from Parkinson disease. Preliminary clinical data suggest that pimavanserin may also be beneficial for the short-term treatment of dementia-related psychosis. One useful effect of $5HT_{2A}$ receptor activation is a reduction in intraocular pressure, and this has led to the development of compounds that reduce pressure inside the eyes but without crossing the BBB and producing hallucinogenic side effects.

$5HT_{2B}$ receptors have a restricted expression in the CNS, which contrasts with their relative abundance in the periphery. Research on $5HT_{2B}$ has been limited due to the cardiotoxicity of $5HT_{2B}$ agonists, yet the addition of the atypical antipsychotic, aripiprazole (Abilify) which has a high affinity for $5HT_{2B}$ receptors, to antidepressants such as SSRIs have been reported to produce beneficial effects in treatment-resistant depressed patients.

The $5HT_{2C}$ receptor has a widespread and heterogeneous distribution in the brain. $5HT_{2C}$ receptors have been implicated in the mechanism underlying weight gain resulting from chronic administration of antipsychotic drugs, as those with the potential to produce weight gain, such as clozapine (Clozaril) and olanzapine (Zyprexa), have a greater affinity for the $5HT_{2C}$, compared with $5HT_{2A}$ receptor. Antipsychotic drugs that are more selective antagonists at the $5HT_{2A}$ subtype have less liability for weight gain. Agonists at the $5HT_{2C}$ receptor are being investigated as antiobesity agents. Interestingly, $5HT_{2C}$ in humans is located at the X chromosome, whereas all other 5HT receptors are autosomal. Thus, it is possible that polymorphisms at this receptor would affect the two sexes differently. $5HT_{2C}$ polymorphism appears to influence levels of circulating leptin, providing a potential mechanism underlying the genetic association of the $5HT_{2C}$ receptor with weight gain. $5HT_{2C}$ receptors are closely linked with the midbrain dopamine neurons, being able to regulate dopamine release in its terminal regions. For example, the firing rate of VTA dopamine neurons is inhibited or increased by $5HT_{2C}$ agonists or antagonists, respectively, such that $5HT_{2C}$ receptors regulate the release of dopamine in the nucleus accumbens. The basis for this interaction is the location of $5HT_{2C}$ receptors in the VTA on both dopamine and GABA neurons that innervate the nucleus accumbens. Because of the involvement of $5HT_{2C}$ receptors with the VTA-nucleus accumbens pathway, specific ligands for this receptor subtype are under development for the treatment of schizophrenia and substance abuse disorders.

$5HT_3$ Receptors. As mentioned above, the $5HT_3$ receptor is a ligand-gated ion channel, so it differs markedly in structure and mechanism from the other 5HT receptor subtypes. $5HT_3$ receptors are located in many brain areas, with the highest densities in the medulla and spinal cord. Some $5HT_3$ receptors can be located postsynaptically, but in many regions, they also are frequently expressed presynaptically, where their activation modulates the release of a variety of neurotransmitters. $5HT_3$ antagonists, such as ondansetron (Zofran), granisetron (Kytril), dolasetron (Anzemet), and palonosetron (Aloxi) are used clinically in the treatment of emesis associated with cancer chemotherapy and radiotherapy and to combat symptoms of irritable bowel syndrome. Owing to the unfavorable effects of $5HT_3$ agonists (e.g., nausea and anxiety), no clinical use of these is likely in the near future. In the periphery, $5HT_3$ receptors are prominently expressed in a variety of peripheral ganglia, and they have been proposed to modulate nociception and pain responses, as well as enteric and cardiovascular reflexes.

$5HT_4$ Receptors. These receptors are present in the brain and periphery. The $5HT_4$ agonist cisapride (Propulsid) is in clinical use as a gastroprokinetic agent to increase motility in the upper GI tract.

$5HT_5$ and $5HT_6$ Receptors. Although $5HT_5$ receptors have been detected in the brain, so far, no drug with selectivity for this subtype is used clinically. However, animal studies suggest that $5HT_{5A}$ receptor antagonists have the potential to treat cognitive impairments associated with schizophrenia. The $5HT_6$ receptor is expressed almost exclusively in the brain, and its abundance in limbic and cortical regions has stimulated considerable research interest, as it is blocked by some antipsychotic medications. Several selective $5HT_6$ ligands reached clinical trials to treat cognitive deficits in Alzheimer disease, but none achieved significant efficacy in the selected populations.

$5HT_7$ Receptors. The $5HT_7$ receptor has been identified in many brain regions, in addition to its presence in the periphery. There is evidence for the existence of both presynaptic and postsynaptic $5HT_7$ receptors. The function of this receptor has been most firmly linked with the control of circadian rhythm and thermoregulation. However, a major recent interest in $5HT_7$ receptors derives from their possible relevant role in cognitive processes, and the presence of $5HT_7$ receptors in the hippocampus and prefrontal cortex supports this. Furthermore, it is relevant that several antipsychotics and antidepressants have a high affinity for the $5HT_7$ receptor, which may contribute to their beneficial effects. $5HT_7$ has also been implicated in the modulation of structural plasticity in adolescent and mature brain circuits. Lurasidone (Latuda) is an atypical antipsychotic drug that is a particularly potent $5HT_7$ antagonist and is used to treat schizophrenia and depressive episodes associated with bipolar 1 disorder. Studies have even indicated that lurasidone can have procognitive properties in normal monkeys.

ACETYLCHOLINE

Anatomy and Function

In the brain, the axonal processes of cholinergic neurons either project to distant targets or contact cells locally within the same region (interneurons). Widely projecting cholinergic neurons originate from several clusters of cells within the basal forebrain complex and mesopontine complex in the upper brainstem. The basal forebrain population of cholinergic neurons comprises locations in the medial septal nucleus, the diagonal band, and the nucleus basalis of Meynert, and these neurons provide the vast majority of the cholinergic innervation to the telencephalon. Within the mesopontine complex, cholinergic neurons are located in the pedunculopontine nucleus and in the laterodorsal tegmental nucleus and innervate the thalamus, and midbrain regions (including the substantia nigra and VTA), in addition to descending innervations to regions such as the LC and dorsal raphe. While long projecting cholinergic neurons do innervate the striatum, the principal source of striatal acetylcholine is the cholinergic interneuron, which comprises only about 1% to 2% of all striatal cells, yet sends dense arbors of projections throughout the striatum. As would be predicted from their widespread distribution in the brain, central cholinergic neurons are involved in a wide variety of processes such as cognition, learning and memory, arousal, motor control, and CBF. In Alzheimer disease, there is significant degeneration of neurons in the nucleus basalis, leading to a substantial reduction in cortical cholinergic innervation. The extent of neuronal loss correlates with the degree of dementia, and the cholinergic deficit may contribute to the cognitive decline in this disorder, consistent with the beneficial effects of drugs that promote acetylcholine signaling.

In the ANS, acetylcholine is responsible for preganglionic transmission for both parasympathetic and sympathetic neurons and also at postganglionic synapses for the parasympathetic system. However, there are exceptions to this organization, such as the sympathetic innervation of adrenal glands and sweat glands that are provided by acetylcholine.

Life Cycle

The intraneuronal synthesis of acetylcholine involves only a single-step reaction (Fig. 1.7–6). The substrate choline is transported into cholinergic neurons by both high- and low-affinity mechanisms, and acetylcholine is formed when the enzyme choline acetyltransferase catalyzes the transfer of an acetyl group from cytoplasmic acetyl coenzyme A to choline. The rate-limiting step in acetylcholine synthesis is the high-affinity uptake of choline, and while it is not clear how this is regulated, it is known that increased neuronal activity enhances choline entry into neurons, and high-affinity uptake is blocked by hemicholinium. Once synthesized, acetylcholine is taken up into vesicles by the vesicular cholinergic transporter, a process that can be inhibited by vesamicol.

Several potent toxins affect the release of acetylcholine from vesicles into the synapse. Botulinum toxin A and tetanus toxin are derived from bacteria and prevent the release of acetylcholine, resulting in paralysis. However, if it is injected in small amounts, botulinum toxin can weaken a muscle locally, and this effect has been utilized in the treatment of spasms and dystonias and as a cosmetic application in smoothing facial wrinkles (Botox). Once released from the presynaptic neuron into the synapse, acetylcholine is not recaptured by an uptake mechanism, as occurs with the other biogenic amines. Instead, the termination of cholinergic transmission is primarily dependent on the breakdown of acetylcholine to choline and acetate, a reaction catalyzed by AChE, an enzyme that exists both in soluble and membrane-bound forms. Almost half the choline released by the metabolism of acetylcholine is taken back up into neurons for reuse. Inhibition of AChE activity by drugs enhances the stimulation of cholinergic receptors by acetylcholine. Neostigmine (Prostigmin) is a reversible inhibitor that does not cross the BBB and is used to improve muscle tone in cases of myasthenia gravis. As AChE inhibitors decrease fluid pressure in the eye, they are used to treat certain types of glaucoma. Centrally acting reversible inhibitors of AChE that penetrate the brain well after oral administration, such as donepezil (Aricept) and rivastigmine (Exelon), are used to improve the symptoms of Alzheimer disease and dementia associated with Parkinson disease. Irreversible inhibitors of AChE permanently inactivate the enzyme, such that restoration of activity requires synthesis of new protein, and such compounds are employed as insecticides and have been used as nerve gases (e.g., sarin, soman) in chemical warfare.

Receptors

Acetylcholine receptors fall into two major classes, muscarinic and nicotinic receptors, named for their respective naturally occurring agonists, muscarine and nicotine (Fig. 1.7–6).

Muscarinic Receptors. Five subtypes of muscarinic receptors (M_1 to M_5) have been cloned, and all are present in the brain. They are coupled to G proteins and either act directly on ion channels or are linked to a variety of second-messenger systems. M_1, M_3, and M_5 are Gq/11 coupled, whereas M_2 and M_4 are Gi/o coupled. Owing to the lack of specific activators or inhibitors of the subtypes, the roles of each subtype in the brain have not been well delineated. M_1 and M_3 are primarily located in the cerebral cortex and hippocampus and mediate some of the effects of acetylcholine on learning and memory. High densities of M_1 and M_4 are located in the striatum and presumably mediate cholinergic signaling in extrapyramidal motor circuits and response to rewards. M_2 receptors are concentrated in the basal forebrain, where they function as autoreceptors to control the synthesis and release of acetylcholine. The M_5 receptor is expressed at low levels in the brain and is present in substantia nigra and VTA. A recent short-term trial of the M1- and M4-selective muscarinic receptor agonist, xanomeline, in combination with a peripherally acting cholinergic antagonist to limit side effects, revealed a significant improvement in positive and negative symptoms in schizophrenia, which is an interesting development as xanomeline has no appreciable affinity for dopamine receptors. Nonspecific muscarinic agonists include some naturally occurring alkaloids such as pilocarpine and arecoline and synthetic compounds such as carbachol, oxotremorine, and bethanechol. Such drugs are not used to treat CNS disorders but are employed to reduce symptoms of glaucoma and nonobstructive urinary retention and to treat the dry mouth that occurs in Sjogren syndrome. Arecoline is the active ingredient in the areca nut and betel leaf that are chewed in many Asian cultures for the stimulating effect they induce. The most prominent adverse effects of muscarinic cholinergic agents (bradykinesia, GI distress, salivation, and sweating) are mediated by activation of peripheral M_1, M_2, and M_3 receptors.

FIGURE 1.7–6. Schematic model of an acetylcholine synapse with sites of drug action. **Site 1:** Choline is transported into the presynaptic terminal by an active uptake mechanism and converted to acetylcholine by a single enzymatic step. Acetyl coenzyme A required for acetylcholine synthesis is provided by presynaptic mitochondria. **Site 2:** Acetylcholine is taken up and stored inside vesicles. The vesicular transporter in cholinergic neurons is distinct from VMAT-2 present in other biogenic amine neurons and is blocked by vesamicol. **Site 3:** Release is promoted by black widow spider venom and blocked by botulinum toxin (peripheral synapse) and tetanus toxin (central synapse). **Sites 4 and 5:** After release, acetylcholine may interact with both G-protein–coupled muscarinic receptors (**sites 4 and 5**) on the postsynaptic cell. There are no muscarinic receptor subtype selective drugs, although some agents with partial selectivity are used experimentally. A clinically relevant nonselective muscarinic agonist is carbachol (Miostat), which is used in ophthalmologic procedures. A typical antagonist is atropine, which is also in ophthalmology and to reduce salivary secretions during surgery. A subtype of nicotinic receptors is activated by varenicline, which is used to treat nicotine dependence. Nicotinic receptors are blocked by the pharmacologic tools, α-bungarotoxin and hexamethonium. **Site 6:** Acetylcholine released from presynaptic terminals may also bind to nicotinic ligand-gated ion channels. A subtype of nicotinic receptors is activated by varenicline (Chantix), which is used to treat nicotine dependence. Nicotinic receptors are blocked by the pharmacologic tools, α-bungarotoxin, and hexamethonium. **Site 7:** Acetylcholine interacts with presynaptic muscarinic receptors to modulate subsequent release of transmitter. **Site 8:** In contrast to monoamine synapses, the plasma membrane transporter at a cholinergic synapse does not return the neurotransmitter to the presynaptic terminal but rather recycles precursor choline liberated after metabolism of acetylcholine. Hemicholinium-3 is a drug used to block choline transport experimentally. **Site 9:** Acetylcholine is metabolized by AChE, which present on both pre- and postsynaptic membranes, and serves to terminate its action. Examples of AChE inhibitors are physostigmine, which is used in eye drops to treat glaucoma, and donepezil (Aricept), which improves symptoms of Alzheimer disease. AChE, acetylcholinesterase; cAMP, cyclic AMP; DAG, diacylglycerol; G, G protein; IP3, inositol triphosphate; M1–5, subtypes of muscarinic receptor; MAO, monoamine oxidase; nAChR, nicotinic acetylcholine receptor; VMAT, vesicular monoamine transporter. (Modified from Nestler E, Hyman S, Holtzman D, Malenka R. *Molecular Neuropharmacology*. McGraw-Hill Companies, Inc; 2015.)

The prototypical muscarinic antagonists are atropine and scopolamine, which occur naturally in the plant deadly nightshade (Atropa belladonna). The translation of “belladonna” from Italian is “beautiful woman,” and this name was given because some women in Renaissance Italy applied belladonna berry juice to their eyes in order to dilate the pupils, giving them an alluring appearance, albeit with impaired vision. Ingestion of muscarinic antagonists leads to other effects resulting from inhibition of the parasympathetic nervous system, such as dry mouth, constipation, and urinary retention, in addition to central effects such as cognitive impairment and, in extreme cases, delirium. However, muscarinic antagonists have some therapeutic uses. For example, scopolamine has antiemetic activity and is used to treat nausea and vomiting caused by motion sickness. In addition, muscarinic antagonists such as benztropine (Cogentin) and trihexyphenidyl (Artane) are employed to treat the motor symptoms of Parkinson disease and are also sometimes helpful in ameliorating tardive dystonia, a possible side effect induced by long-term use of “typical” antipsychotic drugs. Many psychotropic drugs possess unwanted muscarinic antagonistic properties, including some TCAs and antipsychotic drugs. Some first-generation H_1 antagonist antihistamines are sold in over-the-counter hypnotics and antiallergy medications, and these drugs also have significant muscarinic antagonist actions that are responsible for side effects such as dry mouth, constipation, urinary retention, and even delirium to which geriatric patients are more susceptible.

Nicotinic Receptors. These are ligand-gated ion channels located at the neuromuscular junction, autonomic ganglia, adrenal medulla, brain, and spinal cord. Nicotinic receptors that are expressed in both neurons and muscle mediate rapid, excitatory signaling but differ in their subunit composition. Every nicotinic receptor consists of five subunit molecules organized around a central channel that opens to admit ions when the receptor is activated; they are arranged either in various homomeric (all one type of subunit) or heteromeric (at least one α and one β) groupings. The most common subtypes in the brain are the heteromeric α4β2-subtype and homomeric α7 receptors. The subunit combination affects the pharmacologic and functional properties of an individual complex, such as cation permeability and the rate of desensitization. These various nicotinic acetylcholine receptor subunits are categorized into functional classes: (1) neuronal (α_2–α_8 and β_2–β_4) and (2) skeletal (α_1, β_1, δ, γ, and ε). Neuronal nicotinic acetylcholine receptors are widely distributed in the brain, but they do not function only in the classical postsynaptic, directly excitatory manner of their muscle counterparts. Indeed, a large proportion of nicotinic binding sites are found on pre-, peri- and extrasynaptic sites in addition to the classic postsynaptic location. Nicotinic receptors have been implicated in several disorders and pathologic conditions. The most obvious role of neuronal nicotinic acetylcholine receptors is the mediation of reinforcing and addicting properties of nicotine in chronic tobacco and e-cigarette users, in addition to the symptoms of withdrawal experienced on cessation of use. The reinforcing effects of nicotine depend on its interaction with nicotinic receptors in the brain’s reward system, notably in releasing dopamine from neurons that originate in the VTA and innervate the nucleus accumbens. Mutations in one of the nicotinic receptor subunit genes contribute to a specific form of epilepsy, autosomal dominant frontal lobe epilepsy (ADNFLE). In addition, abnormal expression of α4β2 nAChRs has been implicated in several disorders, including autism spectrum disorders, nicotine addiction, and Parkinson disease. Alterations of α7 nAChR expression have been associated with various brain disorders, such as dementia and schizophrenia spectrum disorders. An interesting, distinctive property of ionotropic α7 receptors is their ability to activate downstream metabolic cascades, much like the metabotropic G-protein–coupled receptors. α_7-Nicotinic receptors have emerged as a potential therapeutic target for the treatment of neurocognitive dysfunctions in schizophrenia, Alzheimer disease, and Parkinson disease. Because of the evidence for their involvement in a number of CNS disorders, there is great interest in the future development of selective nicotinic receptor agonists as therapeutics. Although drugs such as hexamethonium and mecamylamine are useful pharmacologic tools used to block nicotinic receptors, there are relatively few nicotinic agonists or antagonists that are currently used therapeutically. One example is succinylcholine, a weak partial agonist at nicotinic receptors, which is used clinically during anesthesia as a paralytic agent. Varenicline (Chantix) is a partial agonist with selectivity at the α_4/β_2 nicotinic receptor, which is now widely marketed as medication to treat nicotine dependence and as an aid in the cessation of smoking. Galantamine (Razadyne) is an allosteric potentiator of several subtypes of neuronal nicotinic receptors and a weak competitive reversible inhibitor of AChE, which is also used in the treatment of Alzheimer disease.

HISTAMINE

Anatomy and Functions

Despite fulfilling a remarkably wide range of functions throughout the body, the role of histamine in the brain has not received as much attention as the other biogenic amines. Histamine-containing neuronal cell bodies are restricted to the tuberomammillary complex of the posterior hypothalamus. Like other biogenic amine neurons, the histaminergic system comprises long, highly divergent, mostly unmyelinated, varicose fibers that provide diffuse projections to many telencephalic, mesencephalic, and cerebellar structures. Individual neurons can innervate widely divergent areas but make few typical synaptic contacts. Functions closely associated with histaminergic projections are the regulation of sleep and arousal and the control of feeding and appetite. In the periphery, histamine released from mast cells plays an important role in allergic reactions, and histamine released from enterochromaffin-like cells and mast cells stimulates acid secretion in the stomach.

Life Cycle

Histamine is formed in the brain primarily by decarboxylation of histidine by the enzyme histidine decarboxylase (Fig. 1.7–7), although histidine is also a substrate for AADC, which is also involved in the synthesis of the catecholamines and serotonin. A mutation in the histidine decarboxylase gene has been implicated as a rare genetic cause of Tourette syndrome, and research with a mouse model bearing a knockout of this gene has shown it to recapitulate the core phenomenology of the disorder and has bolstered evidence for histamine-dopamine interactions in the basal ganglia to be a locus of pathology. The transporter protein responsible for concentrating histamine in synaptic vesicles has not been definitively established, although both reserpine and tetrabenazine, which interfere with VMAT-2 function, induce the release of brain histamine. In the brain, histamine is principally metabolized by histamine methyltransferase to the n-methylhistamine (tele-methylhistamine). In the periphery, histamine is also metabolized by diamine oxidase to imidazole acetaldehyde, an intermediate that is rapidly oxidized to imidazoleacetic acid. Unlike the other biogenic amines, there is no evidence for a specific high-affinity plasma membrane transporter to recapture and terminate the effects of released histamine in the brain. However, histamine is a substrate for some of the low-affinity transporters in the organic cation transporter (OCT) family and the low-affinity plasma membrane transporter.

Receptors

Four subtypes of histamine receptors have been identified (H_1 to H_4), and all belong to the G-protein–coupled superfamily of receptors (Fig. 1.7–7). In the brain, both H_1 and H_2 receptors are expressed in neurons postsynaptic to histamine terminals and also in glia. Blockade of H_1 receptors results in sedation, a side effect inherent in some antipsychotic drugs, such as clozapine (Clozaril), antidepressant drugs, such as doxepin (Deptran), and allergy medications, such as diphenhydramine (Benadryl) that inhibit H_1 receptors. In fact, the sedative property of doxepin is used therapeutically to alleviate the symptoms of primary insomnia. To overcome the sedating effect of H_1 antagonists in treating allergic reactions, newer nonsedating antihistamines, such as loratadine (Claritin), have been designed that do not cross the BBB. H_1 antagonists, such as meclizine (Antivert) and dimenhydrinate (Dramamine), are also employed in the treatment of motion sickness and vestibular disturbances such as Meniere disease.

FIGURE 1.7–7. Schematic model of a central histaminergic synapse with site of drug action. **Site 1:** Histidine is taken up into histamine-containing neurons and converted to histamine by histidine decarboxylase. This enzyme is distinct from AADC that is used in the synthesis of other biogenic amines. No inhibitors of the histidine decarboxylase are used clinically. **Site 2:** Histamine is accumulated in storage vesicles by the action of VMAT. Reserpine interferes with vesicular storage of histamine. **Sites 3 and 4:** After release histamine interacts with postsynaptic receptors. Chlorpheniramine and diphenhydramine possess H1 antagonist properties and are used as antiallergy medications. H1 antagonists, such as meclizine (Bonine) and dimenhydrinate (Dramamine) have proved useful in the treatment of motion sickness and vestibular disturbances. **Site 5:** Activation of autoreceptors serves to regulate subsequent release of histamine. Pitolisant is a selective inverse agonist at the H3 receptor that increases histamine release, and is used to treat excessive diurnal sleepiness. There are no therapeutic products that act as selective antagonists for H3 receptors. **Site 6:** There is no recapture of synaptic histamine, and its actions are terminated by metabolism by histamine n-methyltransferase. No selective drugs are used therapeutically to inhibit this enzyme. The metabolite, n-methylhistamine is a substrate for MAO. AADC,

aromatic amino acid decarboxylase; AC, adenylate cyclase; cAMP, cyclic AMP; H1–3, subtypes of histamine receptor; HNMT, histamine N-methyltransferase; G, G protein; MAO, monoamine oxidase; VMAT, vesicular monoamine transporter. (Modified from Nestler E, Hyman S, Holtzman D, Malenka R. *Molecular Neuropharmacology*. McGraw-Hill Companies, Inc; 2015.)

H_2 receptors are expressed in neurons postsynaptic to histamine terminals. Compared with H_1 receptors, much less is known of the function of H_2 receptors, partly due to the paucity of specific agonists and antagonists that penetrate the BBB, but their involvement has been implicated in memory retention and nociception. H_2 antagonists that do not cross the BBB, such as cimetidine (Tagamet) and famotidine (Zantac 360, Pepcid), are used to lower the secretion of gastric acid and so reduce the pain and hasten the healing of gastric ulcers.

H_3 receptors are located presynaptically on histamine neurons, where they serve as autoreceptors to inhibit the release of histamine. In addition, H_3 receptors are present as heteroreceptors on terminals of other neurotransmitters to regulate their function. Recently, a selective inverse agonist at the H_3 receptor, pitolisant (Wakix), has been shown to be effective at counteracting excessive diurnal sleepiness in narcolepsy, Parkinson disease, and obstructive sleep apnea. Antagonists and inverse agonists for the H_3 receptor have potential as treatments for cognitive disorders.

The presence of H_4 receptors in the brain is not well established, although they are expressed in the periphery at several sites, including the spleen, bone marrow, and leucocytes, and are linked with the regulation of the immune system. Increasing attention has been directed toward the therapeutic modification of H_4 receptor signaling in disorders such as allergy, asthma, chronic pruritus, and autoimmune diseases.

TRACE AMINES

Several biologically active compounds with structural similarity to the classical biogenic amines are termed trace amines because of their low concentration in vertebrate brains and other tissues. They include phenylethylamine, tyramine, and tryptamine which are formed by decarboxylation of the amino acid precursors for the catecholamines and serotonin, phenylalanine/tyrosine, and tryptophan, respectively. However, trace amines are also abundant in many common foods and are also produced by microbiota. They diffuse across membranes easily, and no specific transport proteins or storage compartments have been identified for them. They are substrates for several oxidases, including MAO. Early research identified indirect sympathomimetic, amphetamine-like effects of phenylethylamine, albeit at higher concentrations than occurs endogenously. The identification of specific receptors for trace amine receptors galvanized interest in the function of trace amines and their possible role in the etiology and treatment of psychiatric conditions, especially as some psychotropic agents, such as amphetamines and MDMA, exhibit high affinity for the receptors. Humans possess six functional isoforms (TAAR1, TAAR2, TAAR5, TAAR6, TAAR8, and TAAR9). All except TAAR1 are expressed in olfactory epithelium neurons. However, TAAR1 is most thoroughly studied, and both central and peripheral roles have been linked with it. In the brain, TAAR1 has relatively high expression in VTA and dorsal raphe nuclei, regions where dopamine and serotonin cell bodies, respectively, are clustered. Generation of mice that overexpress TAAR1 or have the receptor knocked out have helped delineate possible contributions of trace amines to neuronal homeostasis. Such studies indicate that activation of the TAAR1 receptor inhibits dopaminergic and serotonin neurons, exemplified by their increased firing rate in TAAR1 knockout mice. There is evidence to suggest that the mechanism for TAAR1 modulation may involve the formation of a heterodimer between TAAR1 and presynaptic dopamine or serotonin autoreceptors that negatively regulate transmission. Although further research is needed to clarify the roles of trace amines in the brain, TAAR1 has been identified as a novel therapeutic target for disorders such as schizophrenia and the prevention of psychostimulant addiction relapse. Indeed, TAAR1 agonists are currently undergoing clinical trials for the treatment of schizophrenia, with available evidence indicating no abuse potential of TAAR1-directed agents.

1.8 Neuropeptides: Biology, Regulation and Role in Neuropsychiatric Disorders

Michael J. Owen, B.Sc. (Hons.), M.B., Ch.B., Ph.D., F.R.C.Psych., Shaun P. Brothers, Ph.D., M.B.A., Larry J. Young, Ph.D., and Charles B.

NEMEROFF, M.D., PH.D.

Neuropeptides represent the most diverse class of signaling molecules in the central nervous system (CNS). Initially discovered for their role in the hypothalamic regulation of pituitary hormone secretion, the complex role of peptides in brain function has emerged over the last 40 years. Neuropeptides and their receptors are widely distributed throughout the CNS, where they exert an extraordinary array of direct or neuromodulatory effects, ranging from modulating neurotransmitter release and neuronal firing patterns to the regulation of emotionality and complex behaviors. Over 100 unique biologically active neuropeptides have been identified in the brain, a subset of which is presented in Table 1.8–1. Adding to the complexity of neuropeptide systems in the CNS, the actions of many peptides are mediated via multiple receptor subtypes localized in different brain regions. In fact, the discovery of new peptides and receptor subtypes has outpaced our understanding of the roles of these peptides in normal or aberrant CNS function. Pharmacologic, molecular, and genetic approaches are now leading the way in our understanding of the contribution of neuropeptide systems to psychiatric disorders. The first half of this chapter provides a general overview of neuropeptide biology, including their biosynthesis, distribution, and signaling. The second half of the chapter provides specific, detailed information for a select group of neuropeptides with special relevance to behavior and psychiatric disorders.

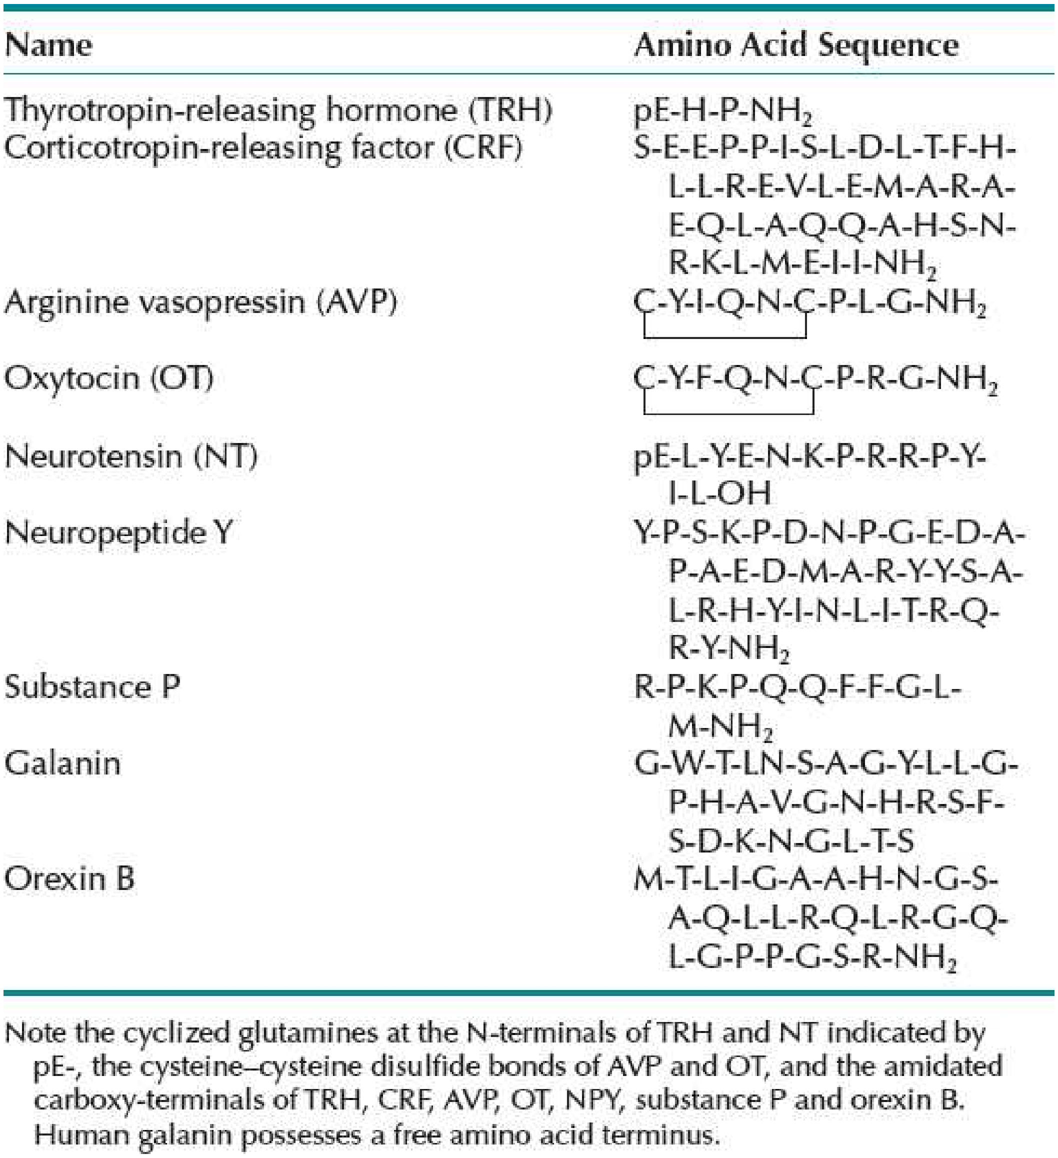
Table 1.8–1.
Selected Neuropeptide Transmitters

Adrenocorticotropin hormone (ACTH)
Angiotensin
Apelin
Atrial natriuretic peptide
Bombesin
Calcitonin
Calcitonin gene–related peptide (CGRP)
Cocaine- and amphetamine-regulated transcript (CART)
Cholecystokinin (CCK)
Corticotropin-releasing factor (CRF; corticotropin-releasing hormone; CRH)
Dynorphin
β-Endorphin
leu-enkephalin
met-enkephalin
Galanin
Gastrin
Ghrelin
Gonadotropin-releasing hormone (GnRH)
Growth hormone
Growth hormone–releasing hormone (GHRH; GRF)
Insulin
Kisspeptin
Motilin
Neurokinin A (formerly Substance K)
Neuropeptide S
Neuropeptide Y (NPY)
Neurotensin
Neuromedin-N
Nociceptin
Orexin (also known as hypocretin)
Oxytocin
Pancreatic polypeptide
Prolactin
Secretin

Somatostatin (SS; SRIF)
Substance P
Thyrotropin-releasing hormone (TRH)
Urocortin (1,2, and 3)
Vasoactive intestinal polypeptide (VIP)
Vasopressin (AVP; ADH)

By definition, a neuropeptide is a chain of two or more amino acids linked by peptide bonds and differs from other proteins only in the length of the amino acid chain. Neuropeptides range in length from 2 (e.g., carnosine and anserine) to over 40 amino acids (e.g., corticotropin-releasing factor [CRF] and urocortin). By convention, peptides greater than 90 amino acids in length (about 10,000 molecular weight) are considered proteins. The neuropeptides highlighted in detail in this chapter include thyrotropin-releasing hormone (TRH), CRF, oxytocin (OT), arginine vasopressin (AVP), neurotensin (NT), and neuropeptide Y (NPY) with brief summaries of relevant data for cholecystokinin (CCK), substance P (SP), galanin, and orexins. The structures of these highlighted neuropeptides are illustrated in Table 1.8–2 and are written using the single-letter amino acid code by convention from the amino terminus (NH_2^-) beginning on the left to the carboxyl terminus (-COOH) on the right. A detailed discussion of all neuropeptide systems of potential relevance to psychiatry is beyond the scope of this chapter, and other signaling peptides, including the opioid peptides, growth factors, and cytokines, are considered elsewhere in this volume. TRH and CRF are hypothalamic hypophysiotropic hormones, which stimulate the release of thyroid-stimulating hormone (TSH) and adrenocorticotropic hormone (ACTH), respectively, from the anterior pituitary (adenohypophysis) into the bloodstream. OT and AVP are neurohypophysial peptides that are released directly into the bloodstream from the posterior pituitary (neurohypophysis) under specific physiologic conditions. However, all of these above-mentioned peptides, including NT, also function in the CNS as neurotransmitters, neuromodulators, or neurohormones in ways that are often quite distinct and independent from their effects on peripheral endocrine systems. Indeed, many neuropeptides appear to have evolved two distinct activities, one in the CNS and a sometimes highly different one in the periphery. OT and AVP, for example, are thought to contribute to emotionality in the CNS and stimulate uterine contraction peripherally during pregnancy. Perhaps more confounding to being able to achieve clear research outcomes is that these seemingly disparate systems may even have some overlap, such as contributing to postpartum nurturant behavior in mothers. Another example is with μ-opioid receptors in the CNS that regulate nociception and reward and peripherally regulate respiration and gut motility. For this reason, opiate drugs have the side effects of respiratory depression and constipation.

Table 1.8–2.
Selected Neuropeptide Structures



Name	Amino Acid Sequence
Thyrotropin-releasing hormone (TRH)	pE-H-P-NH_2
Corticotropin-releasing factor (CRF)	S-E-E-P-P-I-S-L-D-L-T-F-H-L-L-R-E-V-L-E-M-A-R-A-E-Q-L-A-Q-Q-A-H-S-N-R-K-L-M-E-I-I-NH_2
Arginine vasopressin (AVP)	C-Y-I-Q-N-C-P-L-G-NH_2
Oxytocin (OT)	C-Y-F-Q-N-C-P-R-G-NH_2
Neurotensin (NT)	pE-L-Y-E-N-K-P-R-R-P-Y-I-L-OH
Neuropeptide Y	Y-P-S-K-P-D-N-P-G-E-D-A-P-A-E-D-M-A-R-Y-Y-S-A-L-R-H-Y-I-N-L-I-T-R-Q-R-Y-NH_2
Substance P	R-P-K-P-Q-Q-F-F-G-L-M-NH_2
Galanin	G-W-T-LN-S-A-G-Y-L-L-G-P-H-A-V-G-N-H-R-S-F-S-D-K-N-G-L-T-S
Orexin B	M-T-L-I-G-A-A-H-N-G-S-A-Q-L-L-R-Q-L-R-G-Q-L-G-P-P-G-S-R-NH_2

Note the cyclized glutamines at the N-terminals of TRH and NT indicated by pE-, the cysteine–cysteine disulfide bonds of AVP and OT, and the amidated carboxy-terminals of TRH, CRF, AVP, OT, NPY, substance P and orexin B. Human galanin possesses a free amino acid terminus.

Neuropeptides have been implicated in the regulation of a variety of behavioral and physiologic processes, including thermoregulation, food and water consumption, sex, sleep, locomotion, learning and memory, responses to stress and pain, emotion, and social cognition, to name a few. Involvement in such behavioral processes suggests the likelihood that neuropeptidergic systems contribute to the symptoms and behaviors exhibited in the major psychiatric disorders, including autism, schizophrenia, mood disorders, and anxiety.

INVESTIGATING NEUROPEPTIDE FUNCTION

The roles of neuropeptides in CNS function and behavior have been examined using a multitude of experimental techniques. The levels of analysis include molecular structure and biosynthesis of the peptide and its receptor(s), the neuroanatomical localization of the peptide and its receptor(s), the regulation of the expression and release of the peptide, and finally, the behavioral effects of the peptide. Much of the information on neuropeptide biology has been derived from laboratory animal studies; however, there is an ever-increasing database on the localization, activity, and potential psychiatric relevance of several neuropeptides systems in humans.

Most neuropeptide structures have been identified based on chemical analysis of purified biologically active peptides leading ultimately to the cloning and characterization of the genes encoding them. Characterization of the gene structure of peptides and their receptors has allowed for an understanding of the molecular regulation of these systems, and their chromosomal localization is useful in genetic studies examining the potential roles of these genes in the pathogenesis of psychiatric disorders. Structural characterization permits the production of immunologic and molecular probes that are useful in determining peptide distribution and regulation in the brain. Quantitative enzyme-linked immunosorbent assay (ELISA) on microdissected brain regions or immunocytochemistry on brain sections are typically used to characterize the regional distribution of peptides throughout the brain. Both techniques use specific antibodies generated against the neuropeptide to detect its presence. Immunocytochemistry allows researchers to visualize the precise cellular localization of peptide-synthesizing cells as well as their projections throughout the brain, though the technique is generally not quantitative. Using molecular probes homologous to the mRNA encoding the peptides or receptor, *in situ* hybridization can be used to localize and quantify gene expression in brain sections. This is a powerful technique for examining the molecular regulation of neuropeptide synthesis with a precise neuroanatomical resolution, which is impossible for other classes of nonpeptide neurotransmitters that are not derived directly from the translation of messenger RNAs, such as dopamine, serotonin, and norepinephrine. In addition to immunocytochemistry and *in situ* hybridization, receptor autoradiography on brain sections (Fig. 1.8–1) or “grind and bind” receptor binding assays on microdissected brain tissue are frequently used to localize and quantify neuropeptide receptors in specific regions of the brain. Receptor autoradiography involves allowing a radiolabeled ligand to bind the receptor on a thin slice of tissue and then detecting the bound by visualizing it on x-ray film or other means. Other molecular techniques, such as quantitative real-time polymerase chain reaction (RT-PCR) and RNA sequencing (transcriptomics), are also commonly used to measure neuropeptide and receptor expression and regulation by quantifying the mRNAs encoding the peptide or receptor. However, quantification of neuropeptide gene expression or immunoreactivity within a cell or tissue homogenate does not provide information on neuropeptide release. *In vivo* microdialysis, in which peptides concentrated in the extracellular fluid and presumably originating from neuronal release, are collected at sequential time intervals using dialysis probes implanted into specific brain regions, may be used to quantify neuropeptide release under defined physiologic or behavioral circumstances.

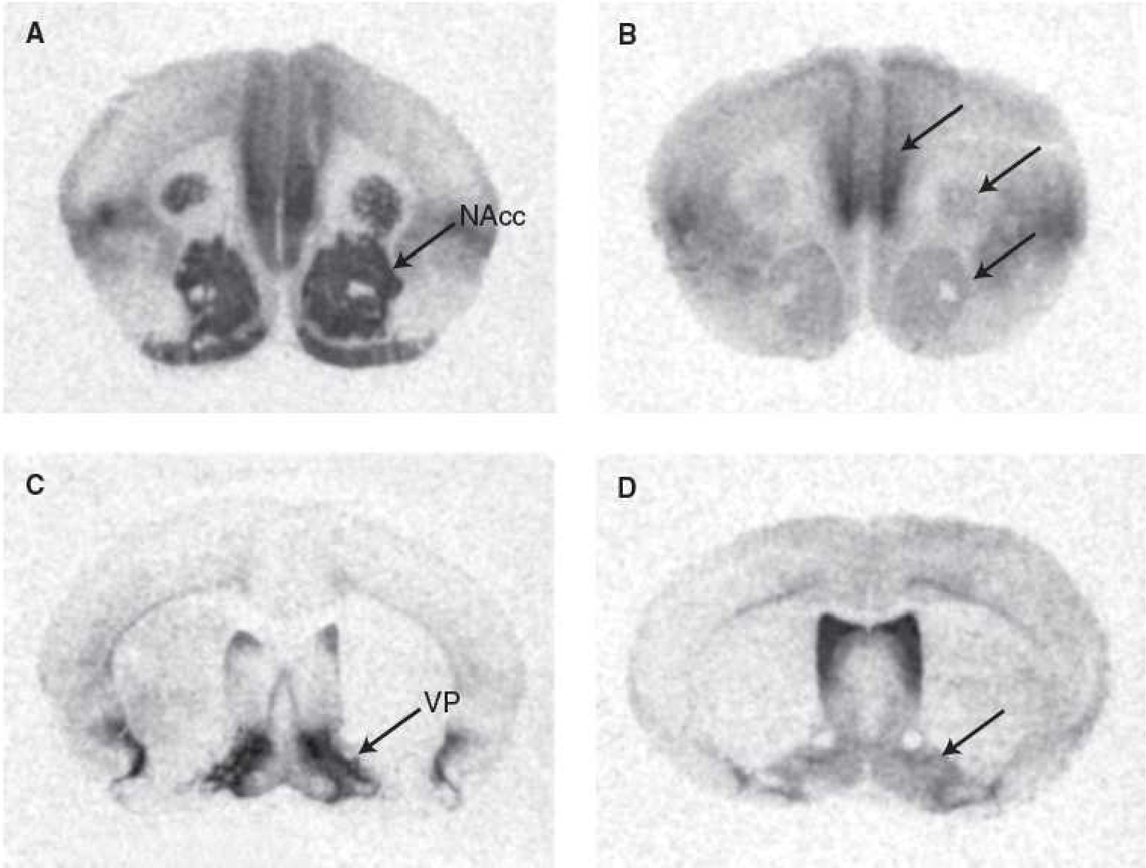


FIGURE 1.8–1. Oxytocin and vasopressin receptor distribution patterns in the brain are associated with social behavior. The **upper panels** depict receptor autoradiograms illustrating the localization of oxytocin receptor binding in the highly social and monogamous prairie vole (**A**) and the asocial montane vole (**B**). The **lower panels** illustrate vasopressin V1a binding in the monogamous prairie vole (**C**) and nonmonogamous montane vole (**D**). Note the high density of oxytocin receptor in the nucleus accumbens (NAcc) and V1a receptor binding in the ventral pallidum (VP) of the prairie vole but not the montane vole. These receptor populations are critical for social attachment in monogamous rodents. (Adapted by permission from Young LJ, Wang ZX. The neurobiology of the social bond. *Nat Neurosci* 2004;7:1048–1054. Copyright © 2004. Nature Publishing Group.)

In general, the behavioral effects of neuropeptides are initially investigated by infusions of the peptide directly into the brain. Unlike many nonpeptide neurotransmitters, most neuropeptides do not penetrate the blood–brain barrier in amounts sufficient enough to produce CNS effects. Furthermore, serum and tissue enzymes tend to degrade the peptides before they reach their target sites. The degradation is usually the result of the cleavage of specific amino acid sequences targeted by a specific peptidase designed for that purpose. Thus intracerebroventricular (ICV) or site-specific infusions of peptide in animal models are generally required to probe for behavioral effects of peptides. However, there are some examples of the delivery of neuropeptides via intranasal infusions in human subjects, which in some cases appears to permit access of the peptide to the brain (e.g., OT), though this remains controversial.

In many cases, the interpretation of neuropeptide infusion studies is complicated because of the considerable cross-talk between specific neuropeptides and several heterologous receptors. For example, OT and vasopressin differ by only 2 of 9 amino acids and both peptides cross-react to some degree with both receptor types. In some cases, highly selective peptide receptor synthetic agonists or antagonists have been developed that allow researchers to examine the role of specific neuropeptide receptors in the regulation of behavior or physiologic processes. In addition, transgenic and knockout mouse approaches are commonly used to investigate neuropeptide function. For example, mutant mouse strains with null mutations (knockouts) in either the peptide gene or the corresponding receptor have been developed and have proven quite useful for exploring the role of neuropeptides in behavioral processes. Small interfering RNA (siRNA) or short hairpin RNA (shRNA) techniques, which lead to the selective degradation of the targeted mRNA in specific brain regions, have been used to examine the function of specific neuropeptide-producing neuronal populations. The CRISPR/Cas system that has been used for gene editing holds the potential to begin to separate spatiotemporal effects of up-/downregulating neuropeptides and genes. Similar efforts with viruses to selectively overexpress or knock down neuropeptide or receptor RNA in specific microinjected brain regions have been pursued as well. Transgenic and viral vector approaches are increasingly being used to interrogate the activity and function of neuropeptide or receptor-expressing neurons using optogenetics, chemogenetics, and fiber photometry. These approaches are made possible by genetically engineered rodents, typically mice, that express Cre recombinase in tandem with the peptide or peptide receptor transcript. When combined with Cre-dependent viral vectors that express light-sensitive opsins, novel “designer” receptors, or intracellular calcium indicators (e.g., GCaMP), researchers can exquisitely control or monitor activity in specific populations of peptide or receptor neurons. This approach must be combined with pharmacologic manipulations to dissect the functions of the neurons from neuropeptide signaling.

As noted above, one of the greatest impediments to exploring the role and potential therapeutic value of neuropeptides is the inability of the peptides or their peptidergic agonists/antagonists to penetrate the blood–brain barrier. Thus, the behavioral effects of most peptides in humans are largely uninvestigated, with the exception of a few studies utilizing intranasal delivery. However, in some instances, small-molecule, nonpeptide agonists/antagonists have been developed that can be administered peripherally and permeate the blood–brain barrier in sufficient quantities to affect receptor activation. Other approaches include pharmacologically evoking endogenous neuropeptide release using a brain-penetrant drug.

Humans are less-than-ideal subjects for neuropeptide research for several reasons. First, although blood samples to determine plasma hormone concentrations are relatively easy to obtain, the independent regulation of peripheral and CNS peptide release, the high concentration of plasma peptidases, and the blood–brain barrier make it virtually impossible to infer CNS peptide physiology from plasma hormone concentrations. Also, the use of biopsy to directly assess tissue peptide concentrations is not ideal because it is not routinely repeatable, is limited to superficial structures, and suffers from potential morbidity. In contrast, however, cerebrospinal fluid (CSF) has been shown to reflect extracellular fluid concentrations of several transmitter substances, is in direct contact with the CNS, is screened from peripheral serum sources by the blood–brain barrier, and may be sampled across time. The limitations of human CSF studies include a lack of information about the regional CNS source of any changes in peptide concentration detected, the use of lumbar CSF, which is somewhat removed from higher forebrain CNS sources of peptides and subject to spinal cord peptide contributions, the potentially confounding effects of previous drug treatments or disease episodes, and the reluctance of research subjects to consent to this procedure. Postmortem tissue studies of neuropeptide concentration changes in psychiatric disease have been informative in many cases, but interpretation must include consideration of postmortem delay, previous drug treatment, and coexisting illnesses. Most of the data on alterations in CSF or tissue concentrations of neurotransmitters have been derived from comparisons between diagnostically defined psychiatric groups and control groups. However, the controls may be so-called “neurologic or psychiatric controls,” not healthy volunteers, and the accuracy and consistency of the diagnoses may be less than optimal. In addition, the etiology of a syndromal diagnosis may differ among subjects in the same diagnostic group. Even after matching for age, gender, or other demographic variables, heterogeneity among human research populations results in individual variations of absolute peptide values that are often quite wide. Such variances severely reduce the power of group comparisons to detect alterations in peptide concentrations. The use of pre- and posttreatment CSF samples, or of samples obtained during the active disease state versus when the patient is in remission, addresses some of the serious limitations in study design. For such progressive diseases as schizophrenia or Alzheimer disease (AD), serial CSF samples may be a valuable indicator of disease progression or response to treatment. Even with these constraints, significant progress has been made in describing the effects of various psychiatric disease states on neuropeptide systems in the CNS.

BIOSYNTHESIS

Unlike other neurotransmitters, the biosynthesis of a neuropeptide involves transcription of an mRNA from a specific gene, translation of a polypeptide preprohormone encoded by that mRNA, and then posttranslational processing involving proteolytic cleavage of the preprohormone to yield the active neuropeptide. Over the past 40 years, the gene structures and biosynthetic pathways of most neuropeptides have been elucidated. The gene structure of selected neuropeptides is illustrated in Figure 1.8–2. Neuropeptide genes are generally composed of multiple exons that encode a protein preprohormone. The N-terminus of the preprohormone contains a signal peptide (SP) sequence, which guides the growing polypeptide to the rough endoplasmic reticulum (RER) membrane. The single preprohormone molecule often contains the sequences of multiple peptides that are subsequently separated by proteolytic cleavage by specific enzymes. For example, translation of the gene encoding NT yields a preprohormone, which upon enzymatic cleavage produces both NT and neuromedin-N. Other neuropeptide genes, such as the TRH gene, encode multiple copies of the peptide sequence or, as in the case of OT and vasopressin, also encode other proteins essential in the posttranslational processing and transport of the neuropeptide. The neuroanatomical localization and abundance of neuropeptides are determined primarily by the region-specific expression and regulation of their gene. Each neuropeptide gene is expressed in well-defined populations of neurons within the brain. The precise neuroanatomical pattern of peptide hormone gene expression is determined by regulatory DNA sequences surrounding the gene. This has been elegantly demonstrated for the OT gene. Viral vector constructs containing the 5′ regulatory region of the OT gene reliably direct transgene expression in OT neurons, permitting opto- or chemogenetic manipulation of the activity of these neurons and OT release in behavioral contexts. Transcription factor binding sites located in the promoter of the gene are also involved in the physiologic regulation of peptide gene expression. Analysis of promoter sequences of peptide genes has provided insights into the molecular regulation of peptide biosynthesis.

The mRNA encoding the preprohormone is translated by ribosomes associated with the RER, and the growing polypeptide is translated with the SP anchored in the RER membrane within the cisternae. Once translated, the SP of the *pre*prohormone is cleaved by a signal endopeptidase, freeing the *pro*hormone polypeptide. The prohormone is then shuttled to the Golgi apparatus, where packaging into granules or vesicles occurs. Proteolytic cleavage of the prohormone into the biologically active neuropeptide begins in the Golgi and continues in the granules. Production of biologically active neuropeptides from prohormones begins with cleavage at specific sites adjacent to the neuropeptide sequence by specific endopeptidases known as prohormone convertases. Prohormone convertases generally cleave at pairs of basic amino acids (e.g., Lys-Arg, Lys-Lys, and Arg-Arg), flanking the neuropeptide sequence. There are at least seven prohormone convertases, each with unique properties, including substrate specificity and neuroendocrine distribution. Prohormone convertases are co-packaged with the prohormones in the granules at the Golgi apparatus. The substrate specificity and differential distribution of the prohormone convertases provide a mechanism by which different neuropeptides encoded by a single prohormone can be differentially produced in an active form. Following endopeptidase cleavage, the peptide fragments are subjected to exoproteolysis by carboxypeptidases and/or aminopeptidases in order to remove the residual basic residues on the carboxy- or amino-terminus of the peptide fragments. The synthesis and processing of neuropeptides are illustrated in Figure 1.8–3.

FIGURE 1.8–2. Schematics illustrating the gene structure, preprohormone mRNA, and processed neuropeptides of TRH, CRF, OT, AVP, and NT. Boxed regions indicate the locations of the exons in the respective genes. Shaded or hatched regions indicate coding regions. Each preprohormone begins with a signal peptide sequence (SP). *Black boxes* indicate the location of the sequences encoding the neuropeptide.

Although many known peptides are complete and biologically active when cleaved from the prohormone, many others are subjected to additional posttranslational processing. Certain peptides have a metabolically blocked carboxy-terminus that is often amidated. A glycine residue in the prohormone sequence often acts as the amide donor and, in the case of TRH, is cleaved by a monooxygenase that is contained in secretory granules. TRH is further processed on the N-terminus, where glutamine is cyclized by a glutamyl cyclase to yield a pyroglutamyl moiety. These alterations are usually effective in reducing susceptibility to degradation and are often required for biologic activity, as is the case for TRH, which is rendered inactive when the C-terminal amide is removed by proline endopeptidase to generate the free-acid structure. Other posttranslational processing events for active peptides include glycosylation, phosphorylation, and the formation of disulfide bonds, which are often required for either biologic activity or transport. Several neuropeptides, including OT, vasopressin, and orexin A, contain one or more cysteine–cysteine disulfide bonds, resulting in cyclic peptide structures (see Table 1.8–2). Finally, neuropeptide diversity can occur through alternative splicing of the primary RNA to generate different mRNAs and, ultimately, peptides with markedly differing actions (e.g., calcitonin and calcitonin gene–related peptide [CGRP]).

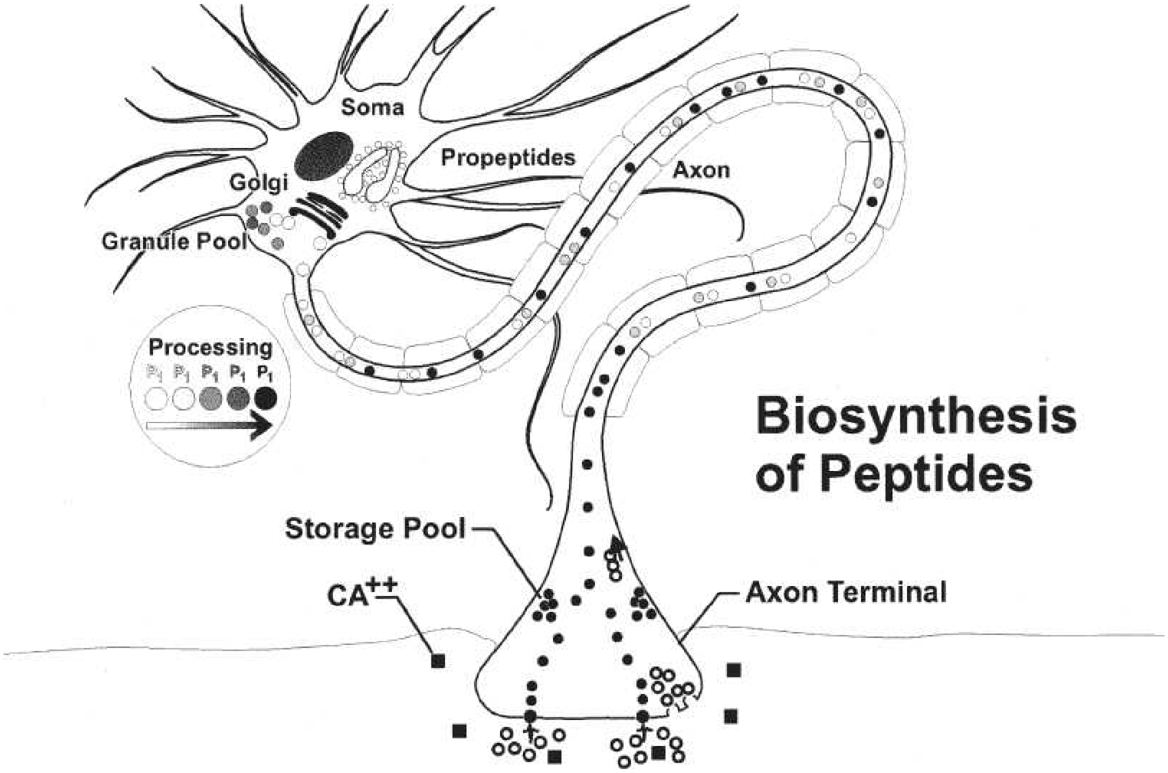

FIGURE 1.8–3. The peptidergic neuron. The figure shows the main steps in the chain of events, from the information stored in the DNA molecule to the peripherally detected peptide fragments. The DNA sequence in the nucleus is transcribed to the mRNA molecule for further transport to the endoplasmic reticulum, where a translation takes place to form a large precursor protein (preproprotein). That protein is prepared for axonal transport by packaging into neurosecretory vesicles or granules within the Golgi complex. During transport, the precursor protein is processed by specific cleavage enzymes into active and inactive peptide fragments. After release, the peptides are further degraded into smaller peptide fragments or constituent amino acids.

DISTRIBUTION AND REGULATION

Although many neuropeptides were originally isolated from the pituitary and peripheral tissues, the majority of neuropeptides have been found to be widely distributed throughout the brain. Those peptides involved in regulating pituitary secretion are concentrated in the hypothalamus. Hypothalamic releasing and release-inhibiting factors are produced in neurosecretory neurons adjacent to the third ventricle that send projections to the median eminence, where they release peptides into the hypothalamohypophysial portal circulatory system. Peptides produced in these neurons are often subject to feedback regulation by the peripheral hormones that they regulate. For example, TRH regulates the activity of the hypothalamic–pituitary–thyroid (HPT) axis, and thyroid hormones negatively feedback TRH gene expression. However, neuropeptide-expressing neurons and their projections are found in many other brain regions, including limbic structures, cerebral cortex, midbrain, hindbrain, and spinal cord. Neuropeptides are usually, if not exclusively, colocalized and released with other neuropeptides or classic neurotransmitters. The colocalization of neuropeptides within classical neurotransmitter circuits, first described for somatostatin in 1977, suggests an interaction between these systems and the modulation of monoamine neurotransmitter (e.g., norepinephrine) function by neuropeptides (e.g., NPY and galanin) is common and well established. Indeed, neuropeptides are co-transmitted with nonpeptide neurotransmitters and serve to modulate neurotransmission in both the pre- and postsynaptic cells.

NEUROPEPTIDE SIGNALING

Neuropeptides may act as neurotransmitters, neuromodulators, or neurohormones. Neuropeptide neurotransmitters are typically released from axonal terminals into a synapse where binding to neuropeptide receptors changes the postsynaptic membrane potential, either depolarizing or hyperpolarizing the cell. For classical neurotransmitters, this often involves direct modulation of voltage-gated ion channels. In contrast, neuropeptide neuromodulators and neurohormones do not directly affect the firing of the target cell itself but may alter the response of the cell to other neurotransmitters through the modulation of second messenger pathways. Neuropeptide release is not restricted to synapses or axon terminals but may occur at multiple sites along the axon or even from dendrites. Neuropeptides may also diffuse quite a distance from the release site to the target cell, which possesses the neuropeptide receptor, where it acts as a neurohormone and has been labeled volume neurotransmission. Such paracrine neuropeptide release can even occur from nonneuronal cell populations in the brain, such as glial cells. In fact, there are numerous examples of a mismatch between neuropeptide and neuropeptide receptor distribution in the brain. Neuropeptides are released by exocytosis of the granules in response to electrical or hormonal stimulation of the neuron containing the neuropeptide. Typically, neuropeptide release occurs when neurons fire at a high frequency or in burst patterns. Stimulation results in an increase in intracellular calcium concentrations, which leads to the fusion of the peptidergic granules to the plasma membrane and expulsion of the peptide into the extracellular space.

The cellular signaling of neuropeptides is mediated by specific neuropeptide receptors. Thus, understanding neuropeptide receptor function is essential for understanding neuropeptide biology. Neuropeptide receptors have undergone the same process of discovery and characterization that receptors for other neurotransmitters have enjoyed. The vast majority of neuropeptide receptors are G-protein–coupled, seven-transmembrane domain receptors (GPCR) belonging to the same family of proteins as the monoamine receptors. Each neuropeptide receptor is usually, but not always exclusively, coupled to one type of G protein (e.g., G_s, G_i, G_q). Receptors can also homo- and heterodimerize, allowing multiple modes of action via a single receptor population, though this process, its regulation, and the physiologic implications are not currently well understood. Depending on the subtype of G protein with which the receptor interacts, receptor activation may result in the stimulation or inhibition of specific second messenger pathways. The most common types of receptor signaling pathways involve the activated G protein modulating the activity of either adenylate cyclase (e.g., Gs or Gi) or phospholipase C (e.g., Gq). Stimulation of adenylate cyclase results in increased cAMP production in the cell, while stimulation of phospholipase C results in increased diacylglycerol (DAG) and inositol triphosphate (IP_3). These so-called “second messengers” then effect increases in intracellular calcium concentrations, activation of protein kinases, and ultimately a host of cellular responses, including altered gene expression, altered membrane potential, and/or cellular degranulation.

Many neuropeptides exert their effects through multiple different receptor subtypes, which have different affinities for the peptides and activate different second messenger pathways. These receptor subtypes are typically differentially distributed throughout the brain. Furthermore, many receptors may be modulated by more than one neuropeptide. For example, there are three subtypes of the vasopressin receptor, the V1a, V1b, and V2 subtypes, with the V1a and V1b predominating in the brain, while the V2 is localized in the kidney. Each of these receptor subtypes exhibits a unique tissue distribution, interacts with different G proteins, and activates different second messenger systems. Within the brain, there are remarkable species differences as well as individual variation in OT and V1a receptor distribution, which has been associated with intra- and interspecies variation in social behaviors. In addition, OT may stimulate vasopressin receptor subtypes, and vasopressin may stimulate the OT receptor (OTR). Likewise, the main two CRF receptors are differentially localized within the brain, and both receptors can be modulated by both CRF and urocortin I, making it difficult to ascertain the relative role of each receptor in CRF functioning.

Many, if not perhaps all, neurotransmitters appear to be co-released with at least one other neurotransmitter at the synapse. ATP, for example, can apparently be co-released from all neuronal types, though the action of the molecule will vary according to the biology of the postjunctional cell. This co-transmission certainly also occurs for neuropeptides. One of the first to be delineated, NPY, is co-released with norepinephrine from the same vesicles within cells to act simultaneously on the target cell. NPY can also act *via* feedback inhibition on the releasing cell to reduce signaling tone. In this instance, NPY appears to play a neuromodulatory role at the synapse to control signal strength and act as a shutoff switch. Galanin also plays a similar role in norepinephrine-releasing neurons.

Other types of co-transmission can occur, including the differential release of transmitters and cotransmitters (e.g., *via* frequency-modulated release), post- and/or prejunctional targeting co-transmitters, synergistic versus inhibitory co-transmitters, and others. It is important to appreciate neuropeptides as co-transmitters in such systems because co-transmission has the potential to mediate or modulate the underlying disease pathophysiology. Using NPY as an example again, NPY is also co-transmitted with NE in the adrenals, where cortisol is released in response to stress. NPY appears to play an overall suppressive role in NE signaling within the adrenals, thus suppressing the stress response. It has been widely theorized that activation of NPY receptors can ameliorate some of the trauma associated with chronic stress disorders and drug abuse/alcoholism, where there is prolonged activation of the stress response and where stress is viewed as playing a major role in relapse and drug-seeking behaviors.

Most, if not all, genes for neuropeptide receptors and ligands have been cloned and characterized, though some receptors called “orphan receptors” have, as of yet, unknown endogenous ligands. Similarly, some ligands, for example, “cocaine- and amphetamine-regulated transcript”

(CART), are thought to signal via GPCRs, which remain to be identified. It is likely, however, that all known GPCRs and ligands will be “deorphanized” within the next decade, as numerous efforts are underway to do so. Once the cDNA of the receptor has been isolated, it can be used to produce purified receptor protein for structural and functional studies. By mutating specific amino acids in the receptor structure and determining relative binding affinities of peptides with various amino acid substitutions, it is possible to elucidate the nature of the ligand–receptor interaction and to inform crystal structures of the receptors. This information should facilitate the development of compounds that specifically modulate receptor function, including nonpeptide drugs, leading to the ability to manipulate peptide systems in ways that are currently enjoyed by the more classic neurotransmitters. The availability of cDNAs encoding the receptor also permits the neuroanatomical mapping of the receptor-producing cells in the brain by use of probes that target the mRNA of the receptor specifically, which is critical for understanding the neural circuits modulated by the peptide. Finally, with the cloned receptor in hand, it is possible to use transgenic techniques, such as targeted gene overexpression or gene knockouts, to further elucidate receptor function. Viral-mediated RNAi and CRISPR techniques now allow the targeted synthesis disruption of specific receptor populations, allowing researchers to examine the role of these receptor populations on physiology and behavior. Peptide receptor Cre transgenic animals in combination with Cre-dependent vectors enable investigators to identify the role of receptor-expressing neuronal populations in behavior using opto- and chemogenetics.

The three factors that determine the biologic role of a neuropeptide hormone are (i) the temporal–anatomical release of the peptide, (ii) coupling of the neuropeptide receptor to intracellular signaling pathways, and (iii) the subtype of the receptor expressed and their distribution in different cell populations and circuits. Genetic studies have demonstrated that regulatory sequences flanking the receptor coding region determine the expression pattern of the receptor and thus the physiologic and behavioral response to the neuropeptide. For example, mice and voles differ in the localization of AVP receptors in the brain, and they also differ in their behavioral response to AVP. However, when transgenic mice were created carrying the vole AVP receptor gene with the flanking regulatory sequences, the *mice* expressed the receptor in a pattern similar to that of the *vole*, and then displayed behavioral responses to AVP similar to that of voles. This study suggests that polymorphisms in the regulatory region of a neuropeptide receptor gene could result in significant differences in neuropeptide function and interindividual differences in response to neuronal stimulation and, ultimately, behavior relevant to psychiatric disorders. Many receptor genes are being examined in genetic studies for associations with psychiatric disorders.

Historically, the inability to block specific neuropeptide signals pharmacologically has severely hindered research into the roles of endogenous peptides in various behaviors and physiologic effects. However, for many neuropeptide receptors, selective agonists and antagonists are now available, which have been extremely informative in preclinical studies to examine receptor function. As mentioned above, most of these compounds are derivatives of the peptide itself and therefore do not pass the blood–brain barrier. More recently, a number of pharmaceutical companies, and even academic labs, have synthesized nonpeptidergic, lipophilic compounds that can penetrate the blood–brain barrier and may act as neuropeptide agonists or antagonists. The development of these types of compounds is essential for understanding the role of neuropeptide receptor function in human behavior and may also be useful in the development of positron emission tomography (PET) radioligands to study receptor distribution in living human subjects. These compounds also hold promise as therapeutic agents in the treatment of certain psychiatric disorders.

Peptidases

Unlike monoamine neurotransmitters, peptides are not inactivated by being actively taken up by presynaptic nerve terminals. Rather, released peptides are degraded into smaller fragments and eventually into single amino acids by specific enzymes termed peptidases. The enzymes may be found bound to post- or presynaptic neural membranes or in solution in the cytoplasm and extracellular fluid, and they are distributed widely in peripheral organs and serum, as well as in the CNS. As a result, neuropeptides generally have half-lives on the order of minutes once released. There are several general classes of peptidases, with several distinct enzymes in each class. Those classes include the serine endopeptidases containing such enzymes as trypsin and chymotrypsin; the thiol peptidases, such as pyroglutamate aminopeptidase and cathepsin B and C; the acid proteases, such as pepsin and renin; the metalloendopeptidases, such as neural endopeptidase and angiotensin-converting enzymes (ACE); and the metalloexopeptidases, such as the aminopeptidases and the carboxypeptidases such as enkephalin convertase and carboxypeptidase A and B. These degradative enzymes are often the same as those used in processing but have different subcellular locations. An example is carboxypeptidase B, which cleaves the dibasic amino acid residues flanking the active peptide sequence in the prohormone during processing or reduces activity at the receptor if the peptide contains dibasic amino acids in the active sequence, such as NT. Peptidases have pH and temperature optimums for activity and can be inhibited by various chemicals or chelators or by amino acid substitution at vulnerable points in the peptide chain. Alterations in peptidase activity or concentration can contribute to alterations in the synaptic availability of a peptide, and the regulation of peptidase levels may be as exquisitely controlled as receptor number and peptide synthesis and release. Cleavage of the actively released form of the peptide usually ends or significantly reduces biologic activity, but examples abound of partial or complete receptor activation by partially metabolized peptides or their fragment.

Peptidases offer yet another potential opportunity for the integration and regulation of neuropeptide transmitter actions and synaptic availability. Because current peptidase inhibitors are relatively nonspecific in their ability to inhibit various peptidases, there have been few attempts to influence peptide concentrations by pharmacologic blockade of their associated peptidases. The ACE inhibitors such as captopril and lisinopril are one exception to that generality. It is expected that newer generations of peptidase inhibitors, with discrete peptidase and possibly regional specificity, will be developed that eventually may allow the truly elegant manipulation of endogenous neuropeptide concentrations.

NEUROPEPTIDE SYSTEMS AS DRUG TARGETS

Because of the many regulatory roles neuropeptide receptors play in the CNS, it is no surprise that they also make attractive drug targets. There have been numerous attempts to modulate neuropeptide receptors for the treatment of psychiatric diseases, with some success and also some notable failures. The first and most robust class of therapeutics, particularly for peripheral neuropeptide receptors, is in administering the neuropeptide itself, with perhaps some small modifications to make it more drug like. The issue in psychiatric diseases is, however, that the vast majority of the peptides are not brain penetrant. While there have been numerous attempts to either create brain-penetrant peptides or else centrally administer them, these efforts have largely yielded little of clinical value. The field remains focused on this approach, however, and developments in gene editing and other biologic drug approaches hold some potential to yield useful results.

It is because of these and other reasons that most approaches to drugging CNS neuropeptide receptor systems remain focused on the identification and development of low molecular weight (ideally less than 500 Da) brain-penetrant molecules. A plethora of small molecules has been developed that selectively and potently target different neuropeptide receptors. These small molecules are highly versatile and can be designed to have highly specific activities. Typical approaches are to activate the receptor (agonist), inhibit receptor signaling (antagonist), or reduce intrinsic receptor activity (inverse agonist). More specialized approaches have been developed in recent years. A positive allosteric modulator (PAM) small molecule, for example, will potentiate the signaling of a neuropeptide by binding to the receptor at a site on the protein (known as the allosteric site) that is not the site where the neuropeptide binds (known as the orthosteric site) and cause the receptor to initiate more signaling with the same given amount of neuropeptide. The PAM approach is elegant and has the potential benefits of selectively activating only those receptors that would normally be activated, as compared to a typical orthosteric agonist, which may activate receptor populations throughout the body. A similar negative allosteric modulator (NAM) approach can be used to reduce signaling through receptors with the same given amount of neuropeptide present. Finally, a great deal of emphasis has been recently placed on creating “biased” signaling drugs. A given receptor will usually have more than one intracellular signaling pathway that it activates within normal physiology. A biased compound is aimed at selectively activating or inhibiting one pathway over another. A famous example is with the μ-opioid receptor, where it is thought that an opiate drug that does not activate the β-arrestin signaling system will have less tolerance and, therefore, addiction potential. These highly specialized approaches to modulating receptors remain mostly experimental at this point, but there are many efforts aimed at developing such drugs. A major unanswered question is whether a relatively minor modulation of receptor signaling systems that are generally only modulators of more robust neuronal firing and network systems can be powerful enough to result in positive clinical outcomes.

This issue that neuropeptide systems appear to be largely highly modulatory may also be the reason why more traditional drug discovery for neuropeptide systems has not lived up to expectations. There have been several notable failures in developing neuropeptide receptor drugs. Particularly, the “big three” failures all around the same time in the mid-2000s seemed to cause the field to reconsider whether neuropeptide small-molecule drugs can be useful for psychiatry. These were phase III clinical trial failures for CRF receptor antagonists for anxiety and depression, NK1 (SP) receptor antagonists for pain, and NPY Y5 receptor antagonists for obesity. While the question of utility potential remains largely unanswered, the same questions and answers have appeared in other neuroscience fields with notable failures, such as in failures of AD drugs. As with AD, it is critical that the exact approach, dosing, and mechanism of action needs to be better defined and evaluated before developing a drug. Moreover, the disease and clinical outcomes deserve much more thorough consideration before initiating a trial. A clear example is CRF receptor antagonists, which failed to have meaningful outcomes for generalized anxiety disorder (GAD). GAD is, like many DSM5 disorders, highly heterogeneous. CRF receptor antagonist approaches may be quite effective in a much more defined, enriched subpopulation of patients, for example, post-traumatic stress disorder (PTSD) patients with a genetic and childhood maltreatment history promoting increased CRF activity. It appears that for all neuropsychiatric disorders, clinical population, clinical trials design, trials outcomes, and other factors must receive considerably more attention than was given in the past if there is any chance for success. As a clear example and expanded upon later in this chapter, the ongoing hypothesis that CRF hypersecretion may represent a pathophysiologic basis for mood and anxiety disorders, as well as alcohol use disorder (AUD), is supported by significant preclinical and clinical research. However, only a subset of individuals, perhaps 20% to 30%, with these disorders are expected to be CRF hypersecreters. Clinical trial designs based on broad diagnostic categories lose tremendous statistical power in assessing the value of these medications as well as potentially causing untoward effects in subjects with normal CRF function. The field appears to largely be working through these issues, and a resurgence in the development of neuropeptide receptor small-molecule clinical trials is expected.

SPECIFIC NEUROPEPTIDES AS EXEMPLARS OF NEUROPEPTIDE BIOLOGY

Thyrotropin-Releasing Hormone

In 1969, TRH, a pyroglutamyl-histidyl-prolylamide tripeptide (see Table 1.8–2), became the first of the hypothalamic-releasing hormones to be isolated and characterized, work that, in part, resulted in the Nobel prize for Drs Andrew Schally and Roger Guillemin in 1977. The discovery of the structure of this hormone led to the conclusive demonstration that peptide hormones secreted from the hypothalamus regulate the secretion of hormones from the anterior pituitary. The gene for TRH in humans resides on chromosome 3q13.3-q21. In the rat, it consists of three exons (coding regions) separated by two introns (noncoding regions) (see Fig. 1.8–2). The first exon contains the 5′ untranslated region of the mRNA encoding the TRH preprohormone, the second exon contains the SP sequence and much of the remaining amino-terminal end of the precursor peptide, and the third contains the remainder of the sequence, including five copies of the TRH precursor sequence, the carboxy-terminal region, and the 3′ untranslated region. The 5′ flanking region of the gene, or promoter, contains sequences homologous to the glucocorticoid receptor and the thyroid hormone receptor DNA binding sites, providing a mechanism for the regulation of this gene by cortisol and negative feedback by thyroid hormone. Enzymatic processing of TRH begins with excision of the progenitor peptides by carboxypeptidases, amidation of the C-terminal proline, and cyclization of the N-terminal glutamine to yield five TRH molecules per prohormone molecule. TRH is widely distributed in the CNS, with TRH immunoreactive neurons being located in the olfactory bulbs, entorhinal cortices, hippocampus, extended amygdala, hypothalamus, and midbrain structures. As is the case for most neuropeptides, the TRH receptor is also a member of the seven-transmembrane domain, G-protein–coupled receptor family.

Hypothalamic TRH neurons project nerve terminals to the median eminence, where they release TRH into the hypothalamohypophyseal portal system, where it is transported to the adenohypophysis causing the release of TSH into the systemic circulation. TSH subsequently stimulates the release of the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4) from the thyroid gland. TRH neurons in the paraventricular nucleus contain thyroid hormone receptors and respond to increases in thyroid hormone secretion with a decrease in TRH gene expression and synthesis. This negative feedback of thyroid hormones onto the TRH synthesizing neurons was first demonstrated by a decrease in TRH content in the median eminence (due to increased release in trying to drive thyroid function) but not in the paraventricular nucleus of the hypothalamus after thyroidectomy. This effect can be reversed with exogenous thyroid hormone treatment. The treatment of normal rats with exogenous thyroid hormone decreases TRH concentration in the paraventricular nucleus and the posterior nucleus of the hypothalamus. Using a probe against the TRH preprohormone mRNA, *in situ* hybridization studies have demonstrated that TRH mRNA is increased in the paraventricular nucleus 14 days after thyroidectomy. The ability of thyroid hormones to regulate TRH mRNA can be superseded by other stimuli that activate the HPT axis. In that regard, repeated exposure to cold (which releases TRH from the median eminence) induces increases in the levels of TRH mRNA in the paraventricular nucleus despite concomitantly elevated concentrations of thyroid hormones. Further evidence of the different levels of communication of the HPT axis is seen in the ability of TRH to regulate the production of mRNA for the pituitary TRH receptor and for TRH concentrations to regulate the mRNA coding for both the α- and β-subunits of the thyrotropin (TSH) molecule. In addition, TRH-containing synaptic boutons have been observed in contact with TRH-containing cell bodies in the medial and periventricular subdivisions of the paraventricular nucleus, thus providing anatomical evidence for ultrashort feedback regulation of TRH release. Negative feedback by thyroid hormones may be limited to the hypothalamic TRH neurons because negative feedback on TRH synthesis by thyroid hormones has not been found in extrahypothalamic TRH neurons.

The early availability of adequate tools to assess HPT axis function (i.e., radioimmunoassays, synthetic peptides), coupled with observations that primary hypothyroidism is associated with depressive symptomatology, ensured extensive investigation of the involvement of this axis in affective disorders. Early studies established the hypothalamic and extrahypothalamic distribution of TRH. This extrahypothalamic presence of TRH quickly led to speculation that TRH might function as a neurotransmitter or neuromodulator. Indeed, a large body of evidence supports such a role for TRH. Within the CNS, TRH is known to modulate several different neurotransmitters, including dopamine, serotonin, acetylcholine, and the opioids. TRH has been shown to arouse hibernating animals and counteracts the behavioral response and hypothermia produced by a variety of CNS depressants, including barbiturates and ethanol.

Interest in putative CNS actions of TRH was stimulated by studies of the HPT axis and depression by Prange and colleagues. Nearly four decades ago, it was hypothesized that thyroid function was integral to the pathogenesis of and recovery from affective disorders due to the numerous interactions among thyroid hormones, catecholamines, and adrenergic receptors in the CNS. Overall, these studies suggested a role for thyroid dysfunction in refractory depression and are consonant with clinical studies suggesting the existence of an increased rate of hypothyroidism and autoimmune thyroiditis among patients with refractory depression.

The use of TRH as a provocative agent for the assessment of HPT axis function evolved rapidly after its isolation and synthesis. Clinical use of a standardized TRH stimulation test, which measures negative feedback responses, revealed blunting of the TSH response in approximately 25% of euthyroid patients with major depression. These data have been widely confirmed. The observed TSH blunting in depressed patients does not appear to be the result of excessive negative feedback due to hyperthyroidism because thyroid measures such as basal plasma concentrations of TSH and thyroid hormones are generally in the normal range in these patients. It is possible that TSH blunting is a reflection of pituitary TRH receptor downregulation as a result of median eminence hypersecretion of endogenous TRH. Indeed, the observation that CSF TRH concentrations are elevated in depressed patients as compared to controls supports the hypothesis of TRH hypersecretion but does not elucidate the regional CNS origin of this tripeptide. In fact, TRH mRNA expression in the paraventricular nucleus of the hypothalamus is decreased in patients with major depression. However, it is not clear whether the altered HPT axis represents a causal mechanism underlying the symptoms of depression or simply a secondary effect of depression-associated alterations in other neural systems. More recently, Cohen and colleagues have reported that even mild increases in plasma TSH concentrations (>3.5 mIU/mL), though technically in the upper end of the so-called “normal” range, are associated with a poor response to antidepressant treatment.

Corticotropin-Releasing Factor and Urocortins

In the 1950s, it was observed that pituitary extracts contained a factor, referred to as CRF, that could stimulate the release of ACTH from anterior pituitary cells *in vivo*. After a search spanning nearly three decades, Vale and colleagues isolated and characterized CRF as a 41 amino acid peptide in 1981. The gene for CRF in humans is located on chromosome 8q13 and is composed of two exons, with the CRF preprohormone being encoded entirely on exon 2 (see Fig. 1.8–2). More recently, the related neuropeptides, urocortin 1, urocortin 2, and urocortin 3, have been identified and share similar gene structures. CRF is the primary hypothalamic ACTH secretagogue in most species, and it also functions as an extrahypothalamic neurotransmitter/neuromodulator in a CNS network which, along with the urocortins, globally coordinates responses to stressors. There is convincing evidence to support the hypothesis that CRF and the urocortins play a complex role in integrating the endocrine, autonomic, immunologic, and behavioral responses of an organism to stress.

Although it was originally isolated because of its functions in regulating the hypothalamic—pituitary–adrenal (HPA) axis, CRF is widely distributed throughout the brain. The paraventricular nucleus of the hypothalamus (PVN) is the major site of CRF-containing cell bodies that influence anterior pituitary ACTH secretion. These neurons originate in the parvocellular region of the PVN and send axon terminals to the median eminence, where CRF is released into the hypothalamic–hypophyseal portal system in response to stressful stimuli. A small group of PVN neurons also project to the brainstem and spinal cord, where they regulate autonomic aspects of the stress response. CRF-containing neurons are also found in other hypothalamic nuclei, the neocortex, the extended amygdala, brainstem, and spinal cord. Central CRF infusion into laboratory animals produces physiologic changes and behavioral effects similar to those observed following stress, including increased locomotor activity, increased responsiveness to an acoustic startle, and decreased exploratory behavior in an open field.

In a manner similar to that described for TRH and thyroid hormones, CRF gene expression and content in the PVN are negatively influenced by glucocorticoids (cortisol) and positively regulated by a wide variety of stressors. Adrenalectomy results in an increase in CRF mRNA expression in the PVN, and glucocorticoid replacement decreases CRF mRNA expression in a dose-dependent manner. In contrast to their effects on the PVN, glucocorticoids increase CRF mRNA expression in the amygdala rather than decreasing it.

CRF is also found in the raphe nuclei and the locus coeruleus (LC), the origin of the major serotonergic and noradrenergic projections to the forebrain, respectively, circuits long postulated to play a role in the pathophysiology of depression and anxiety. Increased anxiety observed after direct CNS administration of CRF has been hypothesized to be mediated, in part, by increased noradrenergic activity. Stress has been shown to produce an increase in CRF content in the locus ceruleus and a decrease in CRF concentrations in the median eminence (consistent with increased release). Other studies have shown that CRF-containing nerve terminals impinge upon noradrenergic neurons of the locus ceruleus and that exogenous CRF applied to those neurons alters their firing rate. Some of the noradrenergic locus ceruleus neurons, in turn, project to the hypothalamic PVN where their input increases CRF synthesis and release. Because CRF injection into the locus ceruleus elicits fearful or anxious behavior, one could postulate that stress activates the CRF neurons terminating on the locus ceruleus noradrenergic neurons, which then may, acting along with other inputs to the PVN, stimulate the stress-induced increased release of CRF from the median eminence. Another hypothesis that has been pursued in recent years is severe stress causes nucleus accumbens dopamine neurons to become insensitive to CRF, resulting in reduced dopamine release and increased anhedonia. Interestingly, adult animals exposed to maternal separation early in life, an animal model for early adverse childhood experiences and a very severe form of stress, exhibit elevated CRF concentrations in the LC, increased CRF mRNA expression, and exaggerated HPA axis responses to stress. Relatedly, increasing evidence strongly supports a role for CRF in stress-induced relapse in substance abuse disorders.

The physiologic and behavioral roles of the urocortins are less understood, but several studies suggest that urocortin 2 and 3 are anxiolytic and may dampen the stress response. This has led to the hypothesis that CRF and the urocortins act in opposition, but this is likely an oversimplification. Urocortin 1 is primarily synthesized in the Edinger–Westphal nucleus, lateral olivary nucleus, and supraoptic hypothalamic nucleus. Urocortin 2 is synthesized primarily in the hypothalamus, while urocortin 3 cell bodies are found more broadly in the extended amygdala, perifornical area, and preoptic area.

The CRF system is further complicated by the fact that the effects of CRF and the urocortins are mediated by at least two receptor subtypes, CRF_1- and CRF_2-receptor (Fig. 1.8–4). The CRF_1 receptor is abundantly expressed in the cerebral cortex, cerebellum, medial septum, and anterior pituitary, whereas the CRF_2 receptor is predominantly found in the lateral septum ventromedial hypothalamus and choroid plexus of rodents but has considerable expression in the human cortex. The CRF_1 receptor appears to be the predominant receptor mediating the effects of CRF in the stress response. The CRF_1 receptor has a 4- to 10-fold higher affinity for CRF than for urocortin 1, with very low affinity for the other urocortins. In contrast, the CRF_2 receptor has a 40-fold higher affinity for the urocortins relative to CRF. Thus, the urocortins have been proposed to be the endogenous ligands for the CRF_2 receptor, but little is known regarding their physiologic role. As expected, CRF_1 receptor knockout mice display decreased anxiety-like behavior, have an impaired stress response, and exhibit elevated CRF mRNA expression in the PVN due to a lack of glucocorticoid negative feedback. In contrast, CRF_2 receptor knockout mice display increased anxiety-like behavior and are hypersensitive to stress.

Hyperactivity of the HPA axis in major depression remains one of the most consistent findings in biologic psychiatry. The reported HPA axis alterations in major depression include hypercortisolemia, resistance to dexamethasone suppression of cortisol secretion (a measure of negative feedback), blunted ACTH responses to intravenous CRF challenge, increased cortisol responses in the combined dexamethasone/CRF test, and elevated CSF CRF concentrations. The exact pathologic mechanism(s) underlying HPA axis dysregulation in major depression and other affective disorders remains to be elucidated.

FIGURE 1.8–4. Ligands and receptors of the corticotropin-releasing factor (CRF) signaling network and their putative roles. The figure illustrates the complexity of the CRF system with four different ligands modulating two different receptors, each of which regulates divergent physiologic processes. The thickness of the *arrows* represents the relative affinity of each ligand for the respective receptors. (Adapted by permission from Nemeroff CB, Vale WW. The neurobiology of depression: Inroads to treatment and new drug discovery. *J Clin Psychiatry* 2005;66(S7):5–13. Copyright 2005, Physicians Postgraduate Press.)

Once the phenomenon of HPA axis hyperactivity in patients with major depression was established, many research groups utilized various provocative neuroendocrine challenge tests as a “window into the brain” in attempts to elucidate pathophysiologic mechanisms. In normal subjects, the CRF stimulation test, using either rat/human or ovine CRF, yields robust ACTH, β-endorphin, β-lipotropin, and cortisol responses following intravenous or subcutaneous administration. However, in patients with major depression, blunting of ACTH or β-endorphin secretion with a normal cortisol response has been repeatedly reported. Patients with PTSD, 50% of whom also fulfill the criteria for major depression, also show blunted ACTH secretion in response to a CRF challenge. Importantly, researchers have reported normalization of the ACTH response to CRF following clinical recovery from depression, suggesting that the blunted ACTH response, like dexamethasone nonsuppression, may be a state marker for depression. Early-life stress apparently sensitizes the HPA axis and leads to a greater risk of developing depression later in life. Depressed women who were victims of childhood abuse exhibit an exaggerated ACTH and cortisol response to a psychosocial stressor, presumably due to CRF hypersecretion. Depressed men with a history of childhood abuse exhibit marked HPA axis hyperactivity in the combined dexamethasone/CRF test.

Mechanistically, two hypotheses have been advanced to account for the ACTH blunting following exogenous CRF administration. The first hypothesis suggests that pituitary CRF receptor downregulation occurs as a result of hypothalamic CRF hypersecretion. The second hypothesis postulates altered sensitivity of the pituitary to glucocorticoid negative feedback. Substantial support has accumulated, favoring the first hypothesis. However, neuroendocrine studies represent a secondary measure of CNS activity; the pituitary ACTH responses principally reflect the activity of hypothalamic CRF rather than that of the corticolimbic CRF circuits. The latter of the two is more likely to be involved in the pathophysiology of depression.

A potentially more direct method for the evaluation of extrahypothalamic CRF tone may be obtained from measurements of CRF concentrations in the CSF. A marked dissociation between CSF and plasma neuropeptide concentrations has been described, thus indicating that neuropeptides are secreted directly into CSF from brain tissue as opposed to being derived from plasma-to-CSF transfer. Evidence that CSF CRF concentrations originate from extrahypothalamic CRF neurons has been obtained from studies in which CSF CRF concentrations were repeatedly measured over the course of the day. CSF CRF concentrations in rhesus monkeys do not appear to be entrained with pituitary–adrenal activity. The proximity of corticolimbic, brainstem, and spinal CRF neurons to the ventricular system of the brain suggests that these areas make substantial contributions to the CSF CRF pool.

In a series of studies, significant elevations of CSF CRF concentrations in drug-free patients with major depression or following suicide have been demonstrated. In addition, the severity of depression appears to correlate significantly with CSF CRF concentrations in patients with anorexia nervosa, multiple sclerosis, and Huntington disease. The elevation of CSF CRF concentrations in patients with anorexia nervosa reverts to the normal range as these patients approach normal body weight. No alterations of CSF CRF concentrations have been reported in other psychiatric disorders, including mania, panic disorder, and somatization disorders, as compared to controls. It is now clear that patients with early-life trauma in the form of child abuse or neglect exhibit increased CSF CRF concentrations, as has now been demonstrated in patients with major depression, PTSD, and antisocial personality disorder.

Of particular interest is the demonstration that the elevated CSF CRF concentrations in drug-free depressed patients are significantly decreased after successful treatment with ECT treatment, indicating that CSF CRF concentrations, like hypercortisolemia, represent a state, rather than a trait, marker. Other studies have confirmed this normalization of CSF CRF concentrations following successful treatment with fluoxetine. One group demonstrated a significant reduction of elevated CSF CRF concentrations in 15 female patients with major depression who remained depression-free for at least 6 months following antidepressant treatment as compared to little significant treatment effect on CSF CRF concentrations in 9 patients who relapsed in this 6-month period. This suggests that elevated or increasing CSF CRF concentrations during antidepressant treatment may be the harbinger of a poor response in major depression despite early symptomatic improvement. Interestingly, treatment of normal subjects with desipramine or, as noted above, of depressives with fluoxetine is associated with a reduction in CSF CRF concentrations.

In preclinical studies, CRF hypersecretion is associated with CRF-receptor downregulation. Depression is a major determinant of suicide, with more than 50% of completed suicides accomplished by patients with major depression. If CRF hypersecretion is a characteristic of depression, evidence of related CRF-receptor downregulation should be evident in the CNS of depressed suicide victims. Indeed, in two studies, a marked decrease in the density of CRF_1 receptors and CRFR1 mRNA expression in the frontal cortex of suicide victims as compared to matched control samples was observed.

If CRF hypersecretion is a factor in the pathophysiology of depression, then reducing or interfering with CRF neurotransmission might be an effective strategy to alleviate depressive symptoms. Over the past several years, a number of pharmaceutical companies have committed considerable effort to the development of small-molecule CRF_1 receptor antagonists, also termed CRHR1 antagonists, that can effectively penetrate the blood–brain barrier. Several compounds have been produced with reportedly promising drug-like characteristics.

More than 20 clinical trials have been conducted on the effects of CRF receptor antagonists on mood and anxiety disorders. These clinical trials have largely been disappointing because of the lack of efficacy for CRF_1 receptor antagonists in patients with major depression or GAD. It is important to note that these studies have not used narrowly defined depressive patient subtypes such as psychotic, anxious, or atypical depression but instead have utilized a much broader DSM inclusion criterion. Considering the fact that there is overwhelming evidence that CRF is hypersecreted in depressed patients with a history of childhood abuse and neglect, a clinical trial of CRF receptor antagonists in this discrete subset of patients with major depression would be of considerable interest. Moreover, two studies have documented elevated CSF CRF concentrations in PTSD. Here also, clinical trials have been disappointing, with little emerging that suggests a potential for disease modification.

In spite of the overwhelming preclinical and clinical pathophysiologic evidence for the role of CRF circuit hyperactivity in the pathogenesis of depression, PTSD, and several anxiety disorders, as well as AUD, the results of randomized controlled clinical trials in these populations with one or another CRF_1 antagonist have been universally disappointing. Recently, our group conducted a trial of GSK561679, a CRF_1 antagonist in women with PTSD. In the 96 subjects who completed the study, using the primary endpoint, the Clinician-Administered PTSD Scale (CAPS) score, there was no beneficial effect of the CRF_1 antagonist; a secondary analysis revealed that in subjects with a history of child abuse/neglect, who were homozygous for the GG genotype of the CRF_1 receptor, exhibited significant improvement after treatment with the CRF_1 antagonist. In a subsequent study, our group reported that DNA methylation of the PTSD-relevant genes NR3C1 and FKBP5, previously shown to predict treatment outcome of PTSD patients after psychotherapy, interacted with child abuse to predict PTSD symptom change following CRF_1 antagonist treatment.

Oxytocin and Vasopressin

The vasopressor effects of posterior pituitary extracts were first described in 1895, and the potent extracts were named vasopressin. In 1953, OT became the first peptide hormone to have its structure elucidated and the first to be chemically synthesized, leading to the Nobel Prize in Chemistry being awarded to Vincent du Vingeaud in 1955. The human OT and AVP genes are situated tandemly oriented in opposite transcriptional directions on chromosome 20p13, separated by a several kilobase intergenic sequence (see Fig. 1.8–2). Both peptides are cyclical nonapeptides containing a cysteine–cysteine disulfide bond and differ at only two amino acid residues (see Table 1.8–2). Like the sequence homology of the peptides themselves, the genes for OT and AVP share a common structure, suggesting that the two hormones are derived from a single ancestral hormone as a result of a gene duplication event early in vertebrate evolution. The two genes are organized in opposite orientations, and the OT and AVP mRNA are transcribed from opposite DNA strands toward each other. Each gene consists of three exons, with the first exon encoding the 5′ untranslated region and the translation initiation codon followed by the SP sequence and the peptide hormone portion of the preprohormone. Exons 2 and 3 encode the neurophysin portion of the prohormone molecule. The AVP prohormone also contains a glycoprotein, copeptin, whose function is unclear but that has been suggested as a biomarker in a number of diseases. Neurophysin is thought to play a role in the posttranslational processing and transport of the peptides, and copeptin is thought to do the same.

OT and vasopressin mRNAs are among the most abundant messages in the hypothalamus, being heavily concentrated in the magnocellular neurons of the paraventricular and the supraoptic nuclei of the hypothalamus, which send axonal projections to the neurohypophysis. These neurons produce all of the OT and AVP that are released into the bloodstream, where these peptides act as a hormone on peripheral targets. OT and AVP are generally synthesized in separate neurons within the hypothalamus. OT released from the pituitary is most often associated with female reproductive functions such as regulating uterine contractions during parturition and the milk ejection reflex during lactation. AVP, also known as antidiuretic hormone, regulates water retention in the kidney and vasoconstriction through interactions with vasopressin V2 and V1a receptor subtypes, respectively. AVP is released into the bloodstream from the neurohypophysis following a variety of stimuli, including plasma osmolality, hypovolemia, hypertension, and hypoglycemia. The actions of OT are mediated largely via a single receptor subtype (OTR), which is distributed in the periphery and within the limbic CNS. In contrast to the OTR, there are three AVP receptor subtypes, V1a, V1b, and V2 receptors, each of which is a G-protein–coupled, seven-transmembrane domain receptor. The V2 receptor is localized in the kidney and is not found in the brain. The V1a receptor is distributed widely in the CNS and is thought to mediate most of the behavioral effects of AVP. The V1b receptor is concentrated in the anterior pituitary and in the hippocampus. Although its function in the brain is largely unknown, V1b knockout mice display decreased aggression and altered social behaviors.

Some parvocellular neurons in the paraventricular nucleus of the hypothalamus project to the median eminence, where AVP is released into the portal system and delivered to the anterior pituitary. Through interactions with V1b receptors located on corticotrophs in the adenohypophysis, AVP acts to potentiate the effects of CRF on ACTH secretion. AVP is colocalized with CRF in the parvocellular neurons of the paraventricular nucleus. Given the link between HPA axis dysregulation and depression, recent attention has been given to the possible relationship between AVP secretion and psychiatric disorders. Although alterations in CSF AVP concentrations have been reported in patients with major depression, bipolar disorder, schizophrenia, autism, anorexia, and AD, the findings are not as consistent as for CRF, and many discrepant reports have appeared. In a postmortem study, an increase in the number of paraventricular AVP neurons colocalized with CRF cells has been reported in depressed patients compared to controls. Selective, nonpeptide V1b receptor antagonists have been developed as putative antidepressants with mixed results. Microdialysis experiments have demonstrated that AVP is released within the CNS in response to stressful stimuli.

In addition to the hypophyseal OT and AVP systems, magno- and parvocellular hypothalamic and extrahypothalamic neurons produce OT and AVP and send projections to the forebrain and brainstem. The release of peptides from these neurons is generally independent of neurohypophysial release, and it should be noted that OT and AVP released into the bloodstream do not efficiently re-enter the brain due to their inability to traverse the blood–brain barrier. OT and AVP projections from the paraventricular nucleus to the brainstem regulate a host of autonomic functions. However, in the forebrain, these peptides are now known to regulate a number of processes, ranging from anxiety, learning, and memory to complex social behaviors.

Central OT produces clear anxiolytic effects in animal models. This is particularly evident during lactation in rats when OT results in a blunted behavioral and ACTH response to a stressful acoustic stimulus. In contrast, central AVP appears to exert anxiogenic effects. In animal models, OT has been most intensively studied for its role in facilitating specific, complex social behaviors. OT has been reported to facilitate female sexual behavior, increase social interest, and facilitate the onset of maternal behavior. For example, in parturient rats, the onset of maternal behavior is blocked by OT antagonists, whereas maternal behavior can be observed in virgin females after infusion of OT directly into the brain. Stimulating OT release enhances mouse maternal behavior in part by modulating excitatory/inhibitory balance in the auditory cortex, elevating the salience of pup vocalizations. Likewise, in sheep, mother–infant bonding is facilitated by OT infusions. Studies with OT knockout mice suggest that this peptide plays a specific role in the processing of socially salient stimuli. For example, OT knockout mice have normal nonsocial cognitive abilities but have a specific deficit in the ability to recognize previously encountered individuals, even though olfactory processing is intact. Studies in highly social, monogamous rodents suggest that OT is also involved in the formation of selective social attachments between mates as well as empathic responses toward distressed partners.

Furthermore, species differences in OTR expression patterns appear to correlate with species differences in social behavior in rodents. For example, monogamous prairie voles have high densities of OTRs in the striatum, while nonmonogamous species do not (see Fig. 1.8–1). Behavioral pharmacologic studies demonstrate that these ventral striatal receptors are critical for social bond formation. Ventral striatal OTRs mediate social reward in mice. Studies in humans suggest that OT plays a similar role in regulating human social cognition. Polymorphisms in the human OTR gene predict face recognition abilities, and intranasal OT delivery causes men to rate their partner as more attractive and enhances ventral striatal activity in response to viewing the partner's face. OT has also been demonstrated to modulate human–canine interactions. All of these findings have led to the hypothesis that OT is involved in the regulation of the social brain, suggesting that dysregulation of this peptide could potentially explain social deficits in certain psychiatric disorders such as autism. Several studies using intranasal delivery of OT, which may enter the brain via the compromised blood–brain barrier of the nasal epithelium, now confirm that this neuropeptide modulates brain function and cognition in humans. For example, intranasal OT enhances eye gaze and the ability to infer the internal states of others from subtle affective facial expressions. Imaging studies reveal that intranasal OT reduces amygdala activation and reduces the coupling of the amygdala to brainstem regions implicated in autonomic and behavioral manifestations of fear in response to fear-inducing visual stimuli. There is evidence that early-life experience also alters the OT system because women with a history of childhood abuse or neglect exhibit reduced CSF OT concentrations, and polymorphisms of the OTR have recently been shown to mediate vulnerability to depression and anxiety. In voles, individual variation in OTR signaling confers susceptibility or resilience to early-life neglect in relation to adult social attachment behaviors. OT system dysfunction has also been implicated in autism spectrum disorders (ASDs). Several studies have suggested that intranasal OT can improve several aspects of social cognition, including emotion recognition and social reciprocity, as well as enhance activation of the reward system in autistic subjects. The OT system is currently viewed as the most promising target for improving social cognition in psychiatric disorders. However, the efficacy of activating the OT system through intranasal OT administration is limited due to poor brain penetration of the OT peptide, and there are no useful small-molecule brain-penetrant OT agonists. There is potential, however, for enhancing OT signaling by pharmacologically evoking endogenous OT release, such as occurs following melanocortin agonist or MDMA administration.

Studies in rodents suggest that OT enhances the signal-to-noise neurotransmission of social signals through neuromodulation. This effect is thought to amplify the neural response to social signals (olfactory, auditory, and visual) and enhance the flow of social information across brain networks involved in valence, reward, and memory. Hence, OT signaling is thought to enhance the salience and reinforcing value of social stimuli. However, the effects of intranasal administration are transient due to peptidase activity. Thus, optimal therapeutic use of drugs targeting the OT system will likely be as adjunctive therapy with behavioral interventions.

Extrahypothalamic AVP-producing neurons in the extended amygdala are sexually dimorphic, with males having many more AVP-expressing neurons than females. These neurons project through the ventral forebrain to the lateral septum, where they form a dense plexus of AVP-containing fibers in males, much more so than in females. Castration diminishes this sex difference, and androgen treatment re-establishes the sexually dimorphic pattern. Thus, extrahypothalamic AVP is predicted to be involved in the regulation of sex-specific behaviors in males. Vasopressin has been reported to modulate a variety of behaviors in males, including anxiety, aggression, affiliation, and social attachment in several animal models. For example, infusion of AVP into the hamster brain stimulates territorial and aggressive behaviors within minutes of administration. Extending this observation to humans, one study reported that individuals with a history of violent tendencies have elevated levels of AVP in the CSF compared to nonviolent controls.

One of the most intriguing features of the AVP system is the species specificity in the behavioral effects of AVP. Consistent with this observation, the neuroanatomical localization of V1a AVP receptors is highly species specific, often with little overlap between even closely related species. In fact, the specific behavioral role of AVP seems to be correlated with the localization of V1a receptors in specific brain regions. For example, AVP facilitates affiliation and social attachment in monogamous mammals. In the prairie vole, a monogamous rodent, AVP has been identified as the neurochemical trigger that stimulates pair bonding between the male and its mate. Comparisons among monogamous rodents and closely related nonmonogamous species have revealed that species differences in social organization are associated with species differences in receptor distribution within the brain. In several monogamous species, including the prairie vole, the vasopressin V1a receptor subtype is abundant in the mesolimbic dopamine reward pathway. In contrast, this region has few V1a receptors in the nonmonogamous, asocial montane vole (see Fig. 1.8–1). Infusion of a V1a receptor antagonist directly into the ventral pallidum of the prairie vole completely blocks pair bonding. Thus, AVP released during mating facilitates social bonding by modulating the mesolimbic dopamine pathway in prairie voles but cannot do so in nonmonogamous species because of the lack of receptors in that region. Molecular analysis of the V1a receptor genes of these different species has revealed DNA sequences in the promoter of the gene that may be responsible for the differential distribution of the receptor in the brain and thus the differences in behavioral patterns. This variability in distribution across species, along with the association between expression patterns and behavior, has led to the hypothesis that individual differences in receptor expression due to individual variation in gene promoter elements could potentially have important behavioral consequences in humans. In fact, three separate genetic association studies now have reported associations between polymorphisms in the V1aR promoter and ASD. Thus, dysregulation of AVP and/or its receptor may represent a risk factor that contributes to the social cognition deficits in ASD.

There has been increasing attention to the AVP system as a potential biomarker or drug target for psychiatric disorders with impaired social function, such as ASD. Nonhuman primates with low sociality are reported to have decreased CSF AVP compared to more social individuals. In addition, a small study suggested that children diagnosed with ASD, or infants who later developed ASD symptoms, have lower CSF AVP concentrations compared to non-ASD controls. Finally, intranasal AVP administration enhanced social abilities in children with ASD. While this work needs replication, and the importance of context has not been explored, these results suggest that the AVP system may be an important target for improving social functioning in psychiatric disorders.

Neurotensin

NT was isolated, based on its hypotensive properties, from the bovine hypothalamus in 1973. The NT-neuromedin N gene was originally cloned from canine ileal mucosa, and complementary deoxyribonucleic acid (cDNA) probes constructed against this form were used to clone the rat gene. The rat gene contains four exon sequences separated by three introns and spans approximately 10.2 kilobases (see Fig. 1.8–2). In the rat, the NT-neuromedin N sequence is contained in the fourth exon, and the single copy of each peptide sequence is bounded and separated by Lys-Arg basic amino pairs. The human NT gene has been localized to chromosome 12 (12q21). In pheochromocytoma (PC-12) neurons in culture, the NT-neuromedin N gene is regulated by lithium, nerve growth factor, cyclic adenosine monophosphate (AMP) activators, and dexamethasone through their effects on a 5′ flanking promoter region. The distribution of the NT-neuromedin N mRNA is generally the same as described for NT-containing neuronal cell bodies, except in the hippocampus and subiculum, where few neurons stain immunohistochemically for NT, and yet an abundance of the NT-neuromedin N mRNA is found. NT-producing cells are found in the midbrain (ventral tegmental area [VTA] and, to a lesser extent, the substantia nigra [SN]), ventral striatum, extended amygdala, lateral septum, and arcuate nucleus. The actions of NT are mediated by three receptors, the NT_1, NT_2, and NT_3 receptor subtypes. The NT_1 and NT_2 receptors are seven-transmembrane, G-protein–coupled receptors, while NT_3 is a Type I amino acid receptor with a single transmembrane domain and is located intracellularly.

Although NT is found in a number of brain regions, it has been most thoroughly investigated in terms of its association with other neurotransmitter systems, particularly the mesolimbic dopamine system, and has gained interest in research on the pathophysiology of schizophrenia. There are several lines of evidence suggesting that NT and its receptors should be considered potential targets for pharmacologic intervention in this disorder. First, the NT system is positioned anatomically to modulate the neural circuits implicated in schizophrenia. Second, peripheral administration of antipsychotic drugs has been shown to consistently modulate NT systems. Third, there is evidence that central NT systems are altered in schizophrenic patients.

Although likely other neurotransmitter systems are involved, one prevalent model of the pathophysiology of schizophrenia is overactivity of the mesolimbic dopamine system. Within the midbrain, NT-producing neurons are found in the VTA and the SN. Within the VTA, NT is found in dense-core vesicles only in tyrosine hydroxylase–positive staining cell bodies, indicating colocalization with dopamine. These NT-dopamine cells project to the prefrontal cortex, striatum, amygdala, and lateral septum. A subset of those NT-dopamine cells projecting from the VTA to the prefrontal cortex also produces CCK. In contrast to the VTA, the NT-producing cells in the SN are tyrosine hydroxylase negative. In addition to the NT-producing cells, dense fibers in the VTA staining positive for NT and originating from projections from the forebrain do not contain tyrosine hydroxylase. The midbrain also expresses NT receptors, with the vast majority of NT receptor–containing neurons in the VTA being dopamine-positive neurons. NT-producing cells, fibers, and NT receptors are also located in the ventral striatum. Thus, NT is colocalized with DA in the mesolimbic dopamine system, and this system is, in turn, sensitive to NT modulation due to the presence of the NT receptors.

NT was first shown to interact with dopamine systems while undergoing characterization of its potent hypothermic and sedative potentiating activity. Subsequent work indicated that NT possessed many properties that were also shared by antipsychotic drugs, including the ability to inhibit avoidance, but not escape, responding in a conditioned active avoidance task; the ability to block the effects of indirect dopamine agonists or endogenous dopamine in the production of locomotor behavior; and the ability to elicit increases in dopamine release and turnover. Perhaps most importantly, both antipsychotic drugs and NT neurotransmission enhance sensorimotor gating. Sensorimotor gating is the ability to screen or filter relevant sensory input, deficits that may lead to involuntary flooding of indifferent sensory data. Increasing evidence suggests that deficits in sensorimotor gating are a cardinal feature of schizophrenia. Both dopamine agonists and NT antagonists disrupt performance on tasks designed to gauge sensorimotor gating. Unlike antipsychotic drugs, NT is not able to displace dopamine from its receptor. As noted above, NT is colocalized in certain subsets of dopamine neurons and is co-released with dopamine in the mesolimbic and medial prefrontal cortical dopamine terminal regions that are implicated as the site of dopamine dysregulation in schizophrenia. Antipsychotic drugs that act at dopamine D_2 and D_4 receptors increase the synthesis, concentration, and release of NT in those dopamine terminal regions but not in others. That effect of antipsychotic drugs in increasing NT concentrations persists after months of treatment and is accompanied by the expected increase in NT mRNA concentrations, as well as expression of the "immediate early gene" c-fos within hours of initial drug treatment. The altered regulation of NT expression by antipsychotic drugs apparently extends to the peptidases that degrade the peptide because reports have revealed decreased NT metabolism in rat brain slices 24 hours after the acute administration of haloperidol.

While NT is certainly important in schizophrenia, there are numerous other neuropeptides implicated as well. For example, cortical neuropeptides that localize to parvalbumin-positive cells, such as somatostatin and CCK, may also play a role. These cells express parvalbumin calcium-binding protein and coordinate cortical γ-aminobutyric acid (GABA) release. Coordinated GABA release is central to the generation of γ-wave rhythmicity. In schizophrenic patients, γ-oscillations appear to be impaired owing to dysfunctional inhibitory GABA circuits. Neuropeptides such as somatostatin and CCK are also released from GABA-ergic Martinotti and basket cells, respectively, and contribute to the γ-oscillation frequency. Both peptides are also reduced in schizophrenia, and likely contribute to the disease state and represent attractive targets for potential therapies for this disease

With regard to schizophrenia, decreased CSF NT concentrations have been reported in several populations of patients when compared to controls or other psychiatric disorders. Although treatment with antipsychotic drugs has been observed to increase NT concentrations in the CSF, it is not known whether this increase is causal or merely accompanies the decrease in psychotic symptoms seen with successful treatment. Postmortem studies have shown an increase in NT concentrations in the dopamine-rich Brodmann area 32 of the frontal cortex, but that result may have been confounded by premortem antipsychotic treatment. Other researchers have found no postmortem alterations in NT concentrations in a wide sampling of subcortical regions. Decreases in NT receptor densities in the entorhinal cortex have been reported in postmortem samples of schizophrenic patients. A critical test of the hypothesis that NT acts as an endogenous antipsychotic-like substance awaits the development of an NT receptor agonist that can penetrate the blood–brain barrier. Recently, small-molecule full, partial, and inverse NT receptor agonists have been reported, but no psychopharmacology trials have yet been reported.

Other Neuropeptides

A number of other neuropeptides have been implicated in the pathophysiology of psychiatric disorders. These include CCK, SP, galanin, and NPY, though numerous others are implicated, far too many to cover in this chapter. A brief overview of the potential involvement of several of these neuropeptides in therapeutics or psychiatric disorders is provided as exemplars.

CCK, originally discovered in the gastrointestinal (GI) tract, and its receptors (CCK_1 primarily in the GI tract and CCK_2 primarily in the CNS) are found in areas of the brain associated with emotion, motivation, and sensory processing (e.g., cortex, striatum, hypothalamus, hippocampus, and amygdala). CCK is often colocalized with dopamine in the VTA neurons that comprise the mesolimbic and mesocortical dopamine circuits. Like NT, CCK decreases dopamine release. Intravenous infusions of a CCK fragment have been reported to induce panic in healthy individuals, and patients with panic disorder exhibit increased sensitivity to the CCK fragment compared to normal controls. Pentagastrin, a synthetic CCK agonist, dose-dependently produced increased blood pressure, pulse, HPA activation, and physical symptoms of panic. Recently, a CCK receptor gene polymorphism has been associated with panic disorder.

The undecapeptide SP is localized in the amygdala, hypothalamus, periaqueductal gray, LC, and parabrachial nucleus and is colocalized with norepinephrine and serotonin. SP serves as a pain neurotransmitter, and administration to animals elicits behavioral and cardiovascular effects resembling the stress response. More recent data suggest a role of SP in major depression and PTSD. Both depressed and PTSD patients exhibit elevated CSF SP concentrations. Furthermore, in PTSD patients, marked increases in CSF SP were detected following the precipitation of PTSD symptoms. One study has indicated that an SP receptor (termed the neurokinin 1 or NK1 receptor) antagonist capable of passing the blood–brain barrier is more effective than placebo and as effective as paroxetine in patients with major depression with moderate-to-severe symptom severity, though subsequent studies failed to confirm these findings, including in patients with PTSD and/or comorbid alcohol use. SP is present in sensory neurons and the spinal dorsal horn, and antagonism of

SP at the NK1 receptor was examined as a new type of analgesic. It failed in this realm but was serendipitously found to benefit in the treatment of chemotherapy-induced nausea, and several NK1 antagonists, with aprepitant being the first, are FDA approved for this indication.

NPY is a 36 amino acid peptide found in the hypothalamus, brain stem, spinal cord, and several limbic structures and is involved in the regulation of appetite, reward, anxiety, and energy balance. NPY is colocalized with serotonergic and noradrenergic neurons and is thought to facilitate the containment of negative effects following exposure to stress. Suicide victims with a diagnosis of major depression have been reported to exhibit a pronounced reduction in NPY levels in the frontal cortex and caudate nucleus. Furthermore, CSF NPY levels are decreased in depressed patients. Chronic administration of antidepressant drugs increases NPY concentrations in the neocortex and hippocampus in rats. Plasma NPY levels were found to be elevated in soldiers subjected to the “uncontrollable stress” of interrogation, and NPY levels were correlated with the feeling of dominance and confidence during the stress. In addition, low NPY response to stress has been associated with increased vulnerability to depression and PTSD. Remarkably, only a few scattered efforts have focused on developing NPY receptor modulators for psychiatric purposes. Although NPY itself is an anxiolytic-like substance, a synthetic compound that blocks the Y2 receptor (Y2R) will likely also be an anxiolytic because the NPY Y2R is located presynaptically and negatively regulates NPY release in the brain. Consistent with this hypothesis, Y2R null mice have reduced anxiety-like behavior. There are currently only two small-molecule NPY Y2R antagonists, and both are in preclinical development. Thus, this hypothesis remains to be tested in humans.

Galanin, first isolated from porcine intestine, is a 30 amino acid–containing peptide in humans interacting with three receptor subtypes, GalR1, GalR2, and GalR3. Preclinical studies in rodents show that galanin co-released with norepinephrine by noradrenergic cell bodies with the locus ceruleus, the main source of noradrenergic neurons within the brain, acts on GalR1somatodendritic autoreceptors to hyperpolarize and inhibit further noradrenergic cell firing. It is hypothesized that this helps prevent locus ceruleus overexcitation and may be a source of resilience to stressors. Unlike rodents, the GalR3 receptor is most prominent in humans and is hypothesized to play a similar role in both the locus ceruleus and dorsal raphe (the main source of serotonergic cell bodies). The GalR2 receptor is thought to act as a presynaptic autoreceptor in noradrenergic terminal fields, again decreasing norepinephrine release. Galanin also appears to potently enhance norepinephrine α_2 autoreceptor inhibition of LC firing. If inhibition of the noradrenergic or serotonergic system is too strong, depression may be the result. A postmortem study in human brain observed upregulation of galanin and GalR3 mRNA in the locus ceruleus of male and female subjects that completed suicide. Genetic variants for galanin and its receptors have been reported to confer an increased risk of anxiety and depression in individuals with adverse early life experiences or recent severe stressors. A small-molecule GalR3 antagonist, SNAP37889, proposed to disinhibit both noradrenergic and serotonergic pathways, was found to have significant *in vitro* toxicity, and clinical trials to test this therapeutic hypothesis have not proceeded.

Orexin A (hypocretin 1) and orexin B (hypocretin 2) are 33 and 28 amino acid–containing peptides, respectively. They possess approximately 50% sequence identity and are cleaved from the same preprohormone, and interact at the OX_1 and OX_2 G-protein–coupled receptors. Orexins are synthesized in no more than 15,000 to 20,000 neurons in the lateral and posterior hypothalamus but project widely throughout the brain and promote wakefulness. Preclinical studies originally observed that orexins stimulated feeding by delaying normal satiety mechanisms. A loss of function mutation in the orexin receptor was found to be the cause of canine narcolepsy, and this was recapitulated in a knockout mouse model. Subsequently, many humans with narcolepsy have been found to possess markedly low CSF concentrations of orexins. This is presumably due to autoimmune selective destruction of orexin neurons, although the initiating events are not clear. Therapeutic development of small-molecule orexin receptor ligands for sleep, alertness, obesity, and addiction (preclinical) has progressed, and two high-affinity, nonselective orexin receptor antagonists, suvorexant and lemborexant, are FDA approved for the treatment of insomnia.

FUTURE DIRECTIONS

Our current understanding of the role of neuropeptide systems in psychiatric disorders is derived primarily from correlational studies in human samples (e.g., CSF peptide concentrations or postmortem analyses), which preclude inferences of causality, or from animal models, which may or may not accurately reflect psychopathology. The inability to directly modulate CNS neuropeptide receptor activity in human subjects is a major impediment to the direct examination of the role of neuropeptide systems in human psychopathology. Considerable effort is being devoted to the development of small-molecule nonpeptide drugs that readily pass the blood–brain barrier and selectively modulate CNS peptide receptor activity. Small-molecule agonists or antagonists for several neuropeptide systems, including CRF, OT, AVP, orexin, and SP, are the subject of preclinical and clinical investigations. Over the next decade, these new pharmacologic tools will likely contribute significantly to our understanding of the roles of these peptides in both normal human behavior and various psychopathologies. Small-molecule drugs targeting neuropeptide receptors will undoubtedly lead to novel pharmacotherapy approaches for the treatment of psychiatric disorders such as anxiety disorders, depression, and ASDs. Small-molecule agonists or antagonists will also likely lead to the development of novel PET ligands, allowing visualization of peptide receptors in the CNS of human subjects, a great unmet need.

In addition to drug development and novel brain imaging tools, advances in psychiatric genetics are likely to reveal novel relationships between neuropeptide systems and psychopathology over the next few years. Polymorphisms in several neuropeptide receptor systems have already been implicated as risk factors in psychiatric disorders. Combining brain imaging techniques with genetic analyses will aid in understanding how these polymorphisms affect brain functioning. The plethora of recent GWAS studies in patients with mood and anxiety disorders and schizophrenia will likely identify novel neuropeptides associated with disease vulnerability. Finally, psychopharmacogenomics, which examines how genotype influences clinical responses to drugs, may lead to individualized therapies targeting peptide systems based on the patient's genotype. This burgeoning field has been helped along with technology to be able to routinely fully sequence a patient genome but still needs to be broadly informed by examining patient cohorts in order to identify relevant genotypes.

Clearly, we are (still) just beginning to understand the complexity of the brain's rich neuropeptide systems and their contribution to mental health. The unprecedented ability to manipulate neuropeptide circuits with remarkable anatomical and temporal precision is revealing the circuit-based neuropeptide-behavior relationships at a phenomenal pace. The significance of therapeutic contexts of pharmacologic manipulations is only beginning to be considered. This area of research will continue to provide novel insights into the biologic basis of psychopathology over the next few decades and will likely produce the next generation of pharmacologic interventions for psychiatric disorders.

1.9 Novel Neurotransmitters

Thomas W. Sedlak, M.D., Ph.D., Bindu D. Paul, Ph.D., and Adam I. Kaplin, M.D., Ph.D.

Neurotransmitters are chemicals that amplify or inhibit the depolarization signal from one neuron to that of an adjacent neuron. A neurotransmitter is typically released from a *presynaptic neuron* and travels across a small space, the *synaptic cleft* or *synapse*, to act upon the *postsynaptic neuron*. Neurotransmitters may be excitatory (e.g., glutamate) in that they promote depolarization of the target cell or inhibitory by promoting hyperpolarization (e.g., most GABA). Neurotransmitter receptors that are ion channels typically elicit depolarization via sodium or calcium, and hyperpolarization via chloride. Ion channel receptors differ from metabotropic receptors, the latter producing second messengers that have complex effects upon target cells, such as altering gene expression or modulating the propensity to depolarize.

An *action potential* is a wave of depolarization that travels down a neuronal axon to the *presynaptic terminal*, a specialized appendage where neurotransmitters are stored in specialized *vesicles*. The action potential opens voltage-sensitive calcium channels in the membrane, allowing for an increase in cellular calcium that results in vesicles releasing their contents into the synaptic cleft and acting upon receptors on the postsynaptic neuron membrane. When binding to their targets, neurotransmitters are typically full or partial agonists, and therapeutic drugs range from partial to full agonists to antagonists or inverse agonists (Fig. 1.9–1).

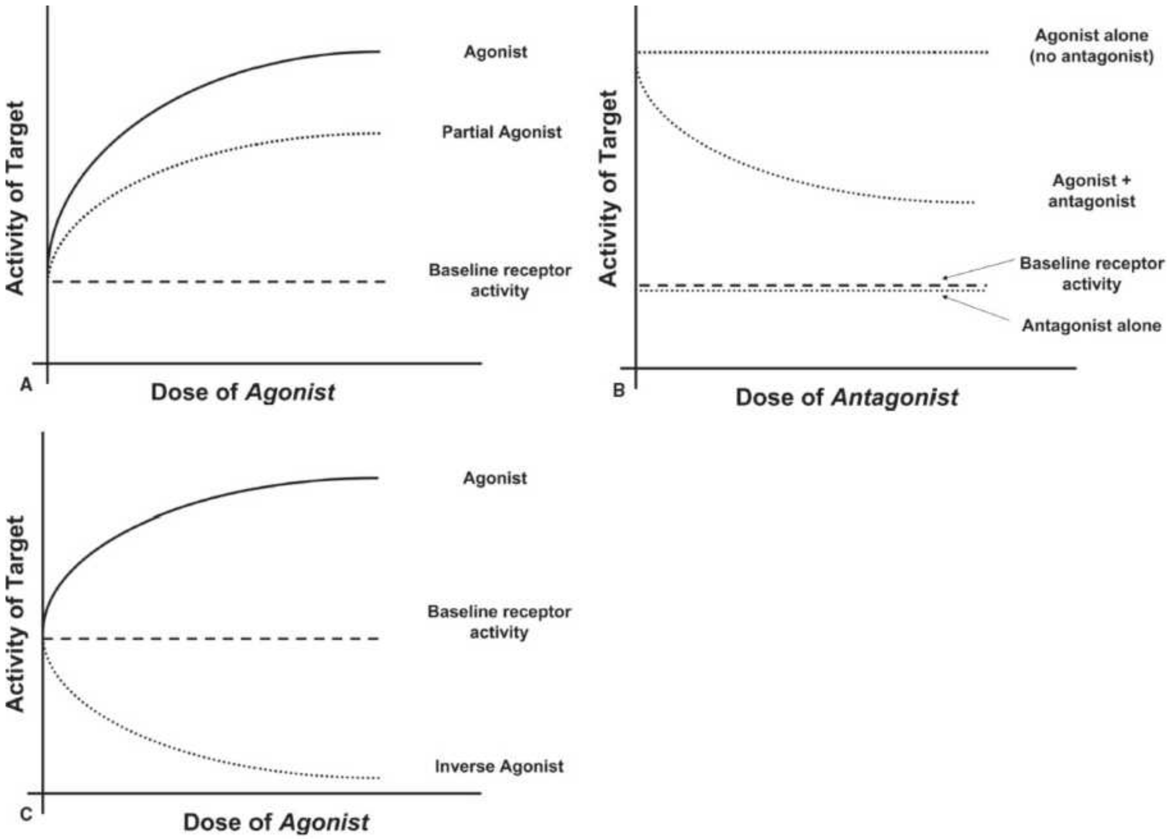

FIGURE 1.9–1. Agonists, antagonists, partial agonists, and inverse agonists. **A:** *Agonist* drugs bind to a target, such as a neurotransmitter receptor, and increase its activity until the receptors saturate. A *partial agonist* increases the activity of its target, but to a level below that of its maximum. In some cases, a partial agonist leads to diminished overall activity of a neurotransmitter receptor because it competes with the full agonist neurotransmitter. Occasionally a drug considered to be an agonist becomes reclassified as a partial agonist once a stronger agonist is found. THC was once considered a full agonist for the CB1 receptor, but was found to be a partial agonist after the discovery of the more potent synthetic cannabinoids, CP55,940 and WIN55,212-2. **B:** An *antagonist* has no intrinsic activity for activating or inhibiting a receptor. It acts to inhibit the activity of an agonist, in many cases by competing with an agonist for the binding site. **C:** An *inverse agonist* inhibits the activity of its target to a level below that of its baseline level with no drug present. Rimonabant is a CB1 receptor inverse agonist. It can block the baseline activity of the receptor even in the absence of cannabinoid agonists.

The definition of what a neurotransmitter is and is not has changed over the decades. The neurotransmitters initially discovered were small chemicals, first acetylcholine and later the biogenic amines such as serotonin, dopamine, norepinephrine, epinephrine, and histamine. Later it was found that amino acids and peptides could act as neurotransmitters, such as enkephalin acting upon the opiate receptor. By the 1990s it became apparent that the neurotransmitter acting on cannabinoid receptors was derived from cellular lipids. Furthermore, even a gas, nitric oxide, could be a neurotransmitter, bypassing membrane receptors and acting directly within postsynaptic neurons.

GASES AS NEUROTRANSMITTERS

Nitric Oxide

The discovery that gases could function as neurotransmitters revealed that highly atypical modes of signaling existed between neurons. In the early 1990s, nitric oxide was the first gas to be ascribed a neurotransmitter function, and proved to be an atypical neurotransmitter for several reasons. First, it was not stored in or released from synaptic vesciles. It was a small gas it could freely diffuse across cell membranes and into the target neuron. Second, its target was not a specific receptor on the surface of a target neuron, but intracellular proteins whose activity could directly be modulated. Nitric oxide also lacks a reuptake mechanism to remove it from the synapse. Although enzymatic inactivation of it is postulated to exist, nitric oxide is limited by a short half-life of a few seconds.

Nitric oxide was initially discovered as a bactericidal compound released from macrophages and as an endothelial cell-derived relaxation factor producing dilation of blood vessels. A role for nitric oxide in the brain followed, revealing a role for the gas in neurotransmission, learning and memory processes, neurogenesis, and neurodegenerative disease.

Synthesis of Nitric Oxide. Nitric oxide is chemically designated NO, with the dot representing that the molecule is a free radical, imparting a highly reactive nature. Nitric oxide is occasionally confused with nitrous oxide (N_2O), the gaseous anesthetic, and nitrogen dioxide (NO_2), a pollutant found in exhaust fumes, although these are not synthesized endogenously in mammals. A specific enzyme exists to generate nitric oxide within cells, nitric oxide synthase (Fig. 1.9–2). This enzyme generates nitric oxide by abstracting nitrogen from the amino acid arginine and reacting it with an oxygen atom. The enzyme utilizes nicotinamide adenine dinucleotide phosphate (NADPH) and generates citrulline as a byproduct.

Three distinct enzymatic forms of nitric oxide synthase exist, each with different locations and activation patterns within the body. *Neuronal nitric oxide synthase* (nNOS) was the first form discovered by Bredt and Snyder and is the predominant form in the brain. Neuronal NOS is expressed in neurons, especially those of the cortex, the dentate gyrus of the hippocampus, the corpus striatum, and the cerebellum. Although nNOS-containing neurons are only 1% of cortical neurons, their neuronal processes are so extensively distributed that almost all neurons make contact with an nNOS-containing nerve terminus. nNOS enzyme activity is markedly augmented by calcium levels via the accessory protein calmodulin. Thus, nitric oxide may be synthesized following neuronal depolarization, in which calcium levels transiently increase.

(Nitric Oxide)

FIGURE 1.9–2. Enzymatic generation of nitric oxide. The gaseous neurotransmitter nitric oxide is generated by the enzyme nitric oxide synthase. The amino acid arginine is converted to citrulline and nitric oxide, employing oxygen and the reductant NADPH. Of note, nitric oxide is not preformed and stored in synaptic vesicles but is synthesized on demand.

Endothelial NOS (eNOS) is predominantly found in blood vessels, where it plays a crucial role in allowing for the relaxation and dilation of blood vessels. Nitroglycerine and sodium nitroprusside exert their vasodilatory effects via conversion to nitric oxide. eNOS activity is augmented by phosphorylation and increases in intracellular calcium. The third NOS, *inducible NOS* (iNOS), exists in many tissues in minuscule amounts. However, its levels are strongly increased by a great variety of cell stressors, especially inflammation. In the brain, it is largely induced in glial cells but also neurons.

Mechanism of Action of Nitric Oxide: Cyclic GMP Pathway. Long-term changes in brain function, such as learning and memory, involve a great variety of cellular processes, including changes in the patterns of gene and protein expression and the physical remodeling of neuronal architecture, such as dendrites. *Signal transduction* is the process by which extracellular signals, such as neuronal depolarization and receptor activation, lead to modified cellular function. Cyclic guanosine monophosphate (cGMP) is a prototypic intracellular messenger whose synthesis by guanylyl cyclase is stimulated after a membrane receptor is activated. cGMP then activates protein kinases that phosphorylate proteins as part of the cascade that elicits the biologic effect. As is the case with other neurotransmitters, such as serotonin, nitric oxide also activates cGMP production in neurons (Fig. 1.9–3). While a typical neurotransmitter activates guanylyl cyclase via a G-protein coupled to a membrane receptor, nitric oxide directly activates soluble guanylyl cyclase, the enzymatic form found in the cytoplasm. The active site of guanylyl cyclase contains a heme-group cofactor whose iron atom is bound by nitric oxide, leading to a protein conformation change and production of cGMP. Nitric oxide can also interact with the heme groups of other proteins, including hemoglobin/myoglobin, ferritin, and cytochrome P450.

Mechanism of Action of Nitric Oxide: S-Nitrosylation Pathway. A second method by which nitric oxide exerts its effects upon cells is the process of S-nitrosylation. In this signaling mechanism, nitric oxide directly modifies the sulfur atom of a protein cysteine residue, forming an S-nitrosothiol group (Fig. 1.9–4) that modifies the activity of select proteins. The generation of this modification requires no enzyme, though there is evidence that some proteins may carry the modification around to different areas of the cell and transfer it to a destination protein that elicits the target effect. Proteins that have been nitrosylated vary in their response to this modification; some are activated, and others are inactivated.

The number of protein targets of S-nitrosylation is rapidly expanding and includes molecules involved in signal transduction, programmed cell death, transcription factors, cytoskeletal proteins, ion pumps, and ion channels. In many cases modification of a single cysteine residue in a target protein is sufficient for nitric oxide to regulate its activity. Specific targets that are *activated* by S-nitrosylation include L-type calcium channels, calcium-activated potassium channels, and GABA-A receptors. Proteins *inhibited* by nitrosylation include several types of sodium channel, the N-methyl-d-aspartate (NMDA) subtype of the glutamate neurotransmitter receptor and several metabolic enzymes. S-Nitrosylation as a means of signal transduction is somewhat analogous to protein phosphorylation, as both are reversible covalent modifications that regulate protein function to change cell activity. S-Nitrosylation might participate in memory, learning, and behavior as many brain proteins are nitrosylated through the activity of neuronal nitric oxide generation.

FIGURE 1.9–3. Neurotransmitter and signaling functions of nitric oxide (NO) via production of cyclic GMP. Gaseous nitric oxide is generated enzymatically and freely diffuses into an adjacent neuron (**upper right**). In comparison to traditional neurotransmitters (**upper left**), NO does not act via a specific neurotransmitter receptor on the surface membrane of a neuron. In contrast, NO freely diffuses across the neuronal membrane and activates the enzyme guanylyl cyclase, which converts GTP into the second messenger, cyclic GMP. Nitric oxide effects are mediated, in part, by cyclic GMP activation of neuronal protein kinases, new gene expression, and effects on neuronal long-term potentiation (LTP) and long-term depression (LTD). ATP, adenosine triphosphate. PDE, phosphodiesterase.

Nitric Oxide and Neurotransmission. Long-term potentiation (LTP) is the process by which repetitive stimulation of a presynaptic neuron leads to stronger firing of a postsynaptic neuron, a process that underlies changes in learning and behavior. Induction of LTP depends on activation of postsynaptic NMDA receptors, while LTP maintenance relies on presynaptic mechanisms. Neurotransmission through the NMDA receptor facilitates LTP, in part, through the activity of nitric oxide. Activation of the

NMDA receptor leads to a cellular calcium increase, promoting nitric oxide synthesis and cGMP formation in the postsynaptic cell (Fig. 1.9–5).

Pharmacologic inhibitors of NOS have revealed deficits in LTP in rodent, bird, and honeybee models, and nitric oxide has been implicated in both short-term and long-term memory acquisition. Genetically modified mice lacking either nNOS or eNOS demonstrate no changes in LTP in the hippocampus, however, mice deficient in *both* nNOS and eNOS show decreased LTP in the CA1 region of the hippocampus. One form of NOS may compensate for the absence of the other, or the two may function cooperatively in LTP. Studies of the enteric nervous system have also revealed roles for nitric oxide in relaxation of the pyloric sphincter, and mice deficient in nNOS reveal a marked hypertrophy of the pylorus. Nitric oxide may also regulate monoaminergic neurotransmission. Inhibition of NOS in rats enhances the effects of cocaine and amphetamine, while the reverse is observed by increasing nitric oxide.

Nitric Oxide and Behavior. Nitric oxide neurotransmission may play a role in behavior as nNOS-deficient male mice display exaggerated aggressive tendencies and increased sexual activity. In female mice, the contrary is true, as they have reduced aggression.

In the periphery, nNOS localizes to neurons that innervate the blood vessels of the penis, including the corpus cavernosum. Stimulation of these nerves releases nitric oxide, leading to cGMP formation, blood vessel wall relaxation and vasodilatation, penile engorgement and initiation of erection. The sustained phase of erection also depends on nitric oxide; turbulent blood flow leads to phosphorylation of eNOS and sustained nitric oxide production. Drugs used in the treatment of erectile dysfunction, sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra), act to inhibit type 5 phosphodiesterase, an enzyme that degrades cGMP in the penis (see Fig. 1.9–3), thereby augmenting nitric oxide neurotransmission and penile erection.

FIGURE 1.9–4. Nitric oxide (NO) signaling via S-nitrosylation. In addition to NO activation of guanylyl cyclase, NO may also directly alter protein function via the process of S-nitrosylation. In this process, which does not require enzymatic catalysis, NO reacts with –SH groups of protein cysteine residues, resulting in an –SNO modification and altered protein function. Some proteins demonstrate robust activation following S-nitrosylation, whereas others are inhibited by the process.

FIGURE 1.9–5. Nitric oxide (NO) generation following NMDA receptor activation. The presynaptic neuron (**top**) releases glutamate (not shown), activating the NMDA glutamate receptor and allowing for calcium entry into the postsynaptic neuron. Calcium binds to the protein calmodulin (CaM), which in turn activates neuronal nitric oxide synthase (nNOS) to synthesize NO. A freely diffusible gas, NO exerts effects upon the target neuron via formation of cyclic GMP and S-nitrosylation (Figs. 1.9–3 and 1.9–4).

Numerous lines of evidence have suggested a role for nitric oxide in the regulation of sleep–wake cycles. nNOS expressing neurons occur in several areas that initiate REM sleep, including the pons, dorsal raphe nucleus, laterodorsal tegmentum, and pedunculopontine tegmentum. In animal models, microinjection of compounds that release nitric oxide results in decreased wakefulness and increased slow-wave sleep. Consistent with this, NOS inhibitors show a trend toward decreasing slow wave and rapid eye movement (REM) sleep. Studies of NOS-deficient mice suggest that nitric oxide may serve a more complex role than merely promoting sleep. nNOS-deficient animals also show reduced REM sleep; however, iNOS-deficient mice demonstrate the reverse, suggesting a complex interplay between NOS enzymatic isoforms.

Nitric Oxide and Mood Disorders. NOS-expressing neurons are well represented in brain areas implicated in depression, including the dorsal raphe nucleus and prefrontal cortex. A role for nitric oxide has been suggested in antidepressant response as selective serotonin reuptake inhibitor (SSRI) antidepressants can directly inhibit NOS activity. Moreover, in animal studies such as the forced swim test, NOS and soluble guanylyl cyclase inhibitors can achieve antidepressant-like effects. Plasma nitric oxide levels were elevated in patients with bipolar disorder compared to healthy control subjects. However, in depressed subjects, studies have found decreased nitric oxide levels and increased plasma nitrite, a byproduct of nitric oxide. Reduced NOS has also been described in the paraventricular nucleus of patients with schizophrenia and depression compared to controls.

Neurogenesis, the process by which new neurons are generated in the adult brain, is increasingly appreciated to participate in both mood disorder pathophysiology and antidepressant response. Increased hippocampal neurogenesis is associated with antidepressant response, and smaller hippocampal volume may be a risk factor for mood and anxiety disorders. Serotonin, itself, appears to promote neurogenesis in the hippocampus, while nitric oxide has been found to inhibit neurogenesis. Pharmacologic inhibitors of NOS result in increased serotonin and neurogenesis in the dentate gyrus of the hippocampus, a paramount site of this process. These NOS inhibitors also lead to an increase in serotonin in the dentate gyrus. Unsurprisingly, nNOS-deficient animals also manifest increased proliferation in the dentate gyrus. As steroids appear to induce NOS expression, nitric oxide may contribute to effects upon mood and anxiety often observed in those treated with these agents.

Nitric oxide has been interrogated for its ability to regulate neurotransmission at serotonin, norepinephrine and dopamine nerve termini. Nitric oxide appears to possess the capability of either increasing or decreasing activity at these neurons depending upon the specific brain region and timing of its activation.

Nitric Oxide and Schizophrenia. Nitric oxide has been investigated as a candidate molecule contributing to symptoms of schizophrenia. Genetic studies have identified schizophrenia-associated single nucleotide polymorphisms (SNPs) in CAPON, a protein that associates with nNOS. SNPs in nNOS have been inconsistently associated with schizophrenia. Changes in NOS levels have been reported in postmortem brain samples of individuals with schizophrenia. Abnormalities have been noted in the cortex, cerebellum, hypothalamus and brainstem, although no specific trend can be discerned. Elevated NOS activity has been noted in platelets from drug-naïve and drug-treated individuals with schizophrenia, but results have been inconsistent. Some investigators find increased nitric oxide activity and others the reverse. In autopsy samples, schizophrenic patients were found to have abnormally localized NOS expressing neurons in the prefrontal cortex, hippocampus and lateral temporal lobe, consistent with abnormal migration of these neuronal types during development. In a rat model, prenatal stress led to reduced NOS expressing neurons in the fascia dentata and hippocampus.

Neuropathologic Roles of Nitric Oxide. Abundant evidence exists that nitric oxide is a direct participant in a variety of neuropathic events. Superoxide, a byproduct of cellular metabolism, can react with nitric oxide to form peroxynitrite (chemical formula, $ONOO^-$). This labile and toxic compound forms chemical adducts with protein tyrosine residues, a process termed protein nitration, and DNA, leading to cellular dysfunction. Cell loss resulting from ischemic stroke is mediated in part by overstimulation of the glutamate NMDA receptor, a process termed *excitotoxicity*. Nitric oxide produced by NMDA activation appears to mediate a significant portion of this excitotoxic neuronal death, and stroke damage is reduced in mice with a genetic deletion of nNOS.

S-Nitrosylation has also been implicated in pathologic processes in the brain. Mutations in the Parkin protein are associated with early-onset Parkinson disease. Parkin is an E3 ubiquitin ligase, adding ubiquitin molecules to proteins and targeting them for destruction in the cell proteasome. In sporadic Parkinson disease, that is, without the early-onset mutation, nitric oxide can nitrosylate the Parkin protein and inhibit its protective E3 ubiquitin ligase function. An overabundance of nitric oxide signaling may thus predispose to the dysfunction and cell death of dopaminergic neurons in Parkinson disease by interfering with proteins essential for cell functioning. In Alzheimer disease, excess oxidation of brain protein, lipids, and carbohydrates has long been appreciated, but nitrosative stress from excess nitric oxide also appears to participate. Protein disulfide isomerase (PDI) is a cellular protective protein that may help combat the accumulation of misfolded proteins such as the amyloid fibrils occurring in the disease. In both Alzheimer and Parkinson disease brains, S-nitrosylation of PDI impedes its cellular protective function.

The discovery that nitric oxide participates in neurodegenerative processes raises the possibility for improved diagnostic processes, such as detecting damage to cellular components produced by nitric oxide prior to the onset of full-blown symptoms. In addition, drugs may be designed to attenuate the damage to crucial neuronal proteins that protect against disease onset. However, completely and nonspecifically inhibiting or stimulating nitric oxide synthesis is likely to produce significant side effects because of its wide-ranging activities throughout the body.

Nitric oxide is one of the most intensively studied compounds in the body, and possesses pleiotropic activities in different organs. While nitric oxide has physiologic roles in the brain, vasculature and immune system, it is a complex and incompletely understood molecule that also participates in disease. However, oxygen, which is a highly reactive molecule like nitric oxide, also possesses the capacity to contribute to disease pathogenesis, such as in oxidative damage, while still being essential for life.

Carbon Monoxide

Although carbon monoxide (chemical formula, CO) is most well known as an air pollutant derived from combustion reactions, it is produced physiologically in a great variety of organisms ranging from human to bacterium. While once thought to be a toxic byproduct of metabolic reactions, carbon monoxide is increasingly recognized to regulate a variety of physiologic processes in the brain and other organs. These varied effects include regulation of olfactory neurotransmission, blood vessel relaxation, smooth muscle cell proliferation, and platelet aggregation.

Carbon monoxide is far more well known for its toxic effects than its activities at physiologic concentrations. It binds tightly to heme molecules within hemoglobin, forming carboxyhemoglobin, which can no longer transport oxygen to tissues. One to two pack per day smokers typically have 3% to 8% of their hemoglobin as carboxyhemoglobin, with nonsmokers have less than 2%. Following acute carbon monoxide poisoning, 5% to 10% carboxyhemoglobin is associated with impaired alertness and cognition, and 30% to 50% carboxyhemoglobin leads to significant drops in oxygen transport to tissues.

Enzymatic Generation of Carbon Monoxide. Carbon monoxide is produced during the metabolism of heme by the action of *heme oxygenase* (HO). This enzyme utilizes oxygen, the reducing equivalents of NADPH and the electron donor cytochrome P450 reductase to break open the carbon ring of heme and release a one-carbon fragment as carbon monoxide (Fig. 1.9–6). The reaction also produces the green pigment, biliverdin, and free iron. Biliverdin is converted to the yellow pigment, bilirubin, which like carbon monoxide is no longer solely considered a toxic byproduct. At physiologic concentrations bilirubin is an enormously potent antioxidant which can be partly recycled back to its precursor, biliverdin.

Three forms of HO exist. HO1 is similar to iNOS in that it typically exists at very low levels, but its expression may be potently induced by a great variety of stimuli, ranging from oxidative stress, inflammation, dopamine, steroids, and growth factors. Indeed, HO1 is one of the most easily induced proteins known. HO2 is not an inducible protein and is predominantly expressed in the brain and testis. HO2 is expressed in discrete neuronal populations throughout the brain, including cortical and hippocampal pyramidal cells, dentate gyrus granule cells, the olfactory bulb, thalamus, hypothalamus, brainstem, and cerebellum. HO3 is an isoform whose significance is poorly understood.

Molecular Actions of Carbon Monoxide. Similar to nitric oxide, gaseous carbon monoxide can freely diffuse across membranes and directly activate soluble guanylyl cyclase, though it is approximately 30-fold less potent than nitric oxide. With the ensuing increase in cGMP, protein kinases are activated leading to some of the manifold effects of carbon monoxide upon cells. The expression of HO2 closely mirrors the expression pattern of guanylyl cyclase, implicating the two as part of a common pathway of neuronal signaling, and inhibitors of HO2 block the generation of cGMP. Similar to the case of nNOS, HO2 can be activated by calcium/calmodulin and phosphorylation, fulfilling the important criterion that a neurotransmitter to be rapidly released in response to neuronal depolarization. Carbon monoxide can also activate p38 MAP kinase, via a mechanism that does not require cGMP. This important kinase promotes a variety of cellular effects including inhibition of inflammation, cell proliferation, and programmed cell death (apoptosis).

Carbon Monoxide and Neurotransmission. Carbon monoxide appears to participate in the neurotransmission of odorant perception. Odorants lead to carbon monoxide production and subsequent cGMP synthesis that promotes long-term adaptation to odor stimuli. Carbon monoxide has the potential to regulate a variety of perceptual and cognitive processes that are yet untested. Similarly, in the rat retina, long periods of light exposure lead to increased HO1 expression, carbon monoxide production, and cGMP signaling. Carbon monoxide may also participate in adaptation to chronic pain. HO2-deficient animals manifest reduced hyperalgesia and allodynia after exposure to chronic pain stimuli. Carbon monoxide may thus tune the threshold for pain perception, although it is unclear whether the effect occurs in the central or peripheral nervous system (PNS). Aside from its role in promoting cGMP production, carbon monoxide may also directly bind to and open the BK_{Ca} channel.

In the gastrointestinal nervous system, carbon monoxide serves as a neurotransmitter to relax the internal anal sphincter in response to nonadrenergic noncholinergic (NANC) nerve stimulation and vasoactive intestinal peptide (VIP). Mice rendered genetically deficient of HO2 demonstrate a 50% reduction in NANC neurotransmission, as do nNOS-deficient animals. Mice that are bred to have loss of both HO2 and nNOS have their NANC neurotransmission abolished, establishing a physiologic process mediated entirely by gaseous neurotransmitters.

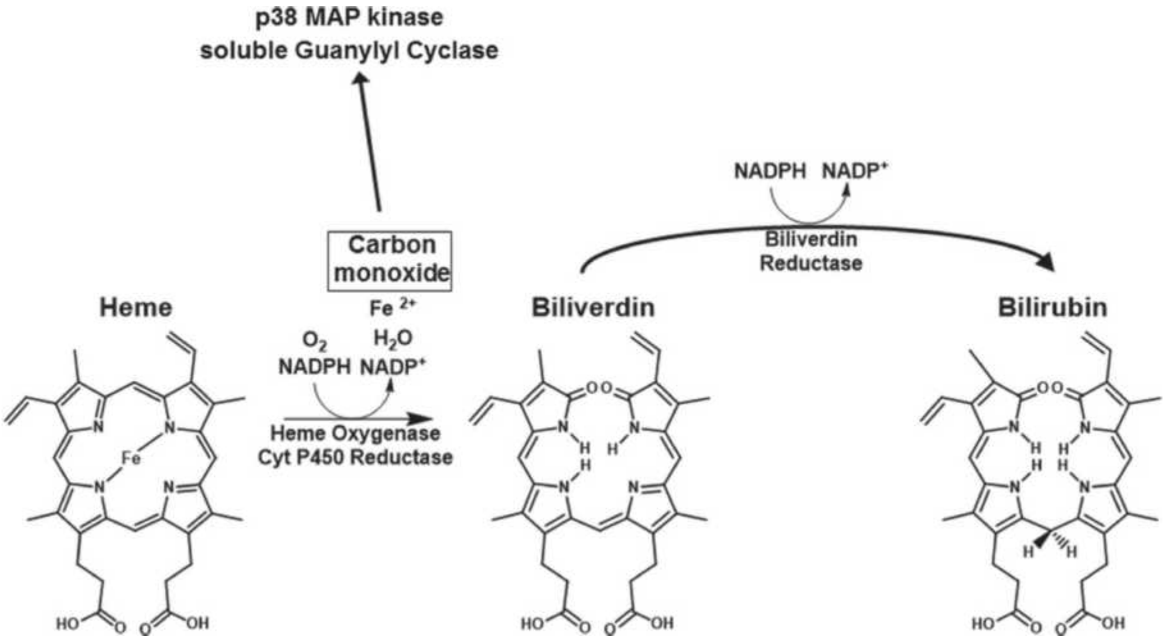

FIGURE 1.9–6. Synthesis of carbon monoxide, an atypical neurotransmitter. Gaseous carbon monoxide (CO) is enzymatically synthesized in neurons via the enzyme, heme oxygenase, also converting heme into the molecule biliverdin, and liberating free iron (Fe). Similar to nitric oxide, CO is not stored in neuronal vesicles and can freely diffuse across neuronal membranes. CO also similarly activates soluble guanylyl cyclase, and leads to activation of multiple intracellular signaling molecules such as p38 MAP kinase. CO exerts its neurotransmitter and signaling functions at concentrations far below that at which classical CO toxicity occurs. The significance of this pathway in neurons is underlined by the existence of two distinct heme oxygenase enzymes, one of which is predominantly expressed in the brain. Biliverdin is converted to bilirubin via the enzyme biliverdin reductase. Similar to CO, bilirubin is no longer relegated to the status of toxic byproduct and may be an important antioxidant.

Carbon monoxide has been implicated in the development of hippocampal LTP, although lines of evidence are contradictory. Carbon monoxide and tetanic stimulation of nerves leads to increased excitatory postsynaptic potentials (EPSPs). HO inhibitors that block carbon monoxide production lead to impaired induction of LTP and reduced calcium-dependent release of glutamate neurotransmitter. However, HO2-deficient animals fail to manifest any differences in LTP. These disparate findings may be explained by a role for HO1 in LTP, or an ability of HO inhibitors to nonspecifically block some other processes important to LTP induction.

Animals with loss of HO2 demonstrate a reduced fear of falling from a suspended wire and greater exploratory behavior in open-field testing. These animal model correlates may suggest a role for carbon monoxide signaling in anxiety states. Subtle abnormalities on memory have been noted in these HO2 knockout mice, although findings have been mixed. As HO2 is abundantly expressed in male testis and penile autonomic ganglia, it is unsurprising that carbon monoxide and nitric oxide both appear to regulate the male reproductive autonomic nervous system. HO2-deficient mice manifest abnormal neurotransmission of the myenteric plexus and diminished bulbospongiosus muscle reflex, leading to ejaculatory abnormalities.

Other Signaling Roles of Carbon Monoxide. The expression of HO2 in the hypothalamus led investigators to test whether carbon monoxide could regulate the release of peptide hormones. In animal models carbon monoxide was found to block the secretion of both oxytocin and vasopressin from the hypothalamus. Cell culture systems have also suggested that carbon monoxide inhibits corticotrophin-releasing factor (CRF) release from hypothalamic cells, but near toxic levels do the reverse, stimulating CRF release.

Heme metabolism and carbon monoxide production appear to be regulated in a circadian fashion, consistent with a role in the regulation of sleep–wake cycles. The mammalian transcription factor NPAS2 binds BMAL1 to form a complex (NPAS2/BMAL1) that, along with Clock/BMAL1, activates transcription of period and cryptochrome proteins. Period and cryptochrome have dual functions, inhibiting the circadian rhythm machinery, but also blocking NPAS2/BMAL1 and Clock/BMAL1, forming a periodic circuit. NPAS2 contains two heme moieties that can bind carbon monoxide, leading to an inhibition of the NPAS2/BMAL1 complex being able to bind to DNA and regulate transcription.

At toxic levels, carbon monoxide is well known to impair oxygen transport by binding to hemoglobin with higher affinity than oxygen. Amazingly, carbon monoxide itself plays a physiologic role in the mechanism by which the carotid body senses oxygen. HO, expressed in glomus cells of the carotid body, uses oxygen as a substrate in the production of carbon monoxide (see Fig. 1.9–6). When oxygen levels drop, so does carbon monoxide production, leading to a resetting of the threshold in which the carotid body senses oxygen. The molecular mechanism may occur via carbon monoxide regulation of the carotid body BK ion channel.

Neuroprotective Roles of the Heme Oxygenase Pathway. Mice rendered genetically deficient in HO2 manifest increased susceptibility to traumatic brain injury and stroke damage. The neuroprotective function of HO may be impaired in Alzheimer disease as HO is found in amyloid plaques. The amyloid precursor protein (APP), a source for toxic amyloid beta fragments, can bind to and inhibit HO neuroprotective function, and APP mutants associated with early-onset Alzheimer disease are the most potent at blocking HO function.

Hydrogen Sulfide: The Newest Gaseous Messenger Molecule

As carbon monoxide and bilirubin had reputations of toxicity prior to the appreciation of their physiologic functions, a similar tale is unfolding for the gas, hydrogen sulfide. While still abundantly recognized as a foul smelling and toxic emission of bacteria and sewage treatment plants, hydrogen sulfide (chemical formula, H_2S) may yet prove to be a significant neuromodulator and atypical neurotransmitter.

At least two different enzymes can generate hydrogen sulfide, cystathionine beta synthase (CBS) and cystathionine gamma lyase (CSE). Each catalyzes the same reaction converting cysteine and water to hydrogen sulfide, pyruvate, and ammonia. Intriguingly, each enzyme also catalyzes an independent reaction. CBS converts homocysteine and serine to cystathionine, which CSE uses to produce cysteine, ammonia, and 2-oxobutyric acid. Similar to nitric oxide, hydrogen sulfide also regulates blood pressure by dilation of arterioles. Mice deficient in CSE are hypertensive, and hydrogen sulfide treatments lower blood pressure.

In the brain, hydrogen sulfide exists at concentrations as high as 160 micromolar, consistent with a role in regulating brain function. CBS is abundantly expressed in brain, while CSE is undetectable. Similar to the enzymes that generate the other gaseous neurotransmitters, CBS is activated by calcium/calmodulin. CBS-deficient mice have altered hippocampal LTP. Hydrogen sulfide also potentiates NMDA receptor currents and has neuroprotective effects at low levels.

Environmental hydrogen sulfide will elicit varied dose-dependent effects. Humans detect the odor at 0.1 to 1 parts per million (ppm), and the olfactory nerve is paralyzed at 100 to 150 ppm. Pulmonary edema occurs at 320 to 530 ppm and 530 to 1,000 ppm produces strong central nervous system (CNS) activation, respiratory arrest, coma, and death. Extremely high levels occur in industrial chemical synthesis and petroleum refineries, with more modest levels in sewage-processing plants, geysers, hot springs, and geothermal sites.

ENDOCANNABINOIDS: FROM MARIJUANA TO NEUROTRANSMISSION

Whether known as cannabis, hemp, hashish, ma-fen, or a variety of slang terms, marijuana has been cultivated and utilized by human populations for thousands of years. Despite long debate as to whether its risks and benefits are evenly matched, is has only been in recent decades that some of the mystery has been revealed by which marijuana exerts its effects on the brain. The “high” users experience, euphoria and tranquility, relates to cannabis acting upon a neural pathway involving cannabinoids endogenous to the human brain, or endocannabinoids.

The first described medicinal use of cannabis dates to approximately 2700 BC in the pharmacopeia of Chinese Emperor, Shen Nung, who recommended its use for a variety of ailments. At this time, adverse properties were also apparent, and large amounts of the fruits of hemp could lead to “seeing devils” or a user might “communicate with spirits and lightens one’s body.” For centuries, cannabis was employed in India as an appetite stimulant, and habitual marijuana users remain well acquainted with “the munchies.”

For many years the mechanisms by which the active components of marijuana, *cannabinoids*, exerted their psychoactive effects remained a mystery. Chemists sought to isolate the psychoactive components of cannabis from the many components of the plant oil. First elucidated in 1940 was cannabinol, a compound now appreciated to be an oxidation product of other cannabinoids, and not a psychoactive compound (Fig. 1.9–7). However, with a structure in hand, chemists were now able to synthesize synthetic cannabinoids that did possess psychoactive properties. Within a few years it was apparent that tetrahydrocannabinols might be the active components of cannabis. Following advances in chemical separation techniques, Mechoulam and Gaoni in 1964 identified delta-9-tetrahydrocannabinol (THC), a compound that accounts for nearly all of the psychoactive effects of cannabis. THC-acid is the predominant form of plant THC, and this is readily converted to THC upon heating, such as when cannabis is smoked.

Discovery of the Brain Endocannabinoid System

Estimates suggest that 20 to 80 micrograms of THC reach the brain after one smokes a marijuana cigarette (i.e., “joint”). Consider that there are 100 to 200 micrograms of norepinephrine neurotransmitter present in the entire human brain. In the 1960s, there were at least two schools of thought on how THC exerted its psychoactive effects. One held that THC worked in a manner similar to the inhaled volatile anesthetics, that is, no specific receptor existed and it might have a generalized effect on neuronal membranes or widespread actions upon neurotransmitter receptors. A competing school hypothesized that specific receptors for cannabinoids existed in the brain, but they were difficult to identify due to the lipophilic nature of these chemicals. Novel cannabinoids were synthesized that were more water soluble, and in the late 1980s, this allowed for the discovery of a specific cannabinoid receptor, named CB1.

Now that a cannabinoid receptor was known to exist in the brain, the research community felt that it was unlikely that such receptors would have evolved solely to allow for action of plant cannabinoids. Indeed, after Pert and Snyder discovered opiate receptors in the 1970s, it was soon apparent that these did not evolve for the purpose of morphine drugs, but as the targets of the endogenous enkephalin neurotransmitters, discovered soon after. A hunt for the endogenous brain ligand for the CB1 receptor was underway, and the existence of such a substance was hypothesized to be an endogenous cannabinoid. This proved true in 1992 when Mechoulam and colleagues reported the discovery of anandamide, a lipid produced endogenously in the brain that could activate cannabinoid receptors and function as a neurotransmitter (Fig. 1.9–8). The name of this substance was derived from the Sanskrit word, *ananda*, which translates as bliss. Anandamide could also mimic THC in a variety of animal behavioral tests that generally predict whether a substance will have psychoactive properties in humans, including inhibition of spontaneous movement, promotion of freezing spells, reducing pain sensitivity, and decreasing body temperature.

Several additional endocannabinoids were soon discovered, 2-arachidonylglycerol (2-AG), N-arachidonyldopamine (NADA), 2-arachidonoylglycerol ether (noladin ether), and virodhamine (see Fig. 1.9–

8). The reason for having several different endocannabinoids may lie with their differing affinities for the cannabinoid receptors, CB1 and CB2. Anandamide appears to have the greatest selectivity for the CB1 receptor, followed by NADA and noladin ether. In contrast, virodhamine prefers CB2 receptors and has only partial agonist activity at CB1. 2-AG appears not to discriminate between CB1 and CB2.

Biosynthesis of Endocannabinoids

Arachidonic acid is utilized as a building block for biosynthesis of endocannabinoids, prostaglandins, and leukotrienes, and is found within cellular phospholipids of the plasma membrane and other intracellular membranes. Synthesis of anandamide requires the sequential action of two enzymes (Fig. 1.9–9). In the first reaction, the enzyme NAT transfers an arachidonic acid side chain from a phospholipid to phosphatidylethanolamine (PE), generating NAPE. In the second reaction the enzyme NAPD-PLD converts NAPE to anandamide. As NAPE is already a natural component of mammalian membranes, it is the second step which generates anandamide that is most crucial to neurotransmission.

Biosynthesis of 2-AG also requires two enzymes. In the first step, a phospholipid containing arachidonic acid at the middle position is converted to sn-1-Acyl-2-arachidonyl glycerol (DAG) via the action of the enzyme phospholipase C. The second reaction generates 2-AG via either of two specific diacylglycerol lipases (DAGL). The enzymes for biosynthesis of the other endocannabinoids are undefined.

Endocannabinoids are not stored in synaptic vesicles for later use but are synthesized on demand as is done for the gaseous neurotransmitters. An important criterion for a signaling molecule to be considered a neurotransmitter is that neuronal depolarization should lead to its release. Depolarization leads to increases in cellular calcium, which in turn promotes synthesis of the endocannabinoids and their release. The mechanism is explained in part by calcium activation of NAPE-PLD and DAGL, leading to augmented biosynthesis of anandamide and 2-AG, respectively.

Endocannabinoids generated in a neuron must cross the synaptic cleft to act upon cannabinoid receptors. Like THC, endocannabinoids are highly lipophilic, and thus poorly soluble in cerebrospinal fluid. It is hypothesized that a specific endocannabinoid transporter exists to allow endocannabinoids to cross the synaptic cleft and allow entry into the target neuron.

FIGURE 1.9–8. Endogenous cannabinoids. At least five endocannabinoids exist in the mammalian brain, each differing in affinity for CB1 and CB2 cannabinoid receptors. All are derived from the essential omega-6 fatty acid,

arachidonic acid, which is also a precursor in the formation of prostaglandins and leukotrienes.

Inactivation of Endocannabinoids

Neurotransmitters are typically inactivated either by reuptake from the neurons that release them or degradation by highly specific enzymes, such as acetylcholine being hydrolyzed by acetylcholinesterase. At least two enzymes exist to target the destruction of endocannabinoids and attenuate their neurotransmission. Fatty acid amide hydrolase (FAAH) converts anandamide to arachidonic acid and ethanolamine (see Fig. 1.9–9). FAAH is found in regions of the brain where CB1 receptors are predominant and localizes to postsynaptic neurons where anandamide is made. Rapid degradation of anandamide in part explains its relatively low potency compared to THC. Confirming the role of FAAH in anandamide inactivation, knockout mice without FAAH exhibit a 15-fold increase of anandamide, but not 2-AG. These mice have greater behavioral responses to exogenous anandamide, owing to its decreased degradation. The endocannabinoid 2-AG is inactivated by FAAH, but also by a monoacylglycerol lipase (MAGL) located in presynaptic neurons.

Pharmacologic inhibitors of FAAH have analgesic effects and reduce anxiety in animal models, but do not have the undesirable effects of THC such as immobility, lowered body temperature or greater appetite. Such a pharmacologic strategy would be analogous to monoamine oxidase inhibitors (MAOI) and catechol o-methyltransferase inhibitors (COMTI). MAOI, used in depression, inhibits breakdown of serotonin and other monoamines, thereby increasing serotonin, while COMTI serve an analogous role in blocking destruction of dopamine and other catecholamines.

Cannabinoid Receptors

Underscoring their importance in neural functions, CB1 receptors are possibly the most abundant G-protein–coupled receptors in the brain. They occur at highest density in the basal ganglia, cerebellum, hippocampus, hypothalamus, anterior cingulate cortex, and cerebral cortex, particularly the frontal cortex. Humans or animals that receive large doses of THC develop catalepsy, a reduction of spontaneous movement and freezing into bizarre and unnatural postures. The action of cannabinoids in the basal ganglia and cerebellum may be associated with these behaviors, which may prove relevant in understanding catatonic symptoms in schizophrenia.

FIGURE 1.9–9. Retrograde neurotransmission of the endocannabinoids, anandamide, and 2-arachidonoylglycerol (2-AG). Anandamide is synthesized on demand for neurotransmission via a two-step process. The enzyme NAT transfers the arachidonic acid chain from a phospholipid (APL) to phosphatidyl

ethanolamine (PE), producing NAPE. A second enzyme, NAPE-PLD, generates anandamide. 2-AG is similarly synthesized in two steps by the enzymes PLC and DAGL. The endocannabinoids made in a postsynaptic neuron cross the synapse and activate presynaptic CB1 receptors, suppressing neurotransmission of the presynaptic neuron (although activation of the presynaptic neuron occurs in some cases). 2-AG is predominantly inactivated in the presynaptic neuron by MAGL, whereas anandamide is destroyed in the postsynaptic neuron by FAAH. PE, phosphatidylethanolamine; APL, arachidonyl phospholipids; NAT, N-acyltransferase; NAPE, N-arachidonoyl-phosphatidylethanolamine; NAPE-PLD, N-arachidonoyl-phosphatidylethanolamine phospholipase D; FAAH, fatty acid amide hydrolase; MAGL, monoacylglycerol lipase; PLC, phospholipase C; PDE, phosphodiesterase; DAG, diacylglycerol; DAGL, diacylglycerol lipase; R_1-R_3, various acyl or alkyl side chains of phospholipids; R’, side chain of phospholipid head group.

CB1 receptors are predominantly found on axons and nerve termini, with little present on neuronal dendrites and the cell body. CB1 receptors tend to be localized to the presynaptic rather than postsynaptic side of the neuronal cleft, suggesting a role in regulation of neurotransmission. A second cannabinoid receptor, CB2, is predominantly expressed on the surface of white blood cells of the immune system, but small amounts appear to be present in the brain.

Effects on Neurotransmission. The cannabinoid CB1 receptor is associated with G proteins that mediate its intracellular signaling, in part, through inhibition of adenylyl cyclase. This leads to a decrease in levels of the important second messenger, cyclic adenosine monophosphate. Activation of the CB1 receptor also leads to activation of potassium channels and inhibition of N-type calcium channels. As calcium is integral to neurotransmitter release, cannabinoids can block neurotransmission through this mechanism. Cannabinoid receptors also activate mitogen-activated protein kinases.

Via the use of cell culture models and slices of brain, cannabinoids have been shown to block the release of a variety of neurotransmitters, including GABA, norepinephrine, and acetylcholine. Norepinephrine and acetylcholine tend to be excitatory neurotransmitters, and cannabinoid inhibition of their release would be expected to have an overall inhibitory effect. However, GABA is an inhibitory neurotransmitter, and cannabinoid inhibition of it would lead to overall excitatory effects, demonstrating that cannabinoids can have complex effects on neurotransmission depending upon the context. Cannabinoids also appear to increase the release of brain endorphin neurotransmitters and increase dopamine release in the nucleus accumbens, a “reward center” relevant to addiction and learning. The endocannabinoids have been implicated in a variety of forms of synaptic plasticity, including LTP and long-term depression (LTD).

Retrograde Transmission Regulated by Endocannabinoids

It has long been apparent to neuroscientists that a postsynaptic neuron could regulate the activity of a presynaptic neuron, for instance, inhibiting further release of neurotransmitter by the presynaptic neuron. Endocannabinoids may be the best candidate to date as the *retrograde messenger* that diffuses from a postsynaptic neuron to act upon a presynaptic neuron. During development the enzymes responsible for cannabinoid synthesis are expressed in both pre- and postsynaptic neurons. However, in adult brain synthesis of endocannabinoids appears to be predominantly in postsynaptic neurons. This suggested that they might work *backward* and regulate neurotransmission of a presynaptic neuron.

A typical presynaptic neuron containing dopamine or glutamate releases its neurotransmitter, leading to depolarization of the postsynaptic neuron. This second neuron can release endocannabinoid that diffuses across the synaptic cleft and inhibits further neurotransmitter release from the presynaptic neuron. Such a mechanism has been identified in the rodent hippocampus, in which CB1 receptor antagonists block suppression of the presynaptic neuron. Similarly, mice rendered genetically deficient in CB1 receptors lose hippocampal suppression of the presynaptic GABA neurons (a process also known as depolarization-induced suppression of inhibition, or DSI). The reverse has also been demonstrated, as inhibitors of endocannabinoid destruction enhance retrograde neurotransmission in the hippocampus. Endocannabinoids have also been implicated in regulation of other neurotransmission processes, such as LTD and depolarization induced suppression of excitation (DSE). The ability of endocannabinoids to inhibit neurotransmitter release may be an important general mechanism by which neurotransmission is regulated.

Endocannabinoids in Anxiety and Mood

Endocannabinoid neurotransmission may be an important regulator of anxiety, and cannabis users regularly describe the tranquilizing effect of THC. Loss of signaling by the endocannabinoid system appears to promote anxiety-like states in animal studies. CB1 receptor–deficient animals exhibit more pronounced anxiety behavior when exposed to stress or new environs.

Marsicano and colleagues suggested a role for cannabinoid signaling in forgetting painful memories. A mouse model was employed in which a tone was paired with an electric shock. Typically, when exposed to the tone, mice “freeze” in anticipation of the shock. Once the shock is no longer paired with the tone, animals demonstrate “extinction,” that is, they no longer freeze in response to just the tone by itself. Remarkably, animals deficient in CB1 receptors failed to demonstrate this normal extinction. Thus, endocannabinoid neurotransmission may mediate the ability to “forget” the anxiety associated with a painful memory. CB1 antagonist drugs, given just before the tone, revealed a similar effect. The amygdala participates in many anxiety responses, and endocannabinoids may act upon this brain region to attenuate anxiety. In support of this, levels of anandamide and 2-AG were found to increase in the amygdala immediately following exposure of mice to the tone.

FAAH knockout mice lack the enzyme that degrades endocannabinoids, and exhibit both increased anandamide levels and reduced anxiety in behavioral tests. Enhancing levels of endocannabinoids may represent a therapeutic target for anxiety. Whereas an agonist might overactivate cannabinoid receptors where little neurotransmission normally occurs, blocking the breakdown of endocannabinoids would be expected to facilitate activity in areas already utilizing these molecules, and thereby having fewer side effects. Novel FAAH inhibitors reduce the breakdown of anandamide and reduce anxiety-like behaviors in animals. Though the “forced swim test” and “tail suspension test” are far from perfect models of depression in the mouse, FAAH inhibitors improved the ability of the animals to cope with these stresses, a benefit also observed by treatment with antidepressant drugs.

The endocannabinoid pathway may represent an attractive target in understanding post-traumatic stress responses and phobias. Although one cannot yet routinely measure brain endocannabinoid levels in human subjects, this model is supported by clinical trials of the cannabinoid receptor blocker, rimonabant, which may offer promise as a strategy for weight loss (see below). A frequent adverse reaction to the drug was increased anxiety and depression. In a 2007 meta-analysis, Christensen et al. reported that those receiving rimonabant had a 2.5 times greater risk of stopping treatment because of depression and a threefold greater risk of stopping due to anxiety. These psychiatric side effects occurred despite the studies having excluded those who had a history of recurrent depressive or anxiety disorders, underlining an important role of this system in the regulation of anxiety and mood.

Endocannabinoids may play a role in mood disorders, as cannabis use is associated with a tranquilizing effect on mood, while some users experience paradoxical anxiety. A postmortem study of depressed individuals who died by suicide found increased CB1 receptors in the prefrontal cortex, also observed in a study of suicide associated with alcohol dependency. Genetic association studies have sought links between the CB1 receptor and psychiatric illness. While results have been mixed, some have suggested links to depression in Parkinson disease and an association with attention-deficit disorder in alcoholic patients.

FAAH inhibitors have yet to meet benchmarks in human trials. SSR-411298 had inadequate improvement in the treatment of depression, and PF-04457845 failed to improve the pain of knee arthritis. In phase 1 clinical trial of BIA, 10–2474, five of 90 participants experienced hemorrhagic and necrotic brain lesions, and one died, highlighting the difficulty of human pharmacologic intervention of this pathway.

Addiction. The endocannabinoid system may be an attractive target for the understanding of addiction. Mice deficient in CB1 receptors are unsurprisingly resistant to the behavioral effects of cannabinoids. However, they also appear to have reduced addiction to and withdrawal from opiates. Further interaction has also been found between the opioid and cannabinoid systems, as cannabinoids appear to increase the release of dopamine in the nucleus accumbens, a key reward area of the brain implicated in addiction. This dopamine release appears to require mu-opioid receptors, as pharmacologically inhibiting these receptors blocks the ability of cannabinoids to increase dopamine release. Rats with a preference for alcohol have decreased FAAH activity, suggestive of greater cannabinoid signaling. CB1 receptor antagonists dampen their alcohol consumption while inhibiting FAAH increases their alcohol consumption. Furthermore, CB1-deficient animals also appear to have reduced alcohol intake. A single amino acid mutation in human FAAH has been found to be associated with drug abuse, and this abnormal enzyme appears to be less stable than its wild-type counterpart.

Endocannabinoids in Psychosis

Heavy use of cannabis can produce psychotic symptoms in individuals with no prior history of psychiatric disorder, though it is unclear whether this is solely due to the drug or an underlying vulnerability to psychosis. Cannabis use often worsens psychosis in schizophrenia, and heavy use has been associated with developing schizophrenia, although some suggest that this association is an accelerated development of symptoms in those who would eventually manifest schizophrenia. Nonetheless, the endocannabinoid system has implications for the pathophysiology of schizophrenia, as cannabinoid signaling appears to increase the release of dopamine. Medications that act as antagonists of dopamine D2 receptors will likely remain a component of schizophrenia treatment for some time.

Elevated levels of anandamide have been noted in the cerebrospinal fluid of individuals with schizophrenia, including in follow-up studies of medication naïve patients. Elevated anandamide levels have also been noted in the blood of those with schizophrenia, and such elevations normalized with clinical improvement.

Elevated CB1 receptor levels have been reported in postmortem brain samples from those with schizophrenia, particularly the dorsolateral prefrontal cortex and cingulate cortex. While some have identified polymorphisms in the CB1 receptors associated with schizophrenia, others found no association. Furthermore, the implications of such polymorphisms on CB1 function are unclear.

Feeding. Following drug ingestion, THC users develop an increased appetite (“the munchies”), and cannabis has been utilized as an appetite stimulant for centuries. This effect may depend on CB1 receptors present in the hypothalamus. Endocannabinoid levels increase in the hypothalamus and limbic system when animals are deprived of food. Mice genetically deficient in CB1 receptors become resistant to developing obesity after being given a high-fat diet. Similarly, the CB1 receptor antagonist, rimonabant, appears to facilitate weight loss by blocking cannabinoid signaling. In a clinical trial of over 3,000 obese patients, those treated with 20 mg/day of rimonabant lost 6.3 kg at 1 year, compared to 1.6 kg in the placebo group. Nausea was the most common side effect reported. A 2007 meta-analysis of clinical trials reported an overall 4.7-kg weight loss with rimonabant treatment, besting the weight-loss drugs orlistat (2.9 kg) and sibutramine (4.2 kg). Unfortunately the severe side effects of anxiety and depression prevented its clinical use.

Effects on Brain Injury and Pain

In mouse models of traumatic brain injury, 2-AG appears neuroprotective, reducing brain edema, infarct size, and cell death while improving functional outcomes. Anandamide also protected against brain injury in a model of multiple sclerosis, and human patients with the disease have increased production of anandamide. A study of cannabinoid agonist, HU-211, led to more rapid clinical improvement following head trauma. FAAH inhibitors improved motor symptoms in a mouse model of Parkinson disease, likely via cannabinoids increasing dopamine neurotransmission.

Neurotransmission via the endocannabinoid pathway is increasingly appreciated to regulate pain perception. THC and cannabinoid agonists have proven effective in animal models of acute and chronic pain, ranging from burn injury to nerve damage and inflammation. The CB1 receptor plays an important role in these effects as the analgesic effects of cannabinoid drugs are lost when the CB1 antagonist rimonabant is given. Similarly, the analgesic effect of THC is lost in mice genetically deficient in the CB1 receptor.

Stress has long been associated with diminished pain perception, such as in cases of injured military personnel who demonstrate remarkable pain tolerance, a phenomenon known as stress-induced analgesia. The endocannabinoid system may mediate these effects. Animal models reveal anandamide and 2-AG production after stress, and stress-induced analgesia is blocked by the CB1 blocker, rimonabant, in these animals. In a placebo-controlled, randomized study of over 600 individuals with multiple sclerosis, Zajicek and colleagues found that oral THC administration led to improvement in mobility and pain. However, THC offered little benefit in postoperative pain following a hysterectomy.

Endocannabinoid regulation of pain perception appears to be distinct from that of the endogenous opiate system, but the two pathways may share overlapping neural pathways. Evidence for this has been provided using CB1 blocker, rimonabant, and naloxone, which blocks opiate receptors. Rimonabant attenuates analgesia provided by THC and cannabinoids but only partly blocks the response to morphine. However, the opposite is true for opiates: naloxone blocks morphine-induced analgesia but also partially blocks the analgesia of THC and cannabinoid drugs. Combinations of cannabinoid and opiate drugs evince synergistic analgesic effects in animal models.

Although it was initially assumed that cannabinoids exert their analgesic effects via the CNS, in animal models, it has been shown that localized administration of cannabinoids may also be effective, including drugs selective for the CB2 receptor, whose expression is minimal in the CNS.

Endocannabinoids may also influence pain sensitivity by mechanisms that do not involve the CB1 and CB2 receptors. Both anandamide and NADA can also activate a calcium channel known as the vanilloid receptor (also known as TRPV-1) found on sensory nerves. This same receptor is notable for being activated by capsaicin, which causes the hot sensation of chili peppers. Thus, endocannabinoids can exert opposing functions: promoting analgesia through the CB1 and CB2 receptors but potentially increasing pain via TRP channels. While CB2 receptors are largely expressed in the periphery, postmortem analyses reveal upregulation in the brain of those with Alzheimer disease.

The rapid development of novel cannabinoid drugs may allow for the targeting of specific symptoms rather than eliciting all of the typical effects of THC. For instance, ajulemic acid demonstrates analgesic and anti-inflammatory properties but may offer the benefit of limited psychoactive side effects. In a randomized clinical trial of this compound, ajulemic acid proved efficacious in reducing chronic neuropathic pain.

Effects in the Periphery

Cannabinoids lead to the direct relaxation of vascular smooth muscle by local CB1 receptors. This vasodilatation extends to the conjunctiva of the eyes, leading to a “bloodshot” appearance in some cannabis users. Relaxation of ocular arteries by cannabinoids may offer utility as a treatment for glaucoma, a condition of high intraocular pressure, and activation of CB1 receptors in the kidney can improve renal blood flow. A role in generalized blood pressure regulation is unproven, and blood pressure is unaltered in persons treated with rimonabant or animals deficient in CB1 receptors. Cannabinoid signaling may also be relevant to ectopic pregnancy, as CB1-deficient mice retain many embryos in the oviduct.

Synthetic Cannabinoids

Hundreds of chemically distinct synthetic cannabinoids have been generated since the 1980s (see Fig. 1.9–7). Initially generated for research purposes, they have grown in popularity for users to seek euphoric effects. Governments have sometimes been quick to ban such uses, only to have new and different chemicals appear. These and many others are variably mixed together in recreational drugs referred to as “Spice” and “K2” that are typically smoked or ingested by mouth and not detected by standard drug tests for THC. Delta-8-tetrahydrocannabinol (delta-8-THC) is a close structural analog of THC. It is present in small quantities in cannabis plants though it is commonly made by chemists using cannabidiol as a precursor. Its psychoactive effects are less potent than THC, in part relating to its binding to CB1 receptors about sixfold less efficiently than THC. Dronabinol (Marinol) is a synthetic THC with FDA approval to treat chemotherapy-induced nausea and vomiting. Nabilone is a partial agonist of CB1 and CB2, once approved for similar applications but subsequently withdrawn from the market.

Nonpsychoactive Cannabinoids

Although THC is the principal psychoactive component of cannabis, the many nonpsychoactive cannabinoids also have intriguing properties and may regulate neurotransmission. Cannabidiol may offer potential therapeutic effects and appears to stimulate TRP-V1 receptors and influence endocannabinoid degradation. Cannabidiol also demonstrated a protective effect in a mouse model of inflammatory arthritis and has been purported to have anticonvulsant properties. Although results have been mixed, purified cannabidiol may also exert antipsychotic activity, although the net effect of plant cannabis use typically exacerbates schizophrenia symptoms owing to the THC component. Tetrahydrocannabivarin is a plant cannabinoid that antagonizes CB1 receptors. It is a candidate marker to distinguish whether a patient has been using plant-derived cannabis or prescription THC, which contains no tetrahydrocannabivarin.

EICOSANOIDS

Overview

Clinical findings suggest that the dietary supplements Omega-3 fatty acids, eicosapentaenoic acid (EPA), its ester ethyl-eicosapentaenoic (E-EPA), and docosahexaenoic acid (DHA), help relieve symptoms of depression, bipolar illness, schizophrenia, and cognitive impairment. DHA and EPA may help reduce behavioral outbursts and improve attention in children.

Chemistry

Essential fatty acids are a group of polyunsaturated fats that contain a carbon–carbon double bond in the third position from the methyl end group in the fatty acid chain. They are essential because, unlike monosaturated and saturated fatty acids, polyunsaturated fatty acids cannot be synthesized de novo and can only be acquired through diet from natural fats and oils. Linoleic acid (LA) is the parent compound of omega-6 fatty acids, and α-linolenic acid (ALA) is the parent compound of omega-3 fatty acids. Both omega-3 and omega-6 groups use the same enzymes for desaturation and chain elongation. Omega-3 fatty acids are synthesized by algae and plankton. Fish such as herring, salmon, mackerel, and anchovy feed on these aquatic species and become a rich dietary source of omega-3. EPA and DHA are highly unsaturated omega-3 fatty acids that contain 6 and 5 double bonds on their long structural chain, respectively. They are positioned in the cell membrane by phospholipids and play a crucial role in cell membrane signaling.

Effects on Specific Organs and Systems

The strongest scientific evidence for treatment with fatty acid supplements comes from the cardiovascular literature. Several human trials have demonstrated that omega-3 fatty acids lower blood pressure, reduce the rate of recurrent myocardial infarction, and lowers triglyceride levels. In the nervous system, fatty acids are essential components of neurons, immune cells, and glial phospholipid membrane structures. They increase cerebral blood flow, decrease platelet aggregation, and delay the progression of atherosclerosis in the cardiovascular system. Omega-6 fatty acids appear to reduce inflammation and neuronal apoptosis and decrease phosphatidylinositol second messenger activity. Omega-3 fatty acids have been suggested to alter gene expression.

In the CNS, fatty acids are selectively concentrated in neuronal membranes and involved in cell membrane structure. Omega-6 arachidonic acid has been shown to enhance glutamate neurotransmission, stimulate stress hormone secretion and trigger glial cell activation in the setting of oxidative toxicity and neurodegeneration. The omega-3 fatty acids DHA and EPA appear to protect neurons from inflammatory and oxidative toxicities. Increases in serotonin, enhancement of dopamine, and regulation of corticotrophin-releasing factor have been demonstrated in cell culture models.

In rodent models of depression, chronic EPA treatment normalized behavior in an open-field test. Serotonin and norepinephrine were also increased in the limbic regions. Mice fed Omega-3 poor diets had reduced memory, altered learning patterns, and more behavioral problems.

Therapeutic Indications

Clinical research on the use of fish oil for mood disorders began with epidemiology studies where there appears to be a negative correlation between fish consumption and depressive symptoms. Countries with lower per capita fish consumption had up to 60 times increased rates of major depression, bipolar disorder, and postpartum depression. Observational studies concluded that the lower incidence of seasonal affective disorder in Iceland and Japan than latitude predicted is related to the amount of fatty acid these populations consume in their diet. A study in Norway showed that the use of cod-liver oil decreased depressive symptoms. Depression after a myocardial infarction shows higher arachidonic acid to EPA ratio. Postmortem studies in the brains of patients diagnosed with major depressive disorder show reduced DHA in the orbitofrontal cortex.

The first randomized, controlled pilot study of omega-3 fatty acids focused on adjunctive treatment in both bipolar and unipolar patients with depression in addition to their standard lithium or valproic acid treatment. The omega-3 fatty acid group had significant improvement on the Hamilton Depression Rating Scale and a longer period of remission than the placebo group. A subsequent larger study supported the benefit of treatment with E-EPA for bipolar illness. However, a study group of patients with either bipolar disorder or rapid cycling treated with E-EPA showed no significant difference in any outcome measure between the

EPA and placebo groups. Bleeding time was also increased in the treatment group.

In 2002, two landmark double-blind, placebo-controlled studies showed that supplementation with E-EPA or DHA in addition to standard treatment for unipolar depression led to a significant reduction in Hamilton Depression Rating Scales. A later study with a longer duration and a larger number of subjects failed to see an effect of EPA and DHA supplementation on depressed mood or on cognitive function but also found no adverse effects from the supplements. Although meta-analysis shows the antidepressant efficacy of omega-3 fatty acids, larger trials may identify favorable target subjects, optimal dosing, and the composition of omega-3 in treating depression.

Limited consumption of seafood during pregnancy is recommended in American guidelines, but Japanese studies suggest that low DHA but not EPA increases the risk for postpartum depression. A randomized trial of omega-3 fatty acids as monotherapy for major depressive disorder during pregnancy showed a reduction in Hamilton Depression rating scores and compliance with treatment compared to the control group.

The most convincing evidence comes from early brain development and learning studies. Pregnant mothers who consumed foods rich in DHA gave birth to infants that had improved problem-solving skills but not necessarily improved memory. Visual acuity and eye development are also associated with DHA supplementation during pregnancy.

The Oxford-Durham study of dietary supplementation with omega-3 fatty acids in children with developmental coordination disorder suggests a potentially controversial role in learning disabilities, attention-deficit hyperactivity disorder, and autism. The authors saw significant reductions in inattention, hyperactivity, and impulsivity. The crossover placebo group improved after switching to fish oil supplements, and a multivitamin showed no additional benefits for ADHD symptoms. This led to a plan by education officials in the Durham County Council in England to spend £1 million on omega-3 fish oils to help 5,000 children as they approach their school placement exams in order to help to improve their performance.

In behavioral studies, prisoners in England that consumed higher amounts of seafood containing mega-3 fatty acids saw a decrease in assault rates. A Finnish study of violent criminals identified lower levels of omega-3 fatty acids in their system compared to nonviolent offenders.

The negative and psychotic symptoms of schizophrenia may be improved with supplementation with omega-3 fatty acids. Antipsychotic medications like haloperidol appear to have fewer extrapyramidal side effects when combined with antioxidants and omega-3 fatty acids.

EPA and DHA have been associated with decreased dementia incidence. After reviewing the Rotterdam study of a longitudinal cohort of over 5,300 patients, fish consumption appeared to be inversely related to the development of new cases of dementia. Later analysis of the study after 6 years demonstrated that low intake of omega-3 fatty acids was not associated with an increased risk of dementia. In contrast, the Zutphen study, also in the Netherlands, concluded that high fish consumption was inversely related to cognitive decline at both 3 years and after 5 years. Well-designed clinical trials are needed before omega-3 fatty acids can be recommended for the prevention of cognitive impairment.

Precautions and Adverse Reactions

The most adverse complication is an increased risk of bleeding. Dietary sources can contain heavy metals, and there is no standard preparation for capsule formulations. Treatment studies have yielded a variety of different doses.

NEUROSTEROIDS

Background

While steroids are critical for the maintenance of body homeostasis, neurosteroids are synthesized from cholesterol in the brain and independent of peripheral formation in the adrenal gland and gonads. Neurosteroids are produced by a sequence of enzymatic processes governed by P450 and non-P450 enzymes either within or outside the mitochondria of several types of CNS and PNS cells (Fig. 1.9–10).

Neurosteroids can operate through a nongenomic pathway to regulate neuronal excitability via their effects on neurotransmitter-gated ion channels. Receptors are generally located in the nucleus, membrane, or microtubules of the CNS and PNS. Although steroids and neurosteroids may act on the same nuclear receptors, neurosteroids differ from steroids in their topologic distribution and regional synthesis. The most well-known effect of neurosteroids is on the GABA receptor, particularly the GABAA receptor alpha subunit. These agents do not directly activate the receptor but are positive allosteric modulators that increase the ability of GABA to open the GABAA receptor channel. Neurosteroids acting primarily at this site include allopregnanolone (3α5α tetrahydroprogesterone), pregnenolone (PREG), and tetrahydrodeoxycorticosterone (THDOC). DHEA-S (dehydroepiandrosterone sulfate), the most prevalent neurosteroid, acts as a noncompetitive modulator of GABA, and its precursor DHEA (dehydroepiandrosterone) has also been shown to exert inhibitory effects at the GABA receptor. Some neurosteroids may also act at the N-methyl-D-aspartate receptor (NMDA-R), alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propanoic acid receptor (AMPA-R), kainate, glycine, serotonin, sigma type-1, and nicotinic acetylcholine receptors. Progesterone is also considered a neurosteroid and can regulate gene expression at progesterone receptors. Questions remain as to how the neurosteroids differ in spectrum from benzodiazepines, which are also positive allosteric modulators of the GABAA receptor alpha subunits. One clue may be that of the six different types of alpha subunits of GABAA, benzodiazepines do not bind to alpha-4 or alpha-6, whereas the neurosteroids do, among other subunits.

Neurosteroids in Neurodevelopment and Neuroprotection

Neurosteroids have been shown to stimulate axonal growth and promote synaptic transmission. Specific neuroprotective effects are unique to each neurosteroid. DHEA acts to regulate brain serotonin and dopamine levels, suppress cortisol, increase hippocampal primed burst potentiation and cholinergic function, decrease amyloid β-protein, inhibit the production of proinflammatory cytokines, and prevent free radical scavenging. DHEA and DHEA-S have both been shown to have a role in glial development and neuronal growth and to promote their survival in animals; their injection into the brains of mice promoted long-term memory while reversing amnesia. Progesterone is linked to myelinating processes like aiding in the repair of damaged neural myelination. Allopregnanolone contributes to the reduction of contacts during axonal regression.

Role of Neurosteroids in Mental Illness

Neurosteroids have distinct implications for the maintenance of normal neurologic function and contribute to neuropsychiatric illness. Neurosteroids are differentially regulated in males and females and may impact the manifestation of psychological disorders in these two populations. Specifically, they play a distinct role in mood and anxiety disorders. Allopregnanolone (brexanolone, Zulresso) has a salutary benefit for postpartum depression and is an FDA-approved intravenous treatment. Zuranolone (SAGE-217) is an orally available GABAA-positive modulator that has shown benefit in a phase 2 study of major depressive disorder.

Depression. When compared with nondepressed controls, studies show that depressed patients have lower plasma and CSF concentrations of allopregnanolone; additionally, this research has elucidated an inverse relationship between allopregnanolone concentrations and the severity of depressive illness. Antidepressant drugs, specifically fluoxetine, have been shown in multiple studies to increase the levels of certain neurosteroids. Nonetheless, there is debate over the therapeutic properties of neurosteroids, prompting the investigation of neurosteroid concentrations in patients undergoing nonpharmacologic therapies. Preliminary results indicate that the lack of modifications in neurosteroid levels during nonpharmacologic treatments supports the validity of the pharmacologic properties of antidepressants, not their therapeutic action, in the elevation of neurosteroid levels in medicated populations. In a 2006 clinical study with mirtazapine, allopregnanolone concentrations increased in patients with major depressive disorder regardless of the therapeutic benefit.

Anxiety Disorders. In patients with anxiety disorders, the major mechanism of action is on the GABA receptor. Homeostasis, characterized by normal GABAergic activity, is restored after panic attacks as neurosteroids are released in response to stress. Allopregnanolone stimulates GABAergic activity with 20 times the strength of benzodiazepines and 200 times the potency of barbiturates. Both positive and negative regulation of the GABAA receptor is correlated with anxiolytic and anxiogenic action, respectively.

Psychotic Disorders. In addition to their primary relevance to the pharmacologic treatment of mood and anxiety disorders, neurosteroids contribute to psychotic, childhood, substance abuse, eating, and postpartum disorders. The effect of neurosteroids on psychotic disorders like schizophrenia is mediated by DHEA and DHEA-S. DHEA has been dispensed to decrease anxiety in schizophrenics, as DHEA and DHEA-S suppress GABA inhibition and heighten the neuronal response at the NMDA-R and sigma receptors. DHEA and DHEA-S levels are typically elevated first episode psychosis.

Attention-Deficit Disorder. In children, the clinical symptoms of ADHD are inversely correlated with DHEA and pregnenolone levels.

Substance Abuse. Alcohol is theorized to regulate the GABA receptor and induce de novo steroid synthesis in the brain; specifically, pregnenolone, allopregnanolone, and allotetrahydrodeoxycorticosterone levels are increased in the brain and periphery in response to increases in peripheral alcohol levels. It is hypothesized that sharp increases in ethanol concentration may mimic the acute stress response and elevate neurosteroid concentrations by the hypothalamic–pituitary–adrenal axis. To prevent ethanol dependence, researchers are investigating fluctuations in neurosteroid levels and in vivo neurosteroid responsiveness. Neurosteroids (increased allopregnanolone levels in particular) are associated with drug abuse. However, DHEA-S may check the acquisition of morphine tolerance. Past research has shown DHEA-S levels were also increased in patients who abstained from cocaine use as per a treatment program, and as patients relapsed, DHEA-S concentrations decreased accordingly.

Eating Disorders. DHEA has been shown to diminish food intake, temper obesity, moderate insulin resistance, and lower lipids in rodent models of youth-onset, hyperphagic, genetic obesity. By regulating the serotonergic system, DHEA is hypothesized to promote a reduced caloric load. Although hypothetical, low levels of DHEA and DHEA-S are recorded in young women with anorexia nervosa, and 3 months of oral DHEA supplementation increased bone density and tempered the emotional problems associated with the disorder.

Postpartum and Gynecologic Disorders. As estrogen and progesterone levels fluctuate during pregnancy and drop markedly after delivery, neurosteroids are thought to contribute to postpartum disorders.

Low postpartum DHEA concentrations have been linked to mood instability. In addition, allopregnanolone levels correlated with mood disorders during pregnancy and premenstrual syndrome (PMS). It has been noted that women with premenstrual dysphoric disorder have higher allopregnanolone/progesterone ratios than normal controls; women treated for this disorder reported improvement as allopregnanolone levels decreased.

Neurosteroids, Memory Disorders, and Aging. Neurosteroid levels may be irregular in neurodegenerative disorders and aging conditions such as Alzheimer's and Parkinson's. DHEA levels at age 70 are only about 20% of their maximum value recorded in the late 20s, and some researchers believe DHEA supplementation can prevent or slow the cognitive declines associated with the aging process. However, conflicting studies have indicated that DHEA administration does not improve cognitive measures in patients. Additionally, in those patients with Alzheimer disease, the DHEA concentrations have been found to be markedly decreased.

Conclusion

Neurosteroids may play a role in a variety of psychiatric pathologies. Breakthroughs with animal models do not always correlate with advances in understanding the role of neurosteroids in humans, complicating research. Moreover, further research is exploring neurosteroid levels over the treatment course of a diverse array of psychiatric illness to get a more complete picture of disease management. New medications approved for human use are expanding the repertoire of treatments.

NOVEL NEUROTRANSMITTERS: BEYOND THE CLASSICAL DEFINITION OF NEUROTRANSMITTER

The classical criteria for a chemical to be considered a neurotransmitter were (a) synthesis in a presynaptic neuron, (b) storage and release from a presynaptic neuron, (c) binding to a receptor on a postsynaptic membrane, and (d) removal from the synaptic cleft by reuptake or degradation. Within the past few decades, the discovery of novel neurotransmitters has led to a reformulation of these strict criteria. Messengers such as the gases, cannabinoids, and eicosanoids are not stored in vesicles in presynaptic neurons but appear to be generated and released "on demand." The endocannabinoids appear to have an important role as *retrograde messengers*, being released from a conventional postsynaptic neuron and acting upon a presynaptic neuron (see Fig. 1.9–9). Finally, the gases do not act upon a receptor on the extracellular membrane of a postsynaptic neuron but diffuse into the cell and act directly upon multiple cellular proteins, bypassing membrane receptors entirely. Some scientists feel the classical definition of a neurotransmitter should not be altered, and the aforementioned might generically be termed atypical neurotransmitters or novel neural messengers. Additional yet undiscovered chemical messengers may further refine the concept of what a neurotransmitter is.

1.10 Neurotrophic Factors

JIHYE KIM, M.D., FRANCIS S. LEE, M.D., PH.D., AND MOSES V. CHAO, PH.D.

Neurotrophins are a unique family of polypeptide growth factors that influence the proliferation, differentiation, survival, and death of neuronal and nonneuronal cells. The effects of neurotrophins depend on their levels of availability, their affinity of binding to transmembrane receptors, and the downstream-signaling cascades that are stimulated after receptor activation. While the biologic roles for neurotrophins were initially characterized during development of the nervous system, it is now clear that they have multiple roles in the adult nervous system, such as regulating synaptic connections, synapse structure, neurotransmitter release, long-term potentiation (LTP), mechanosensation, and pain.

Alterations in neurotrophin levels have been implicated in neurodegenerative disorders, such as Alzheimer disease (AD), as well as in psychiatric disorders, such as anxiety disorders, depression, and substance abuse. A significant shift has occurred in conceptualizing the role of these growth factors for psychiatric disorders toward their key roles in mediating antidepressant and antianxiety treatment response. These recent insights have informed the role they play in the etiology and treatment of psychiatric disorders.

THE NEUROTROPHIN FAMILY

Many polypeptide factors affect the survival, growth, and differentiation of the nervous system. The neurotrophins, comprising of nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4), are the best understood and the most widely expressed in the nervous system. The neurotrophins are initially synthesized as precursors or proneurotrophins that are cleaved to release the mature, active proteins. The mature proteins, approximately 12 to 14 kDa in size, form stable, noncovalent dimers and are normally expressed at very low levels during development. Proneurotrophin cleavage and processing can occur at multiple sites, including the Golgi apparatus by furin, the dense core vesicle by proconvertases, and extracellularly by plasmin or selective matrix metalloproteinases.

NGF was the first identified neurotrophic factor, and it has a restricted distribution. In the peripheral nervous system (PNS), it acts on sympathetic neurons and sensory neurons involved in nociception and temperature sensation. In the central nervous system (CNS), NGF promotes the survival and functioning of cholinergic neurons in the basal forebrain. These neurons project to the hippocampus and are believed to be important for memory processes, which are specifically affected in AD.

The other neurotrophins are more widely expressed in the CNS. BDNF and NT-3 are highly expressed in cortical and hippocampal structures, and they have been linked to the survival and functioning of multiple neuronal populations. BDNF is present in much higher concentrations after stress, injury, neural stimulation, and exercise. In addition to neuronal survival and differentiation, BDNF is highly responsive to activity-dependent plasticity (see subsection “Neurotrophins and Synaptic Plasticity”). As is the case for other neurotrophins, any pain, injury, or inflammation can result in significant increases in transcription of NGF, BDNF, and other proinflammatory polypeptides.

NEUROTROPHIN RECEPTORS

Neurotrophins are unique in exerting their cellular effects through the actions of two different receptors: the tropomyosin-related kinase (Trk), a receptor tyrosine kinase receptor, and p75 neurotrophin receptor ($p75^{NTR}$), a tumor necrosis factor (TNF) receptor superfamily member. Trk receptors consist of an extracellular ligand-binding region, a single transmembrane domain, and a highly conserved intracellular tyrosine kinase domain. $p75^{NTR}$ consists of an extracellular ligand-binding region, a single transmembrane domain, and an intracellular portion containing a protein association region termed the death domain.

Neurotrophins bind as dimers to Trk family members, leading to receptor dimerization and activation of the catalytic tyrosine protein kinase domains. The dimerized Trk receptors autophosphorylate several key intracellular tyrosine residues, which rapidly initiate intracellular-signaling cascades. This is accomplished by the phosphorylated tyrosines on the receptor acting as recognition sites for the binding of specific adaptor proteins that contain phosphotyrosine-binding motifs, such as Src homology domain 2 (SH2). In particular, the Shc adaptor protein links the activated Trk receptor to two separate intracellular-signaling pathways that mediate most of the biologic effects of neurotrophins.

The primary survival pathway involves Shc, linking the Trk receptor activation to increases in phosphotidylinositol-3-kinase activity. This in turn activates another protein kinase, Akt (protein kinase B), which has multiple effects on the cell's apoptotic pathways. Also, Shc phosphorylation by Trk receptor activation leads to increases in Ras and mitogen-activated protein kinase (MAPK) activities. These events influence transcriptional and translational events, such as the induction of the cyclic adenosine monophosphate (cAMP) response element–binding protein (CREB) transcription factor and mammalian target of rapamycin complex (mTORC). CREB produces a multitude of effects on the cell cycle, neurite outgrowth, and synaptic plasticity. mTORC has been shown to regulate learning and memory by promoting localized activity-dependent translation, which leads to remodeling of spines that accompanies LTP. These mechanisms have been implicated in the antidepressant actions of various drugs, including ketamine (see related subsection "Neurotrophic Hypothesis for Mood Disorders: Therapeutic Potential of Neurotrophins"). In addition, phospholipase-C-γ (PLC-γ) binds to activated Trk receptors and initiates an intracellular-signaling cascade release of inositol phosphates and activation of protein kinase C. Trk receptor activation leads to a multitude of downstream signaling events, leading to changes in transcriptional and translational programs.

NGF binds most specifically to TrkA, BDNF and NT-4 to TrkB, and NT-3 to TrkC receptors (Fig. 1.10–1). $p75^{NTR}$ can bind to each neurotrophin but has the additional capability of regulating a Trk's affinity for its cognate ligand. Trk and $p75^{NTR}$ have been referred to as high- and low-affinity receptors, respectively. However, this is not correct because TrkA and TrkB bind mature neurotrophins with an affinity of 10^{-9} to 10^{-10} M, which is lower than the high-affinity site ($K_d = 10^{-11}$ M). Also, the precursor form of NGF displays high-affinity binding to $p75^{NTR}$. Trk-mediated responsiveness to low concentrations of NGF is dependent on the relative levels of $p75^{NTR}$ and TrkA receptors and their combined ability to form high-affinity sites. This is important since the ratio of receptors can determine responsiveness and ultimately neuronal cell numbers.

Although $p75^{NTR}$ and Trk receptors do not bind to each other directly, there is evidence that complexes form between the two receptors. As a result of these interactions, increased ligand selectivity can be conferred onto Trk receptors by $p75^{NTR}$. One way of generating specificity is by imparting greater discrimination of ligands for the Trk receptors. For example, BDNF, NT-3, and NT-4/5 can each bind to the TrkB receptor; however, in the presence of $p75^{NTR}$, only BDNF provides a functional response. Likewise, NGF and NT-3 both can bind to TrkA, but $p75^{NTR}$ restricts the signaling of TrkA to NGF and not to NT-3. Hence, $p75^{NTR}$ and Trk receptors interact to provide greater discrimination among different neurotrophins.

Neurotrophins acting via Trk receptors promote cell survival and differentiation. Paradoxically, they can also induce cell death. $p75^{NTR}$ serves as a proapoptotic receptor during developmental cell death and after injury to the nervous system. Increase in $p75^{NTR}$ expression is responsible for apoptosis in embryonic retinas and sympathetic neurons during the period of naturally occurring neuronal death. Whereas BDNF binding to $p75^{NTR}$ in sympathetic neurons causes rapid cell death, NGF binding to the TrkA receptor on the same neurons provides a survival signal. In the context of neurotrophin processing, proneurotrophins are more effective than mature NGF in inducing p75-dependent apoptosis. These results suggest that the biologic action of the neurotrophins can be regulated by proteolytic cleavage, with proforms preferentially activating $p75^{NTR}$ to mediate apoptosis and mature forms selectively activating Trk receptors to promote survival.

NEUROTROPHIC FACTORS AND DEVELOPMENT

With their initial discovery, neurotrophins were observed to be highly expressed in the PNS during early development. They are essential for survival of selective populations of neurons during different developmental periods. These findings led to the conceptualization of the neurotrophic hypothesis for development, which provides a functional explanation for the role of neurotrophic factors in the development of the PNS. During development, neurons approaching the same final target, such as in the skin or muscle, compete for limited amounts of target-derived neurotrophic factors. In this way, the nervous system molds itself to maintain only the most competitive and appropriate connections. Competition among neurons for limiting amounts of neurotrophin molecules produced by target cells accounts for selective cell survival. Two predictions emanate from this hypothesis. First, the efficacy of neuronal survival will depend on the amounts of trophic factors produced during development. Second, specific receptor expression in responsive cell populations will dictate neuronal responsiveness.

On one level, neurotrophins fit well with the neurotrophic hypothesis, as many peripheral neuronal subpopulations depend on a specific neurotrophin during the period of naturally occurring cell death. In addition, specificity of the biologic effects of neurotrophins in the PNS during development can be modulated by the intracellular location of the neurotrophin ligand receptor complex. During development, neurotrophins are produced and released from the target tissues. They are internalized into vesicles and transported to the cell body. Interestingly, the biologic effects of neurotrophins require that signals are conveyed over long distances from the nerve terminal to the cell body. Therefore, a central theme of the neurotrophic hypothesis is that neuronal survival and differentiation depend on the retrograde signaling of neurotrophic factors produced at the target tissue.

In contrast to the PNS, the role of neurotrophins in the CNS during development is significantly different, possibly due to predominant expression of the Trk receptors and limited expression of p75^{NTR}. In the CNS, the overlapping expression of multiple Trk neurotrophin receptors and their cognate ligands allows for more diverse connectivity, which extends well into adulthood. Of note, unlike in the PNS, the primary neurotrophins expressed in the CNS are BDNF and NT-3. From genetic knockout studies, it has become clear that their primary functions are not with regard to neuronal survival but rather neuronal differentiation and synaptic plasticity. To date, much of the evidence base for neurotrophin function in the CNS has been focused on BDNF.

One of the first examples to illustrate the roles of neurotrophins in plasticity was identified with regard to regulating plasticity related to critical periods in the visual system. Developmental regulation of synaptic plasticity in the visual system is illustrated by the formation of ocular dominance columns in layer 4 of the cortex. This process is strongly influenced by BDNF, regulating the maturation of inhibitory gamma-aminobutyric acid-producing (GABA) interneurons and thereby, regulating the critical period for visual plasticity. Mice overexpressing BDNF have been shown to have accelerated development of visual acuity and early termination of the critical period. Also, these effects on the visual system plasticity can be blocked by antibodies for the neurotrophins as well as neurotrophin antagonists (e.g., TrkB–IgG fusion proteins that bind neurotrophins), indicating that an alteration in the levels of endogenous neurotrophins has dramatic consequences on the formation of critical periods.

FIGURE 1.10–1. Neurotrophins at the synapse. Neurotrophins are released at the presynaptic side and bind selectively to specific tropomyosin-related kinase (**Trk**) receptors. All neurotrophins bind to p75 neurotrophin receptor (**p75^{NTR}**). Neurotrophin-3 (**NT-3**) and neurotrophin-4 (**NT-4**) bind to multiple Trk receptors. Nerve growth factor (**NGF**) binds to TrkA and brain-derived neurotrophic factor (**BDNF**) binds specifically to TrkB. The boldness of *arrow* correlates with strength of binding affinity of a specific neurotrophin to a specific receptor. (Created with BioRender.com.)

BDNF has also been shown to be involved in regulating the critical period for fear regulation. A single nucleotide polymorphism in the human BDNF gene (rs62565), resulting in a valine (Val) to methionine (Met) substitution at position 66 in the BDNF prodomain region has been shown to lead to decreased BDNF secretion and impaired periadolescent development of the prefrontal cortex–hippocampus neural circuit in mice. The lack of proper development during this critical window of periadolescence leads to a decreased ability to extinguish a cued fear response in adulthood. Both human BDNF Met allele carriers and mice with the human BDNF Met allele have shown prolonged responses to conditioned aversive cues during the acute extinction phase, suggesting less efficient initial cued fear extinction learning process. Consequently, BDNF Met carriers would likely benefit from more intensively tailored psychiatric treatment, such as a longer or more intensive course of exposure therapy to extinguish the conditioned aversive cue. Relatedly, both Met allele–carrying humans and BDNF Met mice exhibit increased anxiety phenotypes when placed under various environmental stressors. In this context, a recent meta-analysis of all the available human BDNF Met allele studies examining gene–environment interactions between the BDNF Met allele and life stressors showed that the Met allele significantly moderated the relationship between stressful life events and childhood adversity and depression. In sum, the BDNF Met allele likely confers a genetic vulnerability for depressive and anxiety-based symptoms that may require personalized psychiatric treatments for full responses.

NEUROTROPHINS AND SYNAPTIC PLASTICITY

BDNF's role in modulating synaptic plasticity in the adult brain has also been established in the various brain regions such as the hippocampus, prefrontal cortex, and striatum. Many studies have shown that BDNF–TrkB signaling plays a key role in synaptic plasticity in the adult brain. Based on application of exogenous BDNF, genetic manipulations, or blocking pharmacologic reagents, it has been established that BDNF–TrkB signaling promotes, but is not required for, the induction of high-frequency stimulation-induced LTP in the hippocampus. Neurotrophins have also been shown to evoke a chemical form of LTP. Brief application of exogenous BDNF produces long-lasting synaptic enhancement in hippocampus. Interestingly, despite strong evidence that BDNF release and BDNF-dependent spine regrowth and synaptic plasticity are required for learning and memory, this chemical "BDNF-LTP" remains only partially understood. What is currently understood about BDNF-LTP is that intracellular calcium signaling is involved, as well as some key downstream pathways involving extracellular signal-regulated kinases (ERKs). Thus, in the postnatal CNS, BDNF can modulate synaptic strengthening and neurotransmission as well as promote axonal and dendritic growth and differentiation. Conversely, the precursor of BDNF, proBDNF, has been shown to facilitate LTD in hippocampal slices by activation of $p75^{NTR}$. Exogenous proBDNF application induces synaptic depression at the neuromuscular synapse, suggesting that proBDNF opposes the actions of mature BDNF on synaptic plasticity. In some contexts, such as in developing neuromuscular synapses, proBDNF and mature BDNF have been shown to be potential "punishment" and "reward" signals, respectively, for inactive and active terminals. Specifically, activity-dependent activation of extracellular proteases can lead to the conversion of proBDNF to mature BDNF in active terminals, leading to stabilization of the synapse. Conversely, $p75^{NTR}$-expressing terminals will bind the proBDNF and are given the "punishment" signal to retract. These counterbalancing effects of proBDNF and mature BDNF are likely most pronounced in the early stages of development, when $p75^{NTR}$ levels are the highest. It has also been shown in rodent models of chronic stress and depression, that there are increased levels of proBDNF which normalizes with fluoxetine treatment. However, human studies comparing peripheral proBDNF and mature BDNF levels in patients with major depressive disorder (MDD) or other related disorders have been largely mixed and inconclusive. Therefore, it is unlikely that levels of proBDNF and mature BDNF in patients would serve as reliable biomarkers for psychiatric disease or response to treatment.

NEUROTROPHINS AND METABOLISM

BDNF and TrkB have also been established to play key roles in the central control of satiety and energy balance regulation. Both processes are regulated by a combination of CNS circuits predominantly in hypothalamic regions, as well as hormones and neurotransmitters produced centrally and by peripheral tissues. Analyses of loss of function genetic knockout mice with reduced expression of either BDNF or TrkB led to consistent phenotypes of increased food intake, as well as body weight. Recent studies have identified the paraventricular hypothalamus (PVH), a heterogenous cluster of nuclei containing separate neuronal populations expressing BDNF and TrkB, as a key brain region for neurotrophin-dependent suppression of appetite. Selective deletion of BDNF in the anterior PVH leads to significant hyperphagia and weight gain, while injection of recombinant BDNF in the PVH of control animals suppresses food intake. Deletion of TrkB in a separate set of PVH neurons also leads to significant hyperphagia and weight gain, which could be mimicked by decreasing neuronal activity in these neurons expressing TrkB.

BDNF–TrkB has also been implicated in the regulation of energy expenditure, which involves basal metabolism, physical activity, and thermoregulation. Deletion of BDNF in the same anterior PVH subregion led to decreased energy expenditure and locomotor activity. This is likely through projections of these neurons to the spinal cord sympathetic neuronal ganglia network-controlling thermogenesis. Conversely, injection of recombinant BDNF in the PVH of control animals led to increased energy expenditure. As BDNF–TrkB has been shown in other brain circuits to mediate enhanced synaptic plasticity, it is likely that BDNF regulation of appetite suppression and energy balance modulates synaptic plasticity within these hypothalamic circuits.

In parallel, human genetic studies have directly linked mutations in BDNF and TrkB with obesity and increased body mass index. A rare de novo missense mutation in TrkB’s kinase domain as well as de novo mutations leading to BDNF haploinsufficiency have been identified in subjects with hyperphagia and severe obesity. Genome-wide association studies of measures of obesity have identified several SNPs in or near the BDNF gene that have met criteria for genome-wide significance including the BDNF Val66Met allele. Finally, a randomized controlled study of human BDNF Met allele carriers taking antipsychotics showed that the BDNF Met allele is a risk factor for antipsychotic-associated obesity and insulin resistance. Together, these findings in rodents and in humans identify novel roles of BDNF and TrkB in the central control of energy expenditure and feeding behavior. While the brain circuitry involved in these processes diverges from their established roles in learning and memory and mood regulation, the underlying facilitation of synaptic transmission and plasticity are likely common themes for their divergent roles involved in this form of regulation of metabolism.

CORRELATES TO NEURODEGENERATIVE DISORDERS

Neurotrophins have been implicated in the pathophysiology of a wide variety of neurodegenerative and neuronal injury disorders. The brain’s response to acute and chronic environmental changes leads to alterations in neuronal function. The hypothesis underlying these clinical correlations, as well as the development of therapeutic strategies using neurotrophic factors, assumes that these disease states result in the following: decreased availability of neurotrophins for the affected neurons; fewer neurotrophin receptors on the affected neurons; and/or decreased neuronal survival. These deficits can be ameliorated by the addition of neurotrophic factors.

An example of how decreased availability of neurotrophins can account for a neuropsychiatric clinical problem is Huntington disease (HD), which is characterized by progressive death of medium spiny neurons in the striatum. One mechanism to explain the pathogenic effects of mutant huntingtin protein is through a decrease in BDNF levels brought on by lower anterograde transport from the cortex to the striatum. Similar logic applies to AD, one of the most common neurocognitive disorders. The addition of NGF or BDNF to vulnerable regions of the brain, such as the entorhinal cortex or hippocampus, increases spatial learning and memory retention. In these disease states, the assumption has been that exogenous neurotrophic factors would provide symptomatic treatment for the disease state rather than a cure for the core pathophysiology of these nervous system disorders. A more complete cell expression profile of the neurotrophins and their receptors in well-defined circuits will provide strategies to target degenerative disorders of different origins.

CORRELATES TO PSYCHIATRIC DISORDERS

The profound effects of neurotrophic factors on synaptic connections, synaptic plasticity, and neurotransmission have formed the basis for their association with psychiatric disorders, such as anxiety disorders, depression, and substance abuse. Neurotrophins became attractive molecular intermediates that may be involved in the pathophysiology of psychiatric disorders. Environmental inputs to neurotrophins can presumably lead to alterations in neuronal circuitry and ultimately, behavior. It has become clear that neurotrophins can produce long-term changes by regulating transcriptional programs on the functioning of adult neurons. This could explain the long delay in therapeutic action of many psychiatric treatments. Again, the clinical correlation assumes that there is a deficit in access or responsiveness to neurotrophic factors contributing to the phenotype of the disease state.

Major Depressive Disorder

The strongest evidence for a role of neurotrophins has come from the pathophysiology of depression, especially those associated with stress. For depression, it is believed that there is a fundamental dysregulation of synaptic plasticity and neuronal survival in regions of the brain such as the hippocampus. There are several lines of evidence suggesting a role of neurotrophins in depression. First, in animal models, restraint stress leads to decreased expression of BDNF in the hippocampus. In addition, chronic physical or psychosocial stress leads to atrophy and death of hippocampal neurons especially in the CA3 region in rodents and primates. Also, magnetic resonance imaging (MRI) studies have shown that patients with depression or post-traumatic stress disorder (PTSD) exhibit a small decrease in hippocampal volume. It is unclear though whether the atrophy and/or death of these neurons is directly related to the decreased availability of BDNF. In addition, not all forms of depression are associated with stress. However, if structural remodeling and synaptic plasticity are involved in the cellular pathophysiology of depression, BDNF is an attractive candidate molecule to mediate these alterations.

Second, exogenously administered BDNF in the hippocampus had antidepressant effects in two animal models of depression (i.e., the forced swim and learned helplessness paradigms) comparable to those of chronic treatment with pharmacologic antidepressants. In addition, BDNF has also been shown to have trophic effects on serotonergic and noradrenergic neurons in vitro and in vivo. Mutant mice with decreased levels of BDNF have been shown to have a selective decrement in serotonergic neuron function and corresponding behavioral dysfunction consistent with serotonergic abnormalities.

Third, serotonin and norepinephrine reuptake inhibitor antidepressants upregulate BDNF and CREB, a cAMP-dependent transcription factor, in a time course that corresponds to therapeutic action (10 to 20 days). The CREB transcription factor is involved in the induction of BDNF gene expression in neurons. This effect on the cAMP pathway provides a link between monoamine antidepressants and neurotrophins. Antidepressant treatments also lead to increases in expression of TrkB receptors in the hippocampus in a time course that also parallels the extended time course of therapeutic action of these treatments.

Notably, although the effects of prolonged serotonin and norepinephrine reuptake inhibitor treatment involve enhancing neurotrophin signaling, exogenously administered BDNF in the mesolimbic dopamine system appears to have an opposite effect—increasing depression-like behavior. In addition, removal of BDNF in this dopamine circuit appears to have antidepressant effects on a social defeat paradigm. These findings emphasize the complexity of BDNF's role in mediating aspects of behavior related to depression. Together, these studies provide a framework to examine further the neurotrophin system as a potential therapeutic target for the treatment of depression.

NEUROTROPHIC HYPOTHESIS FOR MOOD DISORDERS: THERAPEUTIC POTENTIAL OF NEUROTROPHINS

The recent clinical trials have provided limits in designing therapeutic strategies to use neurotrophic factors for neurodegenerative and psychiatric disorders. First, it has become clear that the physical delivery of sufficient quantities to target neurons is a major obstacle. Development of small molecules that readily cross the blood–brain barrier to activate neurotrophin receptors or potentiate the actions of neurotrophins is an approach that is in its infancy. Second, because neurotrophins have multiple effects on neuronal activity, indiscriminate "flooding" of the CNS with neurotrophic factors will likely lead to untoward side effects, such as epileptic activity. It had been noted in the clinical trials that there is a downregulation of the TrkB receptors after unregulated application of BDNF, likely contributing to the minimal therapeutic effects. New strategies are being studied that include more local and regulated application of neurotrophins through stereotactic injection of viral vectors or engineered progenitor cells. This approach is currently being applied to AD, in which there is a defined neuronal population in the basal forebrain cholinergic neurons that undergoes degeneration and is dependent on a specific neurotrophin (NGF).

The activation of the neurotrophin system through other receptor signaling systems offers an alternative strategy. For example, antidepressant agents acting via monoamine G-protein–coupled receptors

(GPCRs) can lead to increased expression of both neurotrophins and neurotrophin receptors. Importantly, only the neurons that express the monoamine GPCRs will have enhanced production of the neurotrophin or Trk receptor. It has also been shown that other GPCRs, the purine adenosine 2A (A2A) receptor, and pituitary adenylate-cyclase–activating peptide (PACAP) neuropeptide receptor can transactivate Trk neurotrophin receptors in the absence of neurotrophins in hippocampal neurons in vitro. Therefore, small molecules can activate Trk receptors in the absence of neurotrophins. These results raise the possibility that small molecules may be used to elicit neurotrophic effects for the treatment of neurodegenerative diseases by selective targeting of neurons that express specific GPCRs and Trk receptors.

Another gold-standard treatment for treatment-resistant and late-life depression that has been shown to depend on BDNF is electroconvulsive therapy (ECT). In rodents, long-term ECT has been shown to increase BDNF transcription and elicit the sprouting of hippocampal neurons. This effect was attenuated in mutant mice that express lower levels of BDNF. Despite the promising rodent studies, clinical studies have been more mixed in terms of the effects of ECT on increasing BDNF levels. Some show increases in serum and cerebrospinal fluid BDNF levels with ECT treatments while others do not. Studies that have attempted to look at BDNF as a biomarker for treatment response have concluded that BDNF levels were a poor predictor of ECT treatment outcome. This is likely because BDNF is affected by wide variety of genetic, biologic, and environmental factors. More rigorously powered studies are necessary to determine whether the clinically significant therapeutic effects of ECT are BDNF dependent.

Other potent ways of increasing the level of neurotrophins involve using specific classes of antidepressant drugs. Various serotonin and serotonin–norepinephrine reuptake-inhibiting antidepressants are clinically effective only after several weeks of administration. Newer approaches have examined the effects of ketamine, a fast-acting, noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist. Ketamine has been shown to mediate a rapid antidepressant response through a BDNF-dependent mechanism. NMDA receptor blockade via ketamine leads to the deactivation of eukaryotic elongation factor-2 kinase (eEF2 kinase). This alleviates the block on BDNF translation, resulting in rapid BDNF protein synthesis (within 30 minutes). This rapid upregulation of BDNF then triggers spine remodeling, synaptogenesis, and induction of synaptic plasticity. Alternatively, the blockade of NMDA receptors by ketamine can lead to a rapid, transient glutamate burst that subsequently stimulates AMPA receptors. The stimulation of AMPA receptors leads to local release of neurotrophins, including BDNF and vascular epithelial growth factor (VEGF). Both BDNF and VEGF then stimulate their respective receptors TrkB and Flk-1 to signal downstream to activate Akt and mTORC1. This leads to translation of various synaptic proteins that promote synaptogenesis and synapse maturation. These findings suggest that the rapid effects of glutamatergic modulators, such as ketamine, may differ from conventional antidepressants in that the pools of neurotrophins that are being upregulated and released in an activity-dependent way lead to enhancement of cellular signaling at separate synaptic sites.

It should be emphasized that all these strategies that utilize neurotrophic factors assume that pathologic symptoms arise from impaired neurons and neuronal circuits. This impairment implies not only cell survival, but also proper physiologic functioning and connectivity of these neurons. With greater understanding of the signal transduction pathways that are activated by neurotrophins, alternate strategies can be devised to manipulate these pathways through new drug development. A completely different approach is to block neurotrophins, such as NGF, which elicits hyperalgesia after tissue damage or inflammation. Development of neutralizing antibodies against NGF and their administration to reduce pain thresholds has proven to be efficacious in many clinical pain conditions. For example, NGF has been shown to activate the nociceptive neurons that send chronic pain signals of osteoarthritis (OA) from the PNS to CNS. Treatment with anti-NGF antibodies has been shown to inhibit joint pain and improve functions in those with moderate to severe OA. Further understanding of the core pathophysiologic mechanism for neurodegenerative and psychiatric disorders will benefit the development of rational therapies that involve engaging the neurotrophin system.

1.11 Intraneuronal Signaling

John A. Gray, M.D., Ph.D.

OVERVIEW OF NEURONAL SIGNAL TRANSDUCTION

Signal transduction is the process by which a cell converts extracellular signals to intracellular signals and the subsequent cascade of events that leads to alterations in cellular function. The initial step in signal transduction usually involves the binding of an extracellular signal, such as a neurotransmitter, to a designated plasma membrane receptor.

Binding of this molecule, or ligand, to its receptor stabilizes a unique conformation of the receptor, resulting in the transmission of the signal across the plasma membrane. In its simplest form, the binding of a neurotransmitter to an ion channel stabilizes a conformation of the channel protein that allows the channel to open and ions to flow into or out of the cell, setting off a cascade of intracellular events. In more complex examples of signal transduction, the stabilized conformation of the receptor allows for the binding of other proteins to the intracellular portions of the receptor. These intracellular proteins subsequently become "activated" and go on to initiate various downstream events.

Before the details of each signaling pathway are discussed, it is useful to understand the common themes in the flow of information from receptor binding to the final alterations in neuronal function. In general, these systems are organized into several layers (Fig. 1.11–1). First, extracellular signals are detected by receptors and transmitted across the plasma membrane to adaptor proteins. These adaptor proteins then activate one or more intracellular signaling pathways, which, in turn, alter the function of effector proteins, either directly or via intermediates, such as protein kinases. A protein kinase is an enzyme that adds a phosphate group to a protein. Protein phosphorylation is a primary mechanism in signal transduction as phosphorylation changes a protein's conformation, which can alter its enzymatic activity or its ability to bind with other proteins. Typically, protein phosphorylation leads to the activation of a protein. The eventual outcome of these signaling pathways is the alteration of neuronal activity and changes in the expression of various genes.

FIGURE 1.11–1. General outline of signal transduction. Transmission of an extracellular signal to an intracellular signal usually involves the binding of a ligand, such as a neurotransmitter, to a receptor. Conformational changes in the receptor protein transmit the signal across the plasma membrane to adaptor proteins which then activate one or more intracellular signaling pathways. These signaling pathways often involve the generation of small-molecule second messengers or the activation of kinase cascades leading to changes in neuronal function and gene expression.

So why do neurons and other cells have these complex intracellular signaling pathways? First, in addition to transmitting an extracellular signal across the plasma membrane, these signal transduction pathways amplify the signal, allowing for cells to have large responses to very minute quantities of extracellular stimuli. Furthermore, the multiplicity of intracellular signaling pathways allows signals to be directed in a specific manner, thus enabling cells to maintain separate channels of information that can be integrated only when appropriate. For example, these separate channels of information allow neurons to detect when different stimuli are presented concurrently, thus enabling them to alter their response accordingly. In addition, each signaling pathway has distinctive spatial and temporal characteristics that allow for the optimal handling of different types of information. For example, in some instances, it may be advantageous for a neuron to have extremely high sensitivity to an uncommon stimulus but to ignore repetitive inputs. Thus, these complex signaling pathways determine a neuron's sensitivity and responsiveness to its environment in the context of its current circumstances and its past experiences.

Overall, a detailed understanding of the complex biochemical processes operating inside neurons is critical to appreciate how the brain not only responds to individual stimuli but also how it can continuously adapt to endless environmental changes. In addition, advances in the understanding of the molecular processes occurring within neurons will lead to improved insight into the basis of behavior and psychotropic drug action and will likely guide the development of improved psychiatric treatments and diagnostic tools.

Major Neuronal Signaling Pathways

There are three main schemes of signal transduction in neurons (Fig. 1.11–2). The first involves ligand-gated ion channels, which are the primary mechanism of signal transduction for amino acid neurotransmitters such as glutamate and γ-aminobutyric acid (GABA). In addition, a number of other neurotransmitters, including acetylcholine and serotonin, have a subset of receptors that are ligand-gated ion channels. Upon binding of a neurotransmitter, these ion channels are stabilized in a conformation that alters the conductance of the channel to particular ions, usually Na^+, K^+, Ca^{2+}, or Cl^-. At synapses, these receptors can very quickly convert an extracellular signal into a postsynaptic electrical signal constituting so-called “fast synaptic transmission.” A prototypical example of a ligand-gated ion channel is the nicotinic acetylcholine receptor, which consists of five protein subunits with two binding sites for acetylcholine enclosing a central aqueous pore. When both acetylcholine-binding sites are filled, the internal pore of the channel opens, allowing Na^+ ions to flow into the cell, down their electrochemical gradient. Channels that allow Ca^{2+} to enter the cell can have effects on the electrical properties of the cell and can stimulate additional calcium-mediated intracellular signaling cascades, as discussed below.

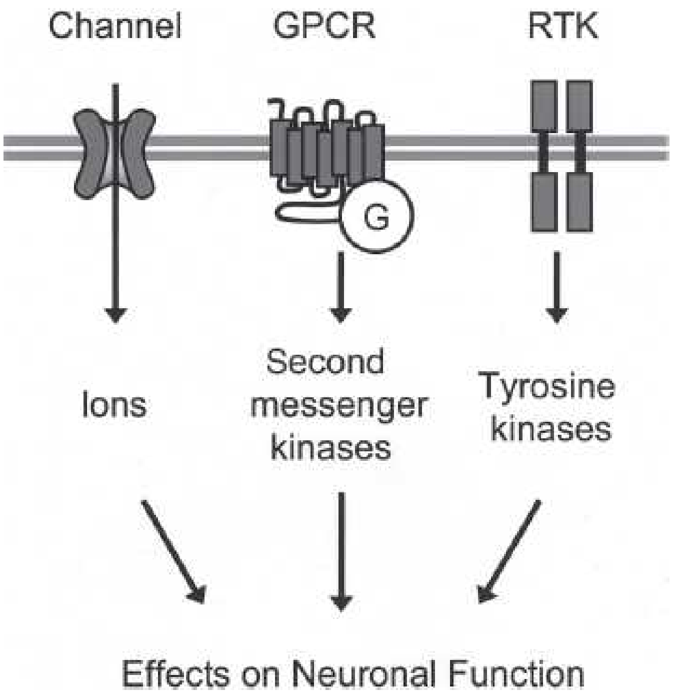

FIGURE 1.11–2. Outline of the three major receptor types mediating intraneuronal signal transduction in neurons: ligand-gated ion channels, G-protein–coupled receptors (**GPCR**s), and receptor tyrosine kinases (**RTK**s). Each receptor type, when activated by its extracellular signal, induces intracellular signaling pathways that result in alterations of neuronal function. G, heterotrimeric G protein.

A second primary scheme of neuronal signal transduction involves the binding of a neurotransmitter to seven-transmembrane domain receptors. These receptors are also known as GPCRs because they activate heterotrimeric guanine nucleotide–binding proteins (G proteins). GPCRs represent the single largest family of receptors (with more than 700 members) in the genome and are the primary form of receptor for many neurotransmitters, including serotonin and dopamine. GPCRs primarily signal by activating G proteins that subsequently activate effector enzymes that generate small molecules termed "second messengers" (the "first messenger" being the extracellular signal itself). Second messengers, in turn, mediate many of the downstream intracellular signaling cascades, largely involving protein kinases. Because of the additional step of creating small-molecule second messengers, signaling through GPCRs generally requires more time to develop than the opening of a ligand-gated ion channel, and thus this scheme accounts for the majority of "slow synaptic transmission" in neurons.

The third common scheme of signal transduction in the brain involves the activation of a distinct class of protein kinases that phosphorylate proteins on tyrosine residues. Activation of these protein tyrosine kinases is the primary signaling pathway for most neurotrophic factors, such as NGF and BDNF, as well as various cytokines and chemokines. The binding of a neurotrophic factor or chemokine to its respective plasma membrane receptor leads to the dimerization of the receptor, with another copy of the receptor transmitting the signal across the plasma membrane. This results in the activation of a cascade of protein kinases. In some cases, the intracellular portion of the receptor itself contains the first tyrosine kinase in the cascade, and in other cases, the dimerized receptors recruit cytoplasmic tyrosine kinases that then become activated. While the cascades of kinases can be complicated, the ultimate purpose is to amplify the initial signal and affect numerous changes in neuronal function.

G-PROTEIN–COUPLED RECEPTOR SIGNALING

Accounting for at least 2% of the genes in the genome, GPCRs comprise a very large family of proteins that represent targets for a wide array of molecules ranging from hormones and neurotransmitters to odorants and even light. The binding of an agonist to its cognate GPCR stabilizes an active conformation of the receptor, inducing the dissociation and activation of a receptor-specific heterotrimeric G protein into its α- and βγ-subunits (Fig. 1.11–3). G proteins were discovered by Alfred Gilman, Martin Rodbell, and colleagues and are a family of proteins named because they use the exchange of guanosine diphosphate (GDP) and guanosine triphosphate (GTP) as a molecular “switch” to regulate cell processes. In their baseline state, heterotrimeric G proteins consist of α-, β-, and γ-subunits, with a GDP molecule bound to the α-subunit. When a GPCR is activated by an agonist, the G-protein α-subunit becomes associated with the receptor, causing conformational changes that release the GDP molecule. This allows a GTP molecule to bind, thus activating the α-subunit. GTP binding to the α-subunit also causes the dissociation of the α-subunit from the βγ-subunits and from the receptor. These dissociated subunits are now biologically active and activate or inhibit a number of downstream effectors, including nucleotide cyclases, phospholipases, kinases, and ion channels, resulting in a variety of downstream cellular effects. The system is returned to its basal state when the α-subunit, which has intrinsic GTPase activity, hydrolyzes the GTP back to GDP. This hydrolysis of GTP to GDP within the α-subunit also leads to the reassociation of the α-subunit with the βγ-subunits and thus the restoration of the inactive heterotrimer. If the receptor remains bound to its agonist, then the GDP can again dissociate from the α-subunit, and another G-protein cycle begins; however, if the receptor becomes inactive, the hydrolysis of GTP to GDP halts intracellular signaling.

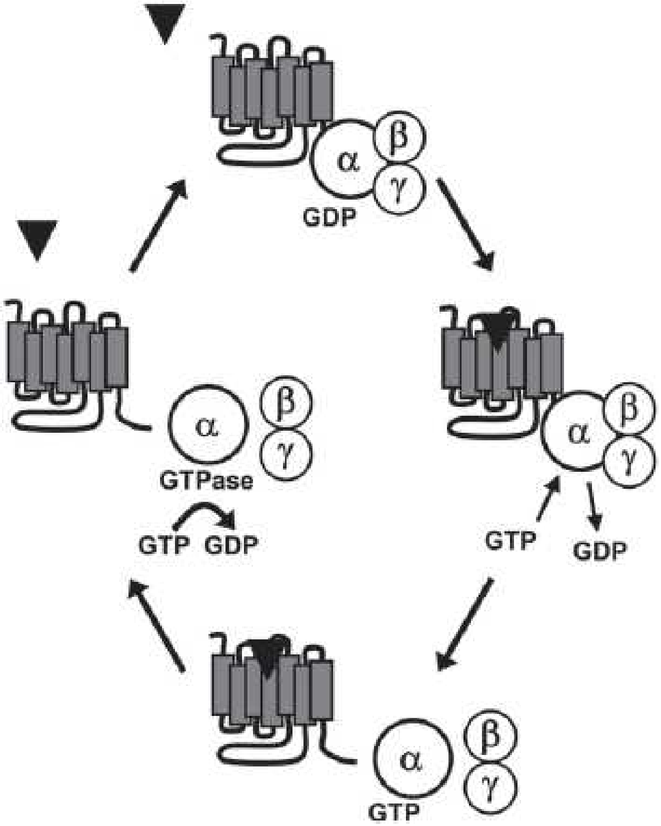

FIGURE 1.11–3. Outline of G-protein function. Under basal conditions, G proteins exist as heterotrimers consisting of single α-, β-, and γ-subunits, with the inactive α-subunits bound to GDP. After the G-protein–coupled receptor is activated by its ligand, it causes the associated G protein to release GDP, allowing GTP to bind. GTP binding to the α-subunit causes the dissociation of the α-subunit from the βγ-subunits and from the receptor. The free G-protein subunits are functionally active and can activate and regulate a variety of downstream effector proteins. The α-subunit has intrinsic GTPase activity that hydrolyzes the GTP back to GDP, causing the reassociation of the α- and βγ-subunit, restoring the system to its basal state.

The primary effector systems mediated by G proteins share a common overall form, whereby the activated G protein activates an effector enzyme that generates small-molecule second messengers that then initiate specific protein kinase cascades. The particular class of G proteins associated with each individual receptor dictates which specific second messenger system is activated. The four major classes of G proteins that are involved in neurotransmitter-mediated signaling are called G_s, G_i, G_q, and $G_{12/13}$ and are discussed below with the details of each second messenger system. Briefly, both the G_s and G_i classes of G proteins regulate the cyclic adenosine monophosphate (cAMP) system, while the G_q class regulates the phosphoinositide (PI) signaling system. The $G_{12/13}$ class modulates Rho/Rac signaling cascades but will not be discussed. Importantly, a single receptor can activate multiple G proteins, which can then activate multiple effector enzymes that synthesize many second messenger molecules, leading to exponential amplification of the initial signal.

Cyclic Adenosine Monophosphate Pathway

The discovery of cAMP in the 1950s by Earl Sutherland and Theodore Rall established the concept that small intracellular molecules can act as second messengers that convey information from cell-surface receptors to their targets within the cell. Since that seminal discovery, decades of intensive research on the cAMP system have elucidated its operating principles, making it the prototypical second messenger system.

GPCRs that activate the cAMP signaling pathway are coupled to the G_s class of G proteins. When G_s becomes activated by a receptor, it dissociates from the receptor and stimulates a membrane-bound effector enzyme called adenylate cyclase that converts ATP to cAMP (Fig. 1.11–4). Conversely, other receptors are coupled to the G_i class of G proteins that inhibit adenylate cyclase and thus decrease cAMP production. The net level of cAMP production by a given neurotransmitter is thus determined by the specific G_s- and G_i-coupled receptor subtypes expressed on a given neuron or synapse. For example, norepinephrine stimulates adenylate cyclase via its interaction with β-adrenergic receptors and inhibits adenylate cyclase via stimulation of α_2-adrenergic receptors.

The major target of action of cAMP in most cells is the cAMP-dependent protein kinase, also known as protein kinase A (PKA), which mediates many of the actions cAMP has on neuronal function. PKA is a multisubunit serine/threonine kinase consisting of two regulatory subunits and two catalytic subunits. In the absence of cAMP, the regulatory subunits are bound to the catalytic subunits, thus keeping the kinase inactive. However, when cAMP is present, it binds to the regulatory subunits, thus causing a conformation change that dissociates the regulatory subunits from the catalytic subunits. The release of the regulatory subunits activates the catalytic subunits, which are then free to phosphorylate various cellular proteins on serine and threonine residues. This kinase has a broad range of substrate proteins involved in regulating virtually every aspect of neuronal function. In particular, several important neuronal targets for PKA have been identified, including various ion channels, synaptic vesicle machinery, neurotransmitter synthetic enzymes, and proteins involved in regulating gene transcription. Thus, alterations in cAMP levels are able to affect neuronal function over a broad range of time scales. For example, rapid effects are achieved by targeting ion channel gating and neurotransmitter release machinery, while slower effects occur with the targeting of neurotransmitter synthesis and cellular energy metabolism. Furthermore, cAMP elicits longer-lasting changes in neuronal function by controlling the expression of specific target genes.

FIGURE 1.11–4. Basic organization of the cyclic adenosine monophosphate (cAMP) signaling pathway. Production of cAMP from ATP by adenylate cyclase can either be stimulated or inhibited by G-protein–coupled receptors. Receptors coupled to the G-protein Gs stimulate cAMP synthesis whereas those coupled to Gi inhibit adenylate cyclase. Many of the cellular actions mediated by cAMP occur through protein kinase A (PKA), which exists at baseline as a tetramer of two regulatory subunits (R) that tonically inhibit two catalytic subunits (C). When the R subunits become bound by cAMP, they dissociate from the C subunits, which become activated and can phosphorylate multiple cellular proteins. One such target is the transcription factor cAMP response element–binding (CREB) protein, which, when activated by PKA, can bind to DNA sequences called cAMP response elements (CREs) and promote gene transcription.

One important substrate of PKA is a transcription factor that enables elevations in cAMP to regulate gene expression. This transcription factor, called CREB protein, regulates the expression of various genes by binding to short deoxyribonucleic acid (DNA) sequences called cAMP response elements (CREs). Phosphorylation of CREB by PKA activates it, thus allowing it to bind to CRE sequences in the regulatory regions of target genes, where it increases or decreases the transcription of certain genes. Proteins whose expression is regulated by cAMP through CREB are thought to be involved in various neuronal processes, including neuronal development and survival and the formation of long-term memories.

Termination of cAMP signaling is mediated by the actions of phosphodiesterases (PDEs), enzymes that cleave cAMP to AMP. There are multiple isoforms of PDEs expressed throughout the brain that are differentially regulated, adding a level of complexity to the precise cellular control of cAMP signaling. At high concentrations, caffeine nonselectively inhibits PDEs, possibly contributing to some of its pharmacologic effects. In addition, considerable efforts have been made to develop PDE inhibitors that are selective for individual isoforms. For example, rolipram, an inhibitor selective for type IV PDEs, showed promise as an antidepressant but was limited due to side effects. In addition, inhibitors of PDE10A, an isoform expressed at high levels in the brain, have antipsychotic potential.

Phosphatidylinositol Pathway

After the discovery of the cAMP system, it became apparent that there were many neurotransmitter receptors that did not act via cAMP, suggesting the possible existence of other second messenger systems. Beginning in the 1950s, there were hints that PIs may be involved in various cellular pathways, though a coherent view of this second messenger system did not emerge until the early 1980s. The phosphatidylinositol signaling pathway parallels many basic aspects of the cAMP system (Fig. 1.11–5), though it also includes several unique features. The phosphatidylinositol signaling pathway is initiated by receptors that are coupled to the G_q class of G proteins, which activate the effector enzyme phospholipase C (PLC). This enzyme cleaves phosphatidylinositol bisphosphate (PIP_2), an inositol-containing phospholipid located in the cytoplasmic leaf of the plasma membrane, into two second messengers, diacylglycerol (DAG) and inositol trisphosphate (IP_3). These two second messengers can then go on to affect distinct cellular pathways.

DAG, which is hydrophobic, remains in the plasma membrane where it activates various isoforms of PKC, a serine/threonine protein kinase. In its inactive state, PKC is found in the cytoplasm, but when DAG is generated, PKC relocates to the plasma membrane, becomes activated, and phosphorylates multiple cellular substrates. The water-soluble IP_3 second messenger is released from the plasma membrane and diffuses to the endoplasmic reticulum, where it binds to the inositol trisphosphate receptor. This receptor is a ligand-gated ion channel that, when bound by IP_3, rapidly releases the large stores of Ca^{2+} from the endoplasmic reticulum. This released Ca^{2+} also functions as a second messenger, regulating various cellular functions. In addition to DAG, some isoforms of PKC also require Ca^{2+} to become activated.

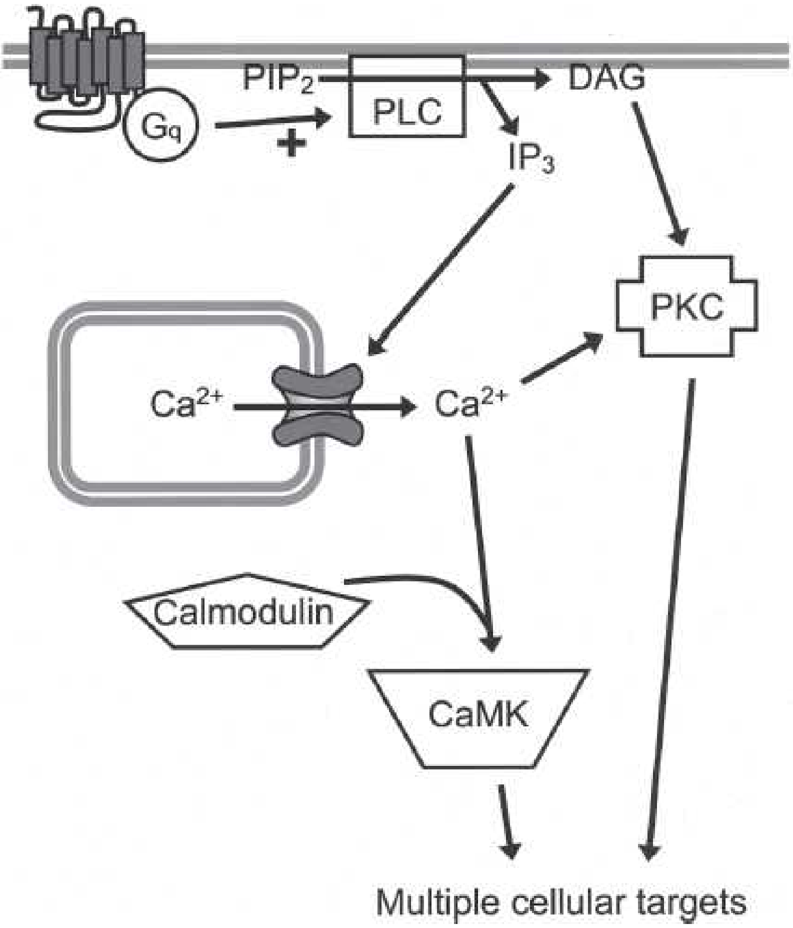

FIGURE 1.11–5. Basic organization of the phosphatidylinositol signaling pathway. The Gq class of G proteins activates phospholipase C (PLC), which cleaves the membrane phospholipid phosphatidylinositol bisphosphate (PIP2) into two second messengers, diacylglycerol (DAG) and inositol trisphosphate (IP3). IP3 diffuses to the endoplasmic reticulum where it binds to the inositol trisphosphate receptor, rapidly releasing large stores of Ca^{2+}, which also functions as a second messenger. DAG activates protein kinase C (PKC), though some isoforms also require Ca^{2+} to become activated. The released Ca^{2+} mediates many of its functions by binding to calmodulin, which can then activate multiple cellular targets, including calcium/calmodulin-dependent kinase (CaMK). PKC and CaMK can phosphorylate multiple cellular targets, including various transcription factors.

The rapid rise in intracellular Ca^{2+}, mediated by IP$_3$-induced release of cellular stores, has both immediate and more delayed effects on neuronal functioning. Immediate effects are triggered by the direct binding of Ca^{2+} itself to various effector proteins and include the release of synaptic vesicles and the opening of calcium-activated ion channels in the plasma membrane. Delayed effects of Ca^{2+} signaling are similar to those of cAMP, such as effects on cellular energy metabolism and gene expression. Many of these slower effects of calcium signaling are mediated by the association of calcium with calmodulin, a small, ubiquitous, calcium-binding protein. Calmodulin is activated when the intracellular concentration of Ca^{2+} is high enough for four ions to bind to the calmodulin protein. Activated calmodulin has multiple cellular targets, including activating various kinases, such as the calcium/calmodulin-dependent (CaM) kinases. It is important to note that calcium-based signaling pathways can also be activated by an influx of Ca^{2+} from the cell surface by various voltage- and ligand-gated ion channels, independent of G-protein signaling.

Termination of the phosphatidylinositol pathway involves multiple steps. DAG is degraded by lipases into glycerol and fatty acids or recycled into membrane phospholipids. Ca^{2+} is rapidly cleared from the cytoplasm by Ca^{2+}–ATPase pumps on the plasma membrane and endoplasmic reticulum, the action of which is enhanced by Ca^{2+} itself through the interaction of activated calmodulin with the transport pump. IP_3 is sequentially dephosphorylated by inositol phosphatases to inositol, which can then be reintegrated into membrane phospholipids. Interestingly, lithium is an inhibitor of these inositol phosphatases and leads to an accumulation of IP_3 and other inositol phosphates within cells. This leads to a depletion of the free cellular inositol needed to replenish membrane PIP_2 for further signaling, prompting the hypothesis that the rundown of the phosphatidylinositol cycle may underlie lithium's therapeutic action, though this remains controversial. Indeed, lithium is also known to inhibit several adenylate cyclases and protein kinases.

Other Second Messenger Systems

In addition to cAMP, another cyclic nucleotide, cGMP, is a second messenger that is regulated by neurotransmitter receptor stimulation. However, there are significant differences between the two systems. Guanylate cyclases are primarily cytoplasmic enzymes that are not directly activated by G proteins but are activated by the gas nitric oxide. Nitric oxide is synthesized in cells by NOS, which is activated by calmodulin and is thus mediated by increases in intracellular Ca^{2+} levels (Fig. 1.11–6). This demonstration that a gas can act as a second messenger blurs the distinction between extracellular and intracellular messengers, as nitric oxide is capable of diffusing across cell membranes and at synapses may act as a retrograde signal to the presynaptic neuron. Synthesis of cGMP also leads to various downstream effects, many through its activation of protein kinase G. Like cAMP, cGMP is degraded by various PDEs. Indeed, drugs for erectile dysfunction, such as sildenafil (Viagra), act by selectively inhibiting a PDE isoform that is highly enriched in the vascular smooth muscle of the penis, highlighting the utility of developing drugs that target intracellular signaling pathways.

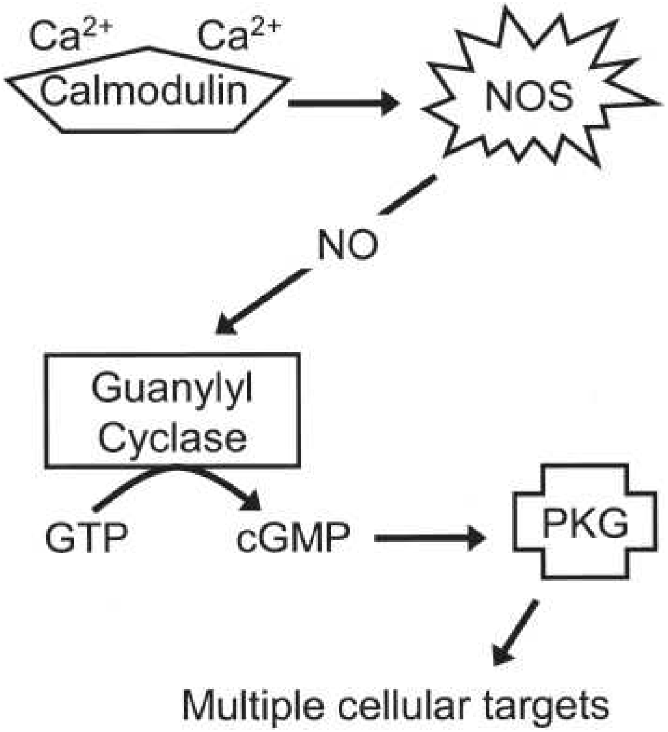

FIGURE 1.11–6. The cyclic guanosine monophosphate (cGMP) signaling pathway. In contrast to the cyclic adenosine monophosphate (cAMP) system, cGMP synthesis via guanylate cyclase is not regulated by G proteins. Instead, guanylate cyclase is activated by nitric oxide, which is synthesized by nitric oxide synthase (NOS) after it is activated by a calcium/calmodulin complex. Like cAMP, cGMP affects neuronal function by stimulating its cognate kinase, protein kinase G (PKG).

Another intracellular signaling system that appears to play an important role in neuronal function involves metabolites of the fatty acid arachidonic acid. Various receptors activate an enzyme called phospholipase A_2, possibly through an unidentified G protein or elevations in cytoplasmic calcium levels. Phospholipase A_2 cleaves membrane phospholipids, typically PIP_2, releasing free arachidonic acid, which is rapidly converted to a number of active metabolites (Fig. 1.11–7). For example, arachidonic acid may be cleaved by cyclooxygenase to yield, after multiple enzymatic steps, several types of prostaglandins and thromboxanes. Alternatively, arachidonic acid may be cleaved by lipoxygenases to yield the leukotrienes. These active metabolites then regulate many intracellular functions, including ion channels and protein kinases, and are important for modulating signaling through other pathways by regulating adenylate and guanylate cyclases. In addition, as these compounds are lipophilic, they can diffuse out of the neuron and act as ligands for their own GPCRs on other neurons. Interestingly, cyclooxygenase inhibitors have been hypothesized to improve schizophrenia and depression, possibly by reducing stress-mediated inflammatory processes in the brain.

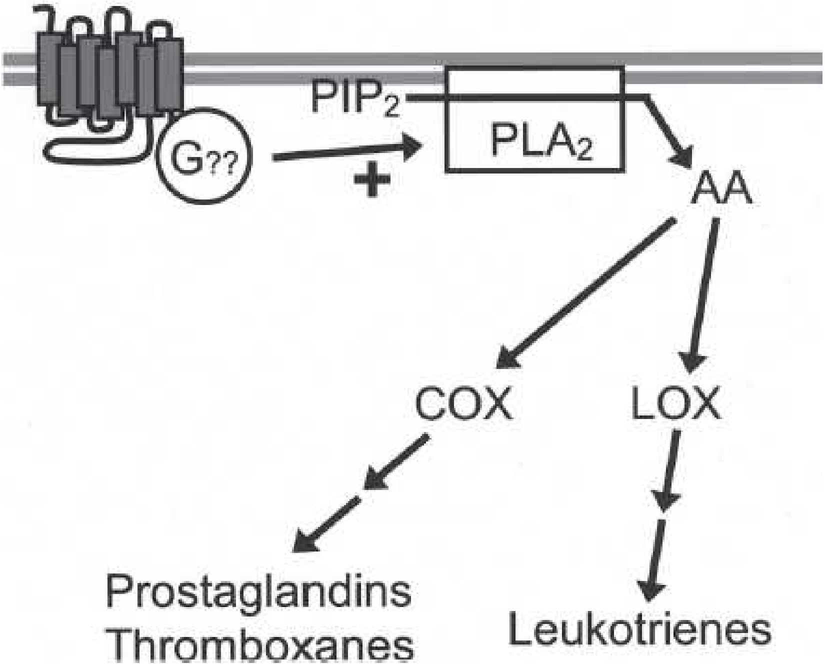

FIGURE 1.11–7. Organization of the arachidonic acid signaling pathway. Various G-protein–coupled receptors activate an enzyme called phospholipase A2 (PLA2), possibly through an unidentified G protein (G??). PLA2 primarily cleaves the membrane phospholipid phosphatidylinositol bisphosphate (PIP2), releasing free arachidonic acid (AA), which is rapidly converted to a number of active metabolites. For example, arachidonic acid may be cleaved by cyclooxygenase (COX) to yield prostaglandins and thromboxanes and by lipoxygenases (LOXs) to yield leukotrienes. These AA metabolites can regulate many intracellular functions and can diffuse out of the neuron and act as ligands for their own G-protein–coupled receptors on other neurons.

Regulation of Ion Channels by GPCRs

As discussed, the primary function of G proteins is to initiate second messenger signaling cascades that go on to affect a multitude of cellular functions, including modulating ion channel gating through phosphorylation by kinases such as PKA, PKC, and CaM kinases. In addition, second messengers such as cAMP and cGMP can regulate ion channels directly. However, it is now clear that the G proteins themselves are also able to directly bind to and regulate ion channels independent of second messenger cascades. This process is best established for receptors that couple to G_i, such as muscarinic acetylcholinergic, α_2-adrenergic, D_2-dopaminergic, and 5-HT_{1A} serotonergic receptors. As before, receptor activation causes the dissociation of the G-protein α- and βγ-subunits. While the α-subunit goes on to inhibit adenylate cyclase, the βγ-subunits can bind directly to the cytoplasmic regions of different ion channels. In some cells, βγ-subunits bind to and directly open specific K^+ channels known as G-protein–regulated inwardly rectifying K^+ (GIRK) channels. These channels are called inwardly rectifying because, if under no electrochemical gradient, they more readily pass current inward; however, under normal physiologic circumstances, K^+ flow through GIRKs is primarily outward, leading to neuronal hyperpolarization. In other cells, βγ-subunits directly inhibit voltage-gated Ca^{2+} channels and can inhibit presynaptic vesicle release. Interestingly, recent evidence suggests that GIRKs may interact directly with GPCRs, likely to promote the near-instantaneous opening of the ion channel following G-protein activation. Another mechanism for the regulation of neuronal ion channels by GPCRs may be through changes in membrane PIP_2 levels. Many ion channels either require PIP_2 to function or are strongly modulated by PIP_2 and other phospholipids. Thus, the activity of these channels may be altered by G_q-mediated PLC activation and local depletion of membrane PIP_2, though the physiologic relevance of this mode of regulation is still under investigation.

Regulation of GPCR Signaling

Because GPCRs play such a key role in cellular signaling, it is not surprising that their activity is tightly regulated. Indeed, regulation occurs at almost every point along the signaling pathways. Above, the termination of second messenger signaling was discussed, such as with the degradation of cAMP and cGMP by PDEs. In this section, regulation of the G proteins and GPCRs will be briefly discussed.

The termination of G-protein signaling is mediated by the intrinsic GTPase activity of the α-subunit, which hydrolyzes GTP to GDP and thus inactivates the G protein. A separate class of proteins, called regulators of G-protein signaling (RGS) proteins, can accelerate the GTPase activity of the α-subunits, thereby shortening the duration of G-protein signaling. There are more than 20 subtypes of RGS proteins that are differentially expressed throughout the brain and are involved in the regulation of all G-protein α-subunits, except for the G_s family. Specific subtypes of RGS proteins have been shown to regulate important neuronal functions, including behavior. For example, mice with a targeted deletion of the gene encoding RGS2, which regulates G_q, show increased anxiety and decreased male aggression, highlighting the important role of RGS proteins in modulating behavior. Interestingly, expression levels of RGS9, which inhibits G_i-mediated dopamine signaling in the striatum, were found to be reduced in the postmortem brains of patients with schizophrenia, consistent with the hypothesis of excessive dopamine signaling resulting in psychosis. Overall, the diversity and heterogeneous distributions of the RGS proteins make them an attractive target for drug development, as drugs affecting individual isoforms may exert highly selective effects.

In addition to initiating intracellular signal transduction cascades, agonist activation of GPCRs also triggers cellular and molecular mechanisms that lead to the attenuation (desensitization) of receptor signaling. Desensitization is an adaptive mechanism to attenuate receptor responsiveness to repetitive environmental stimuli. At the level of the whole organism, the mechanisms underlying receptor desensitization are likely responsible for the development of tolerance to psychopharmacologic agents such as opiates, as well as the delayed therapeutic response to antidepressants and antipsychotics.

Receptor desensitization is typically mediated by feedback phosphorylation of the receptor by a class of kinases called G-protein–coupled receptor kinases (GRKs) (Fig. 1.11–8). The GRKs phosphorylate the intracellular domains of receptors only when the receptors are bound by an agonist. Receptor phosphorylation by GRKs enables a protein called arrestin to bind to the receptor, preventing the G protein from recoupling, thus rendering the receptor inactive. Arrestin binding to a GPCR also causes the receptor to be internalized into endocytic vesicles.

This process is mediated by an interaction of the arrestin molecule with proteins in clathrin-coated pits and membrane invaginations that are pinched off during endocytosis. After internalization, receptors may be recycled back to the cell surface or degraded. While the precise role of receptor endocytosis is not entirely clear, targeting receptors for degradation may be involved in the downregulation of brain receptor levels following chronic drug administration. In addition, while GPCRs have traditionally been thought to signal only from the cell surface, recent studies have shown receptor signaling from intracellular membrane compartments, including endosomes. GPCR signaling from intracellular compartments may be functionally distinct from plasma membrane receptors, and drugs will have differential accessibility to these intracellular receptors. Thus, the regulation of GPCRs by endocytic membrane trafficking may allow for the development of novel pharmacologic agents.

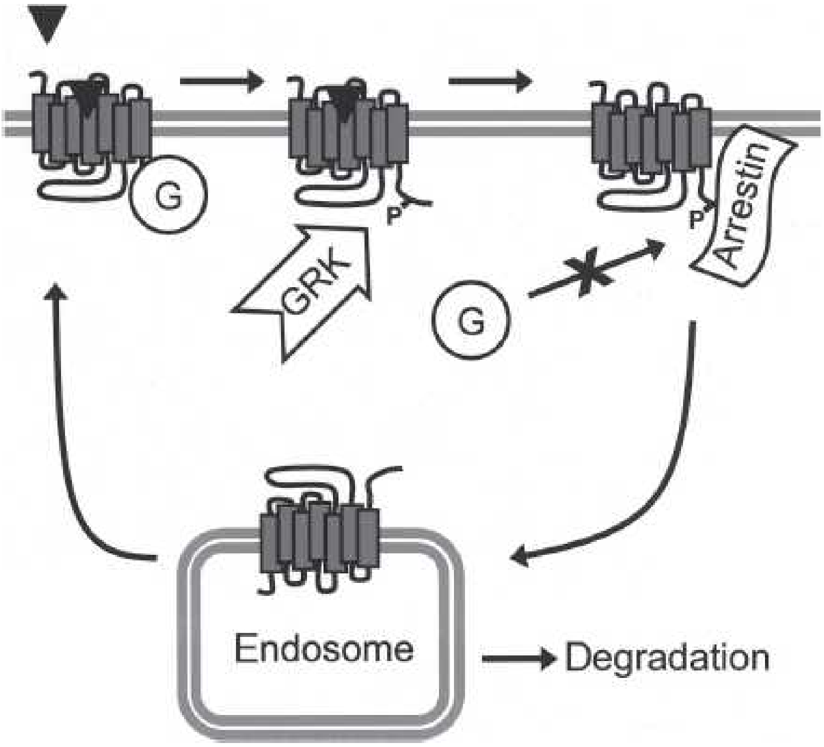

FIGURE 1.11–8. Regulation of G-protein–coupled receptors (GPCRs) by desensitization and internalization. Desensitization is an adaptive mechanism that attenuates receptor responsiveness to repetitive stimuli. GPCR desensitization is typically mediated by feedback phosphorylation (P) by a specific G-protein–coupled receptor kinase (GRK). Receptor phosphorylation by a GRK causes a protein called arrestin to bind to the receptor, effectively preventing G proteins (G) from recoupling to the receptor. Arrestin binding also causes the receptor to be internalized into endocytic vesicles, which may then recycle the receptors back to the cell surface or target them for degradation.

Role of Phosphatases

Because phosphorylation plays such a central role in intracellular signaling pathways, it is not surprising that protein phosphatases, which reverse the effect of protein kinases, also have a major impact on these signaling pathways. There are four major protein phosphatases that are differentially distributed in the brain that dephosphorylate targets of the second messenger kinases, named protein phosphatases 1, 2A, 2B, and 2C. For example, protein phosphatase 2B, also called calcineurin, is activated by the binding Ca^{2+}/calmodulin. Thus, neurotransmitters coupled to G_q proteins as well as Ca^{2+} channels can activate calcineurin and influence the phosphorylation of various cellular proteins. Indeed, phosphatases can be targets for pharmacologic agents, as demonstrated by tacrolimus, an immunosuppressant agent used to prevent organ transplant rejection, which is a selective inhibitor of calcineurin that interferes with T lymphocyte signaling.

Another key mechanism for regulating protein phosphatases involves a separate class of proteins called protein phosphatase inhibitors. These proteins, such as phosphatase inhibitors 1 and 2, are highly potent inhibitors of protein phosphatase 1, a major neuronal phosphatase, and their inhibitory activity is greatly enhanced when they are phosphorylated by PKA and other second messenger kinases. Thus, neurotransmitters that signal through cAMP can influence the phosphorylation of target proteins, both by PKA activation and through PKA-induced indirect inhibition of protein phosphatase 1.

Another protein phosphatase inhibitor, called dopamine- and cAMP-regulated phosphoprotein of 32 kDa (DARPP-32), is of particular interest because it is highly concentrated in regions of the brain that receive dopaminergic input. Similar to other kinase events, phosphorylation of DARPP-32 by PKA greatly enhances its ability to inhibit protein phosphatase 1. Interestingly, DARPP-32 is dephosphorylated by calcineurin, resulting in an increase in protein phosphatase 1 activity. Because calcineurin is activated by increases in intracellular Ca^{2+} concentrations, DARPP-32 may be involved in the integration of current signals from different pathways. Indeed, DARPP-32 is a key mediator of dopaminergic signaling and appears to play an important role in the effects of drugs of abuse. A share of the 2000 Nobel Prize for Physiology or Medicine was awarded to Paul Greengard for elucidating this role of DARPP-32.

TYROSINE KINASE PATHWAYS

While the vast majority of the protein phosphorylation that occurs in cells is on serine and threonine residues, the phosphorylation of tyrosine residues has an extremely important role in a distinct set of intracellular signaling pathways. In particular, tyrosine-phosphorylation–based signaling is mediated by receptors for neurotrophic factors such as NGF and BNDF. Functionally, neurotrophic factors modulate a wide variety of cellular events, such as cell growth and differentiation, synaptic plasticity, metabolism, and cell survival, and thus have been classically studied for their role in neurodevelopment. However, these factors have been shown to be expressed throughout the entire life span, and exciting new research is delineating the roles that neurotrophic factors play in regulating behavior and responses to stress.

Protein tyrosine kinases represent a diverse superfamily of proteins. These include the receptor tyrosine kinases, which are transmembrane receptors with a tyrosine kinase built into the intracellular domains, and nonreceptor tyrosine kinases, which are soluble cytoplasmic enzymes that are often recruited to membrane receptors to become activated. Neurotrophins such as NGF and BDNF bind to the Trk family of receptor tyrosine kinases that will be the primary focus of this section. Neurotrophins bind to two individual Trk receptors, resulting in the dimerization of the two receptors activating the protein tyrosine kinases that reside in the cytoplasmic domain of each receptor (Fig. 1.11–9). The activated Trk receptors subsequently phosphorylate the opposite dimer on tyrosine residues, a process called autophosphorylation. These phosphorylation events produce new binding sites for various other intracellular signaling proteins. For example, an adaptor protein called growth-factor-receptor–bound protein 2 (Grb2) contains an Src homology 2 (SH2) domain that binds to specific phosphorylated tyrosine residues on Trk and leads off a complex signaling cascade.

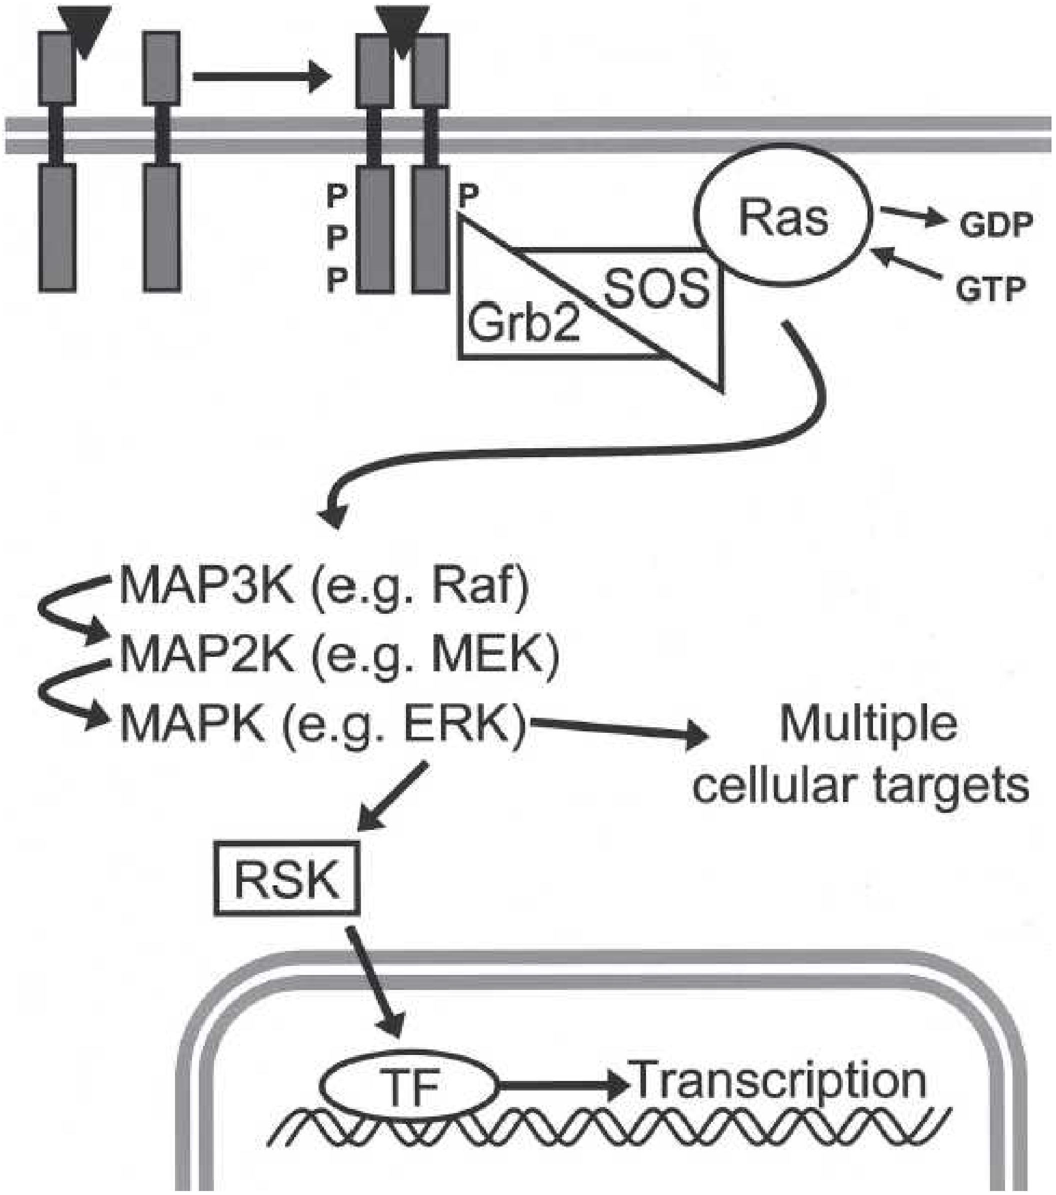

FIGURE 1.11–9. General organization of neurotrophic factor signaling through receptor tyrosine kinases. Receptor tyrosine kinases are transmembrane receptors with a tyrosine kinase built into the intracellular domains. Neurotrophic factor binding induces the dimerization of two receptors and the activation and autophosphorylation of their intrinsic tyrosine kinase domains. These phosphorylated (P) tyrosines become the binding sites for adaptor proteins such as growth-factor-receptor–bound protein 2 (Grb2), which can then attract a protein called Son of Sevenless (SOS) that activates the small G protein Ras by enhancing the exchange of GTP for GDP. In its active GTP-bound form, Ras activates multiple downstream effector pathways, including mitogen-activated protein kinase (MAPK) cascades. A MAPK such as extracellular signal-regulated kinase (ERK) is activated by a MAPK kinase (MAP2K) such as the MAPK/ERK kinase (MEK), which is activated by a MAPK kinase kinase (MAP3K) such as Raf. After the cascade, ERK can

activate various cellular targets including p90 ribosomal S6 kinases (RSK), which translocates to the nucleus and activates various transcription factors (TFs) and regulates gene expression.

As with neurotransmitter receptors, G proteins play a major role in the signal transduction from activated receptor tyrosine kinases. In this case, however, the G proteins are members of the Ras, Rho, and Ral families, collectively referred to as small G proteins. Like the heterotrimeric G proteins described previously, small G proteins are bound to GDP in their inactive state and become active when GTP is bound. However, unlike the heterotrimeric G proteins, the small G proteins are not directly activated by the receptor but by distinct proteins called guanine nucleotide exchange factors (GEFs). For Trk, binding of Grb2 to the phosphorylated tyrosine residues recruits a GEF protein called SOS (for Son of Sevenless), which then activates the small G protein Ras by exchanging GTP for GDP. Once recruited to the receptor complex, SOS can activate many molecules of Ras, thus amplifying the initial signal. In its active GTP-bound form, Ras is able to activate the multiple downstream effector pathways described below. Ras is inactivated by hydrolysis of GTP to GDP, which can be accelerated by a specific GTPase-activating protein (GAP) called RasGAP, which is analogous to the action of RGS proteins on heterotrimeric G proteins.

Mitogen-Activated Protein Kinase Cascades

In contrast to the GPCR-mediated second messenger signaling pathways, the activation of small G proteins such as Ras by receptor tyrosine kinases does not lead to the production of small-molecule intermediates. Instead, the small G proteins stimulate a signaling pathway that is organized as a kinase cascade in which a series of three or more kinases sequentially phosphorylate another kinase. Several parallel kinase cascades can be activated by various receptors and are collectively referred to as MAPK pathways. MAPKs are serine/threonine kinases making up three main classes characterized in mammals: The extracellular signal-regulated kinases (ERKs), the c-Jun N-terminal kinases (JNKs), and isoforms of p38. The ERK pathway is the classical MAPK pathway that is preferentially activated by the neurotrophins and other growth factors, while the JNK and p38 pathways are activated by other receptors, signaling pathways, and various forms of cellular stress.

The kinase cascades that lead to MAPK activation follow an organization that is evolutionally well conserved from yeast to mammals: A MAPK kinase kinase kinase (MAP4K) phosphorylates a MAPK kinase kinase (MAP3K) that phosphorylates a MAPK kinase (MAP2K) that then phosphorylates the MAPK (see Fig. 1.11–9). The cascade of events leading to the activation of ERKs by neurotrophins through the Trk receptor begins with the activation of the small G protein Ras. When Ras is active, it recruits a MAP3K called Raf to the cell surface, where it is phosphorylated by a MAP4K that is not yet well described. Raf then phosphorylates and activates a MAP2K called MEK (for MAP kinase/ERK kinase) that then phosphorylates and activates ERK.

The ERK pathway is the subject of a considerable amount of current biomedical research, as it is involved in regulating a wide variety of cytoplasmic proteins as well as multiple transcription factors. For example, ERK phosphorylates and activates protein kinases such as the p90 ribosomal S6 kinases (RSK), which in turn phosphorylates an array of transcription factors, including c-myc and CREB. Interestingly, stimulation of the ERK signaling pathway has also been linked to neurotransmitter receptors through PKC. Thus, ERK activation plays a key role in modulating long-term neuronal function and may represent a critical node for the interplay between other signaling pathways.

Phosphoinositide 3-Kinase Pathway

The elucidation of the signaling pathways downstream of Ras has identified another major kinase cascade that mediates many of the powerful effects of neurotrophins on neuronal differentiation and survival. This cascade involves the phosphoinositide 3-kinase (PI3K) pathway (Fig. 1.11–10). In this pathway, PIP_2, the same membrane phospholipid that is cleaved to DAG and IP_3 by PLC, is phosphorylated by PI3K, a lipid kinase, to yield PIP_3, which then acts to recruit various proteins to the membrane. One of the proteins that PIP_3 recruits to the membrane is Akt, a serine/threonine kinase that, upon translocation, becomes activated, dissociates from the membrane, and phosphorylates several substrate proteins important for controlling cell survival. For example, Akt activates the “rapid-acting” transcription factor nuclear factor-κB (NF-κB), resulting in the transcription of prosurvival genes. NF-κB is present in cells in an inactive state bound to a protein called inhibitor of κB (IκB). Akt activates a kinase called IκB kinase that phosphorylates IκB, thus tagging it for degradation. This degradation releases NF-κB, which can then migrate to the nucleus and regulate gene expression. Akt also inhibits glycogen synthase kinase 3 (GSK-3), a metabolic regulatory protein that may be a cellular target for lithium (see below). Indeed, a major challenge of current research involves determining which of the many effects of neurotrophins are mediated by these various signaling cascades. Interestingly, some G_i-coupled neurotransmitter receptors can also trigger the activation of PI3K and Akt, suggesting that agonists of these receptors may represent novel strategies for enhancing neuronal survival.

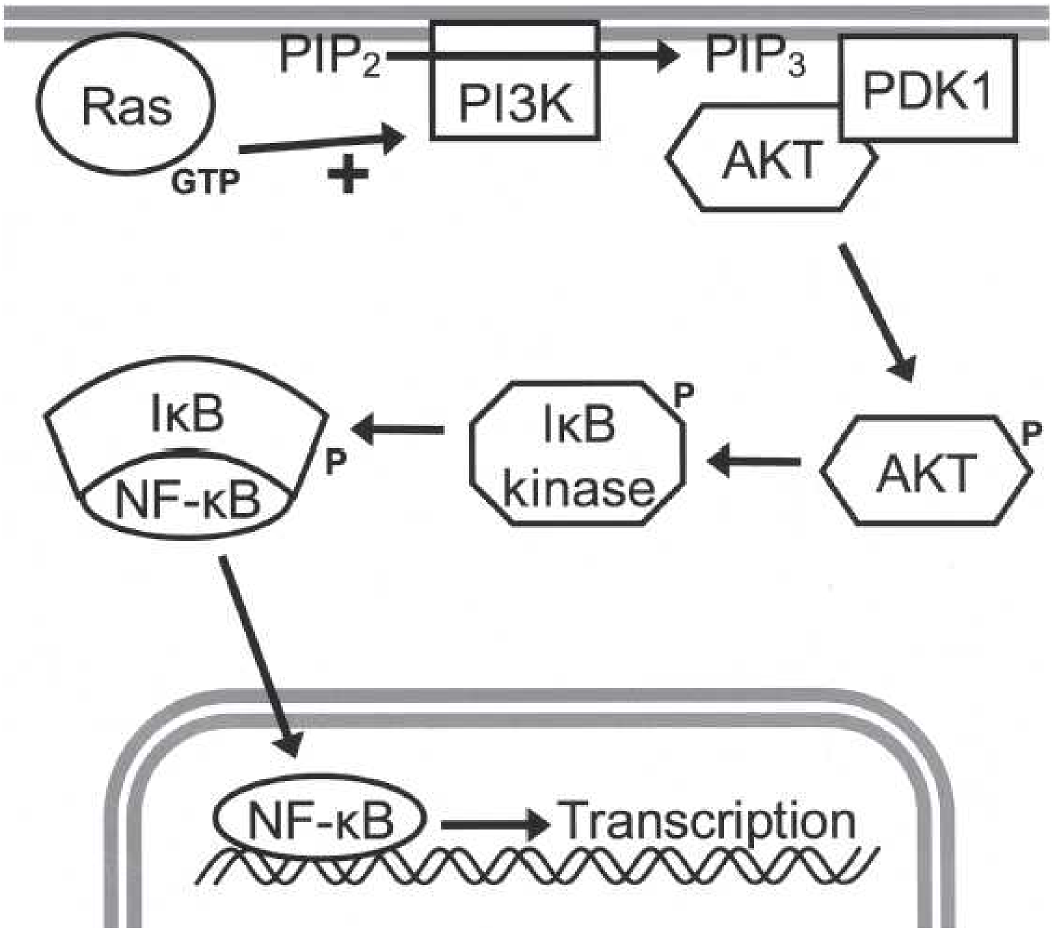

FIGURE 1.11–10. The phosphoinositide 3-kinase (PI3K) pathway. In addition to the mitogen-activated protein kinases (MAPKs), receptor tyrosine kinase activation of Ras can activate the PI3K pathway. PI3K adds another phosphate to the membrane phospholipid phosphatidylinositol bisphosphate (PIP2) to yield phosphatidylinositol trisphosphate (PIP3). PIP3 recruits various proteins to the membrane including 3-phosphoinositide–dependent protein kinase 1 (PDK1) and a kinase called Akt. PDK1 phosphorylates Akt, which then dissociates from the membrane and can phosphorylate multiple cellular proteins important for controlling cell survival. For example, Akt can lead to the activation of a transcription factor called nuclear factor-κB (NF-κB), which is normally found in an inactive state bound to "inhibitor of κB" (IκB). Akt activates a kinase called IκB kinase, which phosphorylates IκB, tagging it for degradation, which releases NF-κB that can then translocate to the nucleus and regulate gene expression.

Mammalian Target of Rapamycin

A downstream target of the PI3K and a central node of integration of multiple extracellular signals is an atypical kinase called mammalian target of rapamycin (mTOR). mTOR is a central controller of local protein synthesis that is required for the formation of new synaptic connections. mTOR function is influenced by the activity of each of the major classes of receptors, including ligand-gated ion channels, GPCRs, and neurotrophin receptors, suggesting that mTOR may act as a signaling “node” at the convergence of several signaling pathways. Indeed, mTOR activity is regulated by multiple signaling pathways, notably the PI3K-Akt pathways.

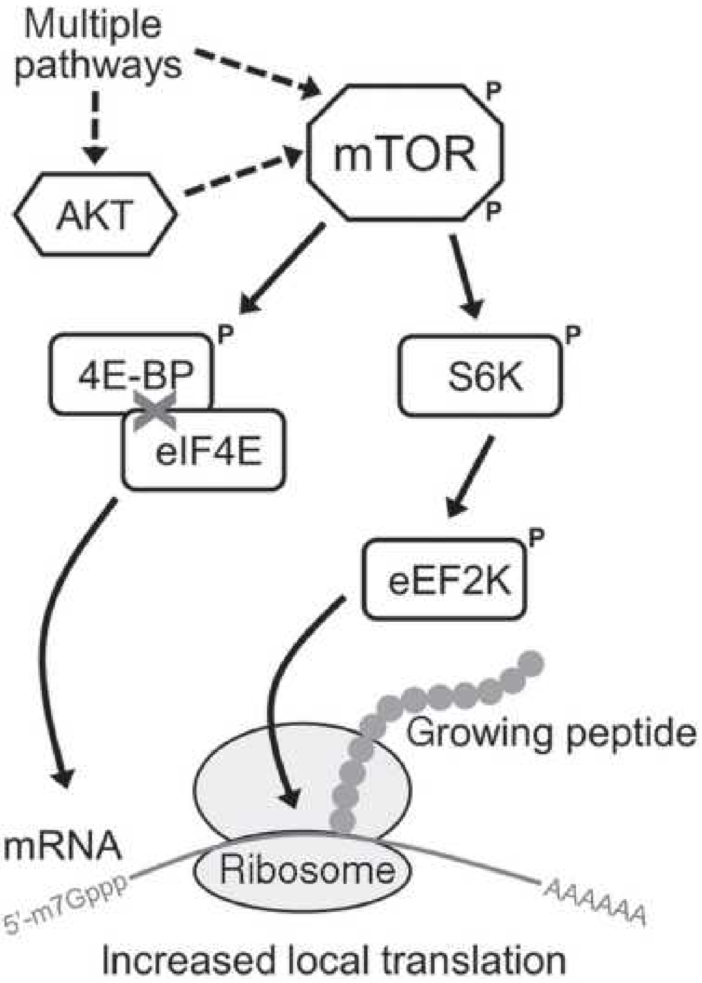

FIGURE 1.11–11. Regulation of protein translation by the mammalian target of rapamycin (mTOR). Research on mTOR regulation has suggested that mTOR is a key point of convergence of multiple signaling pathways, notably via Akt. mTOR is a central controller of local protein synthesis by regulating proteins involved in protein translation initiation and elongation at ribosomes. The activated mTOR complex phosphorylates 4E-BP (eukaryotic initiation factor 4E-binding protein) which dissociates it with eIF4E (eukaryotic initiation factor 4E). eIF4E can then facilitate translation initiation by binding mRNA at the 7-methyl-guanosine cap (5’-m7Gppp). mTOR also facilitates the elongation of nascent polypeptides by phosphorylating p70 ribosomal S6 kinases (S6K) which can then activate the eukaryotic elongation factor 2 kinase (eEF2K).

Protein synthesis is a highly regulated process that can be separated into three general phases: initiation, elongation, and termination. mTOR is a master controller of protein synthesis by regulating both the initiation and elongation steps of protein synthesis (Fig. 1.11–11). One of the first mTOR targets to be discovered was 4E-BP (eukaryotic initiation factor 4E-binding protein) that, when phosphorylated by mTOR, releases eIF4E (eukaryotic initiation factor 4E) which can then initiate local protein translation by binding to the 7-methyl-guanosine cap of mRNAs. In addition, mTOR activates the p70 ribosomal S6 kinases (S6K) which then activates eukaryotic elongation factor 2 kinase (eEF2K), facilitating protein synthesis.

Recently, mTOR signaling has been linked to long-lasting synaptic plasticity and various neuropsychiatric disorders. For example, the rapid antidepressant activity of NMDA receptor antagonists such as ketamine may be mediated by the activation of the mTOR leading to increased translation of synaptic proteins and generation of new spine, particularly in the prefrontal cortex. In addition, genetic mutations that lead to pathologically sustained mTOR activity may underlie several neuropsychiatric disorders, including fragile X syndrome, autism, and tuberous sclerosis.

WNT SIGNALING

Another signaling pathway gaining interest in psychiatry and neurobiology is the Wnt signaling pathway. Wnts are a family of secreted glycoproteins known to play a critical role in embryogenesis. However, components of the Wnt signaling pathway are expressed in the adult brain, and Wnt signaling is important in adult behavior and possibly the pathophysiology of psychiatric and neurologic disorders. The primary, or canonical, Wnt signaling pathway begins with the binding of secreted Wnt proteins to cell-surface receptors of the Frizzled family. Frizzled receptors are seven-transmembrane domain receptors similar to the GPCRs, though it remains unclear whether Frizzled signals through heterotrimeric G proteins. It is clear, however, that Frizzled receptors activate a cytoplasmic protein called Dishevelled, that ultimately leads to the regulation of gene expression through an increase in a transcriptional coactivator called β-catenin.

FIGURE 1.11–12. Basic organization of the canonical Wnt signaling pathway. The primary, or canonical, Wnt signaling pathway begins with the binding of secreted Wnt proteins to cell-surface receptors of the Frizzled family. In the absence of Wnt signaling, a complex of proteins that includes axin, adenomatosis polyposis coli (APC) protein, and glycogen synthase kinase 3 (GSK-3) maintains an active form of GSK-3 (on), which phosphorylates multiple cellular proteins, including the transcriptional coactivator β-catenin. When β-catenin is phosphorylated, it is targeted for degradation. When Wnt

signaling is initiated, Frizzled activates a protein called Dishevelled (Dshvl), which causes the dissociation of the axin/APC/GSK-3 complex, resulting in an inhibition of GSK-3 activity. Decreased GSK-3 activity reduces the degradation of β-catenin, which then translocates to the nucleus, interacts with transcription factors (TFs), and promotes specific gene expression changes.

In the absence of Wnt signaling, a complex of proteins that includes axin, GSK-3, and the protein adenomatous polyposis coli (APC) regulates the intracellular levels of β-catenin (Fig. 1.11–12). Through phosphorylation by GSK-3, this protein complex promotes the proteolytic degradation of β-catenin. However, when Wnt signaling is initiated, the activation of Dishevelled causes this protein complex to dissociate and other proteins to associate and inhibit GSK-3 activity, preventing the degradation of β-catenin. Thus, the cytoplasmic levels of β-catenin increase and β-catenin translocate to the nucleus, interacting with transcription factors and promoting specific gene expression changes. In addition to the canonical signaling pathway, Wnt signaling has also been shown to follow other pathways, including increasing intracellular calcium and activating the MAPK JNK. Thus, while the details of the Wnt signaling pathway are not fully delineated, there is likely some intersection and cross-regulation with other signaling pathways, and this is an area of active research.

Glycogen Synthase Kinase 3

Though initially discovered as a kinase involved in the regulation of glucose metabolism, GSK-3 is emerging as a promising target for the development of psychiatric and neurologic medications. In 1996, it was discovered that lithium inhibited GSK-3, raising the possibility that GSK-3 inhibition might play a role in the treatment of bipolar disorder. Recently, there has been an emergence of research supporting the hypothesis that the inhibition of GSK-3 represents a therapeutically relevant target for mood stabilization.

GSK-3 is a ubiquitous kinase found in both neurons and glia and has two isoforms that are highly homologous but may have slightly different biologic effects. It is generally considered to be constitutively active, meaning that it phosphorylates target proteins until a signal regulates it to stop. For example, as described above, constitutive phosphorylation of β-catenin by GSK-3 leads to its proteolytic degradation but signaling through the Wnt pathway turns off GSK-3, releasing β-catenin to affect gene expression. GSK-3 was initially characterized in 1980 as an enzyme that phosphorylated and deactivated glycogen synthase, leading to studies of its role in insulin signaling and diabetes mellitus. Indeed, insulin binding to the insulin receptor, a receptor tyrosine kinase, leads to the activation of Akt, which also phosphorylates and deactivates GSK-3. Because GSK-3 normally phosphorylates and inactivates glycogen synthase, insulin's ability to turn off GSK-3 allows cells to utilize the elevated plasma glucose levels to make glycogen.

As discussed above, Akt is also activated by neurotrophic factors such as BDNF, low levels of which are implicated in depression and other neuropsychiatric disorders. Other kinases that regulate GSK-3 include PKA, PKC, and RSK, demonstrating that the mechanisms of regulation and biologic targets of GSK-3 are quite diverse. This convergence of diverse signaling pathways onto GSK-3 is a characteristic that has led to the labeling of GSK-3 as a crucial signaling "node." The precise mechanisms that regulate the cross-talk among these distinct pathways are not well established, and this is an area of active research. However, it is likely that the compartmentalization of GSK-3 to distinct regions of the cell minimizes much of the potential cross-talk among pathways.

SYNAPTIC PLASTICITY

Changes in the strength and efficiency of synaptic signaling, termed synaptic plasticity, underlie one of the most important neurochemical foundations of learning and memory. Because these processes play a prominent role in a variety of psychiatric disorders and psychotherapies, there has been intense interest in defining the cellular and molecular events mediating these processes. Because synaptic plasticity is activity dependent, various intraneuronal signaling pathways are important for coordinating these changes. Indeed, there are several mechanisms that cooperatively affect synaptic plasticity, including changes in the release of presynaptic neurotransmitters and changes in how effectively the postsynaptic neuron responds to those neurotransmitters. A postsynaptic mechanism that is widely considered to be a major mediator for enhancing synaptic efficacy is called long-term potentiation (LTP).

LTP is roughly defined as an increase in the strength of a synapse that lasts from hours to several days and is widely considered one of the major mechanisms by which memories are formed and stored in the brain.

Given the diversity of neuronal cell types in the brain, there are many variations in the processes involved in LTP; however, the prototypical model of LTP has been derived from the glutamatergic synapses in the CA1 region of the hippocampus. At these synapses, there are both early and late stages of LTP that are initiated by the actions of two glutamate-gated ion channels α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and NMDA receptors. Early LTP is mediated by modulating proteins already at or near the synapse, while late LTP requires new protein synthesis.

The initiation of early LTP begins with glutamate binding to AMPA receptors, which allows Na^+ to enter the synapse, depolarizing the membrane (Fig. 1.11–13). When the postsynaptic membrane is sufficiently depolarized, NMDA receptors open, leading to a rapid increase in intracellular Ca^{2+} concentrations. The rise in Ca^{2+} levels leads to the activation of CaM kinase II (CaMKII) and PKC, which rapidly phosphorylate AMPA receptors, which increases their conductance for Na^+, enhancing the strength of the postsynaptic response. In addition, CaMKII activation facilitates the insertion of additional AMPA receptors into the postsynaptic membrane. By increasing the number of AMPA receptors at the synapse, future signaling stimuli are able to generate larger postsynaptic responses. This process can additionally be regulated by the concomitant activation of other signaling pathways through various GPCRs.

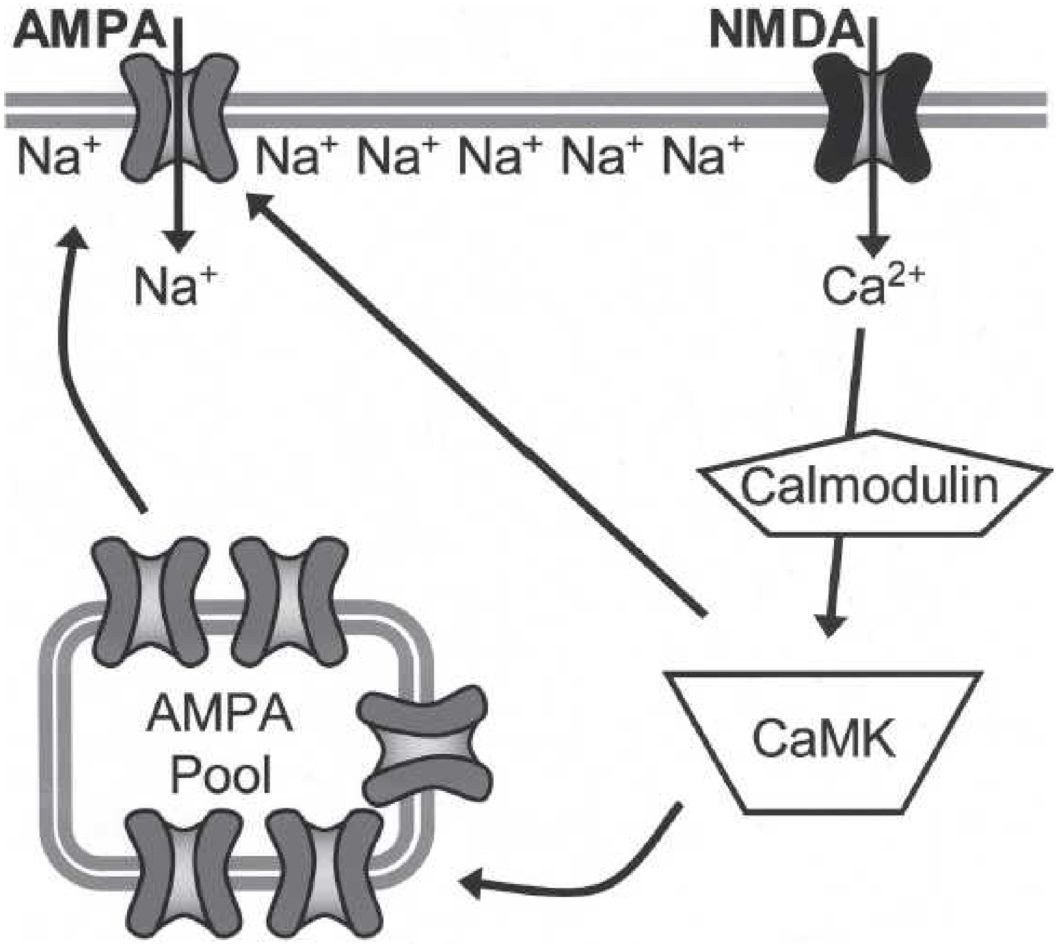

FIGURE 1.11–13. An example schematic of a postsynaptic mechanism involved in long-term potentiation (LTP) and synaptic plasticity. Initiation of LTP begins with glutamate binding to α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors gating the influx of Na^+ ions into the synapse, depolarizing the membrane. When the postsynaptic membrane is sufficiently depolarized, N-methyl-d-aspartic acid (NMDA) receptors open, leading to a rapid increase in intracellular Ca^{2+} levels, which, through binding to calmodulin, activate Ca^{2+}/calmodulindependent kinases (CaMKs) and protein kinase C (PKC). These activated protein kinases can then both phosphorylate AMPA receptors and regulate the insertion of additional AMPA receptors into the postsynaptic membrane intracellular pool. Together, these processes increase the efficiency of future synaptic transmission.

Although these phosphorylation events underlie the rapid changes in synaptic efficacy during early LTP, enduring changes characteristic of “late LTP” depend on the targeting of newly synthesized proteins to the synapses. These newly targeted proteins, which can include additional receptors and scaffolding proteins, induce a remodeling of the synapse and can profoundly strengthen postsynaptic responses to stimuli. At least some of this new protein synthesis occurs locally in the dendrites, allowing direct targeting of the new proteins to the activated synapse, a process largely regulated by mTOR activity.

Overall, LTP and the other cellular mechanisms involved in synaptic plasticity are highly active areas of neuroscience research. The current understanding of these processes highlights the complexity and importance of tight temporal and spatial regulation of synaptic signaling. Continued elucidation of these biochemical mechanisms underlying synaptic plasticity will enhance the understanding of learning and behavior, provide insights into psychiatric diseases, and may allow the development of pharmacologic agents that can improve cognition.

SIGNALING COMPLEXES AND SCAFFOLDS

Several additional types of proteins are central to the organization of signaling pathways. These include scaffolding and anchoring proteins, which provide mechanisms to ensure that information being signaled in cells is transferred to the appropriate targets in a timely and efficient manner. They do this by mediating the localized assembly of multiprotein complexes that contain, for example, receptors, second messenger–generating enzymes, kinases, phosphatases, and substrates. By keeping many of the components of a signaling cascade in close proximity, these complexes minimize the need for activated proteins to diffuse through a dense cytoplasm to find their targets, thus greatly enhancing signaling efficiency. In addition, these systems both maintain the separation, or compartmentalization, of distinct signals when simultaneous signaling events are occurring and are crucially involved in moderating and integrating this information. The characterization of the multitude of ways that signaling pathways interact via these complexes is an active area of research.

Many of these scaffolding and adaptor proteins use specific protein–protein interactions to mediate the transport and localization of signaling proteins and form these specialized multiprotein complexes. Protein interactions are often formed by distinct domains within adaptor proteins that are responsible for recognizing and binding to specific regions of other proteins. An example mentioned above is the Src homology (SH) domain involved heavily in neurotrophin signaling. SH2 domains, found in adaptor proteins such as Grb2, are roughly 100 amino acids long and specifically bind to short amino acid sequences that contain a phosphorylated tyrosine residue. Multiple proteins can bind to these phosphotyrosine sequences via their SH2 domains, some of which are subsequently phosphorylated and activated, and others act as adaptors that recruit other substrates to the kinase. Indeed, activated receptor tyrosine kinases, such as Trk, serve as scaffolds for an array of activated signaling molecules. Another important example is the localization of PKA to distinct sites within cells by a family of scaffolding proteins called A-kinase–anchoring proteins (AKAPs). These AKAPs bind to the regulatory subunits of PKA, holding it near particular substrates while awaiting activation by cAMP. Some AKAPs, for example, are thought to localize PKA next to synaptic ion channels, greatly enhancing the rate of substrate phosphorylation by eliminating delays due to protein diffusion.

Scaffolding also organizes signaling complexes involving the classic neurotransmitter receptors and ion channels at synapses. A common protein domain involved in protein scaffolding in these systems is the PDZ domain. PDZ domains are found in more than 400 proteins in humans and bind tightly to the extreme C-terminal segment of proteins in which the last three amino acids are commonly S/TXV (i.e., serine [S] or threonine [T], followed by any amino acid [X], followed by valine [V] or another hydrophobic amino acid), though other variations exist. Given the large number of proteins containing PDZ domains and PDZ recognition elements, scaffolds containing these proteins can assemble into very large molecular complexes. The best-known example of these large scaffolds is the postsynaptic density (PSD) of excitatory neurons, which organizes glutamate receptors and their associated signaling proteins at the postsynaptic membrane and helps to determine the size and strength of synapses. Indeed, scores of proteins have been identified in the PSD: ion channels, GPCRs, kinases, phosphatases, and cytoskeletal proteins are all targeted and maintained in the PSD by various adaptor and scaffolding proteins. Thus, scaffolding proteins are major players in the organization, efficiency, and specificity of intraneuronal signaling machinery.

Functional Selectivity

Even though most cell-surface receptors have classically been described as activating a single primary intracellular signaling cascade, as discussed above, most receptors also activate one or more additional pathways.

Some GPCRs, for example, have been shown to signal through the phosphatidylinositol pathway, the arachidonic acid pathway, and the MAPK/ERK pathway, among others. In addition, activation of these receptors stimulates the biochemical mechanisms involved in their desensitization and internalization. A classical concept of receptor pharmacology is that a receptor ligand can be either classified as a full agonist, partial agonist, or antagonist at that receptor and that this classification will be consistent for all of the signaling pathways for that receptor. In other words, if a receptor-ligand fully activates the phosphatidylinositol pathway, then it is expected to fully activate all of the other signaling and regulatory pathways linked to that receptor. However, there is now evidence that some ligands may inherently be able to produce different levels of signaling among the various pathways (Fig. 1.11–14). This phenomenon is most often referred to as "functional selectivity" (also called biased agonism).

A well-recognized form of functional selectivity is the differential ability of ligands to activate the classical G-protein–mediated signaling pathway compared to the ability to recruit arrestins for receptor desensitization and endocytosis. Arrestins also act as a scaffold for additional signaling pathways, particularly MAPK/ERK signaling. An example of this form of biased agonism lies with the μ-opioid receptor (MOR), which is a target for endogenous enkephalin peptides as well as opioid analgesics such as morphine. Interestingly, mice with a targeted deletion of a particular arrestin isoform develop less tolerance to the analgesic effects of morphine. Thus, significant efforts are underway to develop new opioids with a strong bias toward the analgesia-mediating G-protein signaling over arrestin signaling. With reduced tolerance, there may be less risk of respiratory depression and overdose due to increased doses. Importantly, however, these arrestin knockout mice still develop morphine dependence. Thus, the overall benefits of biased opioid agonists remain unknown. Indeed, truly balanced opioids similar to endogenous enkephalins may be more beneficial in limiting opioid dependence.

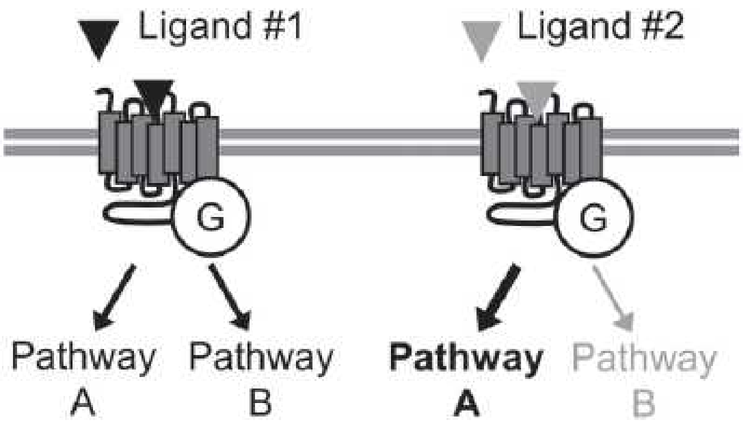

FIGURE 1.11–14. Functional selectivity. In addition to the canonical G-protein–mediated signaling pathways, most GPCRs can activate other signaling pathways. While classical receptor pharmacology theory posits that a full agonist at a receptor will activate all signaling pathways equally, it is now clear that some ligands may inherently be able to produce different levels of signaling from the various pathways. This phenomenon is referred to as "functional selectivity."

While the example above focuses on opioid receptors, functional selectivity has been demonstrated in many GPCRs and may be mediated by a variety of mechanisms. First, different ligands sample and stabilize unique conformational changes in the receptor protein, resulting in differential activation of the various signaling pathways. Second, functional selectivity may also arise through the diversity of G proteins and other signaling and scaffolding proteins or the observed ability of GPCRs to dimerize and oligomerize, the function of which remains poorly understood. Third, as discussed above, drugs can differentially interact with receptors on intracellular membranes suggesting that intracellular bioavailability can lead to a location-biased form of functional selectivity. Thus, not only is the concept of functional selectivity an interesting one, but it is likely to have an important impact on future psychiatric drug development.

REMOTE CONTROL OF INTRANEURONAL SIGNALING

In recent years, emerging synthetic biology technologies have allowed for the targeted activation of intracellular signaling pathways with spatial and temporal precision. These techniques, collectively termed chemogenetics, have facilitated the study of complex circuits and behaviors and are revolutionizing the understanding of brain function. In one approach, chimeric receptors were engineered that replaced the intracellular loops of the light-activated rhodopsin with those of specific adrenergic or serotonergic receptors. These artificial receptors, called “opto-XRs,” allow the use of light to activate the signaling pathways normally recruited by the receptor used for the intracellular loops. Because of the speed of optical manipulation, this approach allows for rapid stimulation of intracellular signaling and examination of the effects of tonic versus phasic activation, though it requires the invasive insertion of optical fibers into the brain. Another approach uses specifically engineered GPCRs, or chemogenetic actuators, that are only activated by synthetic ligands that do not activate endogenous receptors. Termed DREADDs (designer receptors exclusively activated by designer drugs) or RASSLs (receptors activated solely by synthetic ligands), these technologies similarly allow for precise spatiotemporal control of intracellular signaling in vivo. Various versions of these chemogenetic actuators activate the major GPCR signaling pathways (G_s, G_i, and G_q). Additional chemogenetic actuators are being developed that could control intraneuronal signaling cascades, including engineered enzymes and drug-induced dimerization or destabilization domains. Since they are activated by drugs, chemogenetic actuators allow the noninvasive modulation of intracellular signaling and thus have the potential to be used for transformative therapeutic approaches for a host of neuropsychiatric disorders.

FUTURE DIRECTIONS

Translating the advances in molecular neurobiology into improved diagnostic and therapeutic capabilities represents the greatest opportunity and challenge facing modern psychiatry. The current armamentarium of medications used in treating psychiatric diseases has facilitated decades of progress in understanding intercellular signaling mediated by cell-surface receptors. However, dramatic and ongoing advances in the understanding of the intraneuronal signaling pathways activated by these receptors will likely lead to novel, innovative, and improved pharmacologic agents for psychiatric diseases, as has been achieved in other branches of medicine. Thus, future efforts in drug discovery should move beyond the current strategies of solely targeting synaptic neurotransmission at the receptor level to the development of agents acting on components of intracellular signaling pathways. By nature, signaling pathways have significant redundancy and interactions. Thus, identifying and targeting critical points within these networks may lead to improved molecular diagnostic tests and treatments.

1.12 Psychoneuroendocrinology

VICTOR I. REUS, M.D.

Endocrine disorders are frequently associated with secondary psychiatric symptoms, such as depressed mood and disturbances in thought. In addition, certain psychiatric syndromes are associated with distinct patterns of endocrine dysfunction. The term *psychoneuroendocrinology* encompasses the inextricable structural and functional relationships between hormonal systems and the CNS and behaviors that modulate and are derived from both. Classically, *hormones* have been defined as the products of endocrine glands transported by the blood to exert their action at sites distant from their release. Advances in neuroscience have shown, however, that in the CNS, the brain not only serves as a target site for regulatory control of hormonal release but also has secretory functions of its own and serves as an end organ for some hormonal actions. These complex interrelationships make classic distinctions between the origin, structure, and function of neurons and those of endocrine cells dependent on physiologic context. Multiple interactions between the endocrine and immune systems have pointed to a parallel regulatory complexity.

HORMONE EVOLUTION

Over the course of evolution, as organisms have increased in complexity, hormones that first appeared in unicellular organisms have been recruited to serve a multiplicity of functions, a quality that is referred to as *pleiotropy.* A single hormone may act at multiple sites, including binding to receptors on the membrane, cytoplasm, or nucleus, each with different effects, and subtle differences in molecular structure or metabolic processing can have profound physiologic consequences. Hormones are thus ideally suited to regulate complex behavioral activities and to play a role in the *plasticity* of the organism, allowing it to adapt to the changing demands of the environment, as, for example, in the alteration of sexual phenotype in certain amphibians and reptiles in response to changing environmental conditions. Exogenous exposure to endocrine-disrupting chemicals in the environment, such as bisphenol A and phthalates, are additional confounding factors.

HORMONE CLASSIFICATION

Hormones are divided into two general classes by structure—(1) proteins, polypeptides, and glycoproteins; and (2) steroids and steroid-like compounds—and into three classes by location of function (Tables 1.12–1 and 1.12–2). In addition to classical action on a target tissue, hormones may also act as *neuromodulators,* regulating the effects of neurotransmitters and, in some cases, meeting criteria for neurotransmitter function independently.

Table 1.12–1.
Classification of Hormones by Structure

Structure	Examples	Storage	Lipid Soluble
Proteins, polypeptides, and glycoproteins	Adrenocorticotropic hormone, β-endorphin, thyrotropin-releasing hormone, luteinizing hormone, follicle-stimulating hormone	Vesicles	No
Steroids and steroid-like compounds	Cortisol, estrogens, testosterone, progesterone, dehydroepiandrosterone	Diffusion after synthesis	Yes

Table 1.12–2.
Classification of Hormones by Location of Function

Hormone Classification	Function
Autocrine	Self-regulatory effects
Paracrine	Local or adjacent cellular action
Endocrine	Distant target site

HORMONE SECRETION

Hormone secretion is stimulated by the action of a neuronal secretory product of neuroendocrine transducer cells of the hypothalamus. Examples of hormone regulators (Table 1.12–3) include corticotropin-releasing hormone (CRH), which stimulates adrenocorticotropin (ACTH); thyrotropin-releasing hormone (TRH), which stimulates the release of TSH; gonadotropin-releasing hormone (GnRH), which stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH); and somatostatin (somatotropin release–inhibiting factor [SRIF]) and growth hormone–releasing hormone (GHRH), which influence growth hormone (GH) release. Chemical signals cause the release of these neurohormones from the median eminence of the hypothalamus into the portal hypophyseal bloodstream and subsequent transport to the pituitary to regulate the release of target hormones. Pituitary hormones, in turn, act directly on target cells (e.g., ACTH on the adrenal gland) or stimulate the release of other hormones from peripheral endocrine organs. In addition, these hormones have feedback actions that regulate secretion and exert neuromodulatory effects in the CNS.

HORMONE SYNTHESIS AND STRUCTURE

Peptide hormones represent subsections of larger amino acid chains or polypeptides called *prohormones.* Production of a peptide hormone occurs by the cleavage of its prohormone chain at a given site on the chain by the appropriate enzyme. Proopiomelanocortin (POMC) is an example of a prohormone that contains the sequences for ACTH, β-endorphin, β-lipotropin, and melanocyte-stimulating hormone (MSH). Some hormones, called *dimers,* contain two or more peptide chains (e.g., FSH, LH, and TSH). Further cleavage of these hormone peptide chains in the course of metabolism may create additional biologically active peptides that have different effects from those of the parent peptide, and even minor modifications of structure can drastically change binding properties and metabolic processing.

Tropic hormones, such as ACTH and gonadotropins, in turn, induce steroidogenesis in two distinct ways. Acute regulation occurs through activation and rapid synthesis (over minutes) of steroidogenic acute regulatory (StAR) protein, which regulates the rate-limiting step of steroid hormone synthesis, the transport of cholesterol from the outer to the inner mitochondrial membrane. In contrast, chronic stimulation induces transcription and increases P450scc protein and steroidogenesis over hours to days.

Table 1.12–3.
Examples of Regulating Hormones

Regulating Hormone	Hormone Stimulated (or Inhibited)
Corticotropin-releasing hormone	Adrenocorticotropic hormone
Thyrotropin-releasing hormone	Thyroid-stimulating hormone
Luteinizing hormone–releasing hormone	Luteinizing hormone
Gonadotropin-releasing hormone	Follicle-stimulating hormone
Somatostatin	Growth hormone (inhibited)
Growth hormone–releasing hormone	Growth hormone
Progesterone, oxytocin	Prolactin
Arginine vasopressin	Adrenocorticotropic hormone

CELLULAR MODE OF ACTION

Genomic

The first known mode of action of steroid hormones (glucocorticoids, estrogen, and testosterone) and thyroid hormones (triiodothyronine [T_3] and thyroxine [T_4]) is by binding to intracellular receptors in the cytoplasm. The hormone-receptor complex, in turn, binds to common response elements on chromosomal DNA and alters transcription through a conformational change that unmasks the binding site. The hormone complex can also interact with transcription factors such as those produced by c-*fos,* c-*jun,* or activator protein-1 (AP-1) to amplify or inhibit gene expression and, by these mechanisms, regulate the induction of such gene products as enzymes and other cell proteins that affect metabolic change.

Nongenomic

Alternatively, as in the case of estrogen-stimulated prolactin release, certain hormones may exert a physiologic effect within seconds to minutes, a time course precluding a genomic mechanism. Nongenomic action is hypothesized to involve membrane hormone receptors. Some nongenomic effects appear to be mediated through distinct, nonclassical membrane receptors in that they are not blocked by classical receptor inhibitors and do not require gene transcription, protein synthesis, or a coagonist. Hormones also may act through ion-gated neurotransmitter receptors as coagonists or antagonists, as in the modulation of gamma aminobutyric acid type A ($GABA_A$) receptors by neurosteroids or by altering the fluidity and microenvironment of membrane receptors through the intercalation of the steroid in the phospholipid bilayers. Genomic and nongenomic mechanisms may be active simultaneously, with cross-talk a likely occurrence. Rapid actions of glucocorticoids include facilitating the surface diffusion of glutamate receptors and estradiol and the membrane trafficking of neurotensin and GABA-A receptors.

Combined Action

An example of a hormone-induced behavioral response with both genomic and nongenomic mechanisms is corticosteroid stimulation of aggressive behavior in rats. A rapid surge of glucocorticoids precedes the aggressive behavior, but early and later stimulation of aggressive behavior is mediated differently. The initial phase is promoted by a nongenomic mechanism needed for rapid response, which can play a decisive role in the outcome of the encounter. (In the case of rats, an early aggressive response may scare off the intruder and avoid a fight.) The effects of this mechanism rapidly subside, and aggressive behavior in later phases is stimulated by genomic mechanisms. This later, genomic corticosteroid-stimulated behavior is blocked by a protein synthesis inhibitor, but earlier nongenomic stimulation of aggression is not. Besides meeting the immediate need for rapid action, the nongenomic mechanism may serve the purpose of preparing for the genomic response by activating changes needed for an aggressive response, such as changes in energy metabolism.

Tissue Specificity

Many hormones, such as estrogen, act through a multistep process involving a hormone-receptor complex. This complex binds to specific

DNA sites called hormone response elements. The formation of a cluster with coactivators, corepressors, and transcriptional factors stimulates transcription and protein synthesis, with the response specific to the type of cell. Tissue specificity may arise from several mechanisms. Selective estrogen receptor modulators (SERMs) are synthetic hormones developed to target certain actions while avoiding other unwanted responses through coactivators or repressors, or other elements of the cluster that do not recognize the SERM in certain tissues. Alternatively, many hormones, such as estrogen or DHEA, may act directly or indirectly as a prohormone to be converted into other hormones in specific tissues. For example, tibolone is a synthetic hormone structurally related to 19-nortestosterone derivatives that has weak estrogen, progestogen, and androgen effects in specific tissues, in part because it is differentially metabolized. Accordingly, it has been used to reduce hot flashes and sweating, improve mood and libido and sexual functioning, decrease bone loss, stimulate semantic memory, and lessen vaginal atrophy without stimulating the growth of endometrium or breast tissue as do estrogens.

CHARACTERISTICS OF ENDOCRINE ACTIVITY

In general, hormonal compounds often exert their effect in a tonic rather than phasic fashion, being diffused in a less precise manner than a neurotransmitter and over a longer time period. Theoretically, such a characterization would allow hormones to be more closely linked to integrated behavioral responses. The release of many hormones is pulsatile, and the pattern of these pulses (i.e., duration, interpulse interval, the slope of increase or decrease in rate, and amplitude) is crucial to their effects. Other factors that can influence the regulation and effect of a hormone in a given individual include genetic differences, a history of exposure to the hormone during critical developmental encoding periods, the frequency and chronicity of past exposure, the time since last exposure, and the status of other influences on the target system. A decrease in the amplitude of response after repeated exposure is referred to as *habituation,* and an enhancement is termed *sensitization.* Facilitation of a previously habituated response after exposure to a novel stimulus or more severe stressor is called *dishabituation* (i.e., this allows enhancement of the previously habituated response to cope more effectively with the stimulus). In the case of the hypothalamic–pituitary–

adrenal (HPA) system, the release of cortisol by the adrenal gland is dependent on an integration of three separate control systems. These include an underlying circadian rhythm regulated by the suprachiasmatic nucleus, a stress-responsive circuit involving inputs to the hypothalamus from the brainstem, limbic system, and cerebral cortex, and a feedback control system exerted through two classes of corticosteroid receptors.

PHARMACOGENETICS AND PHARMACOGENOMICS

The study of pharmacogenetics and pharmacogenomics is leading to a better understanding of the mechanisms of psychopathology and its response to treatment. Pharmacogenetics refers to the effects of single genes. Pharmacogenomics is the genome-wide approach to discovering individual differences in the outcome of drug therapy. Recent studies of treatment response to antidepressants suggest that polymorphisms in some genes, such as for glucocorticoid receptors (GRs), CRH receptor 1, and a GR-regulating cochaperone, can predict treatment outcome or rapidity of response, but to date, studies have been of insufficient size, and the findings are difficult to replicate. Larger scale genome wide association studies are needed. Polymorphisms in genes that regulate hormonal response or in genes for other chemical messengers that modulate hormonal activity may also explain treatment responsiveness through more indirect mechanisms. Examples include genes for neurotrophic factors; excitatory cytokines, such as tumor necrosis factor; α-adrenergic receptors; GABA receptors; and metabolizing enzymes, such as monoamine oxidase inhibitor (MAO). Treatment interventions, including nonpharmacologic ones such as exercise, can produce changes in the expression of certain genes that may be more beneficial to those with particular genotypes. The use of genetically engineered mice has allowed the targeting of specific genes for the study of the dysfunction of hormonal systems in relation to anxiety and depression, including peptides modulating hormone release, receptors, binding proteins, and proteins controlling the access of hormones into the CNS. This research is still in its early stages, but the clinical implications of discovering genetic differences as biomarkers for subtyping the disorder and selection of treatment agents are exciting.

DEVELOPMENTAL PSYCHONEUROENDOCRINOLOGY AND EPIGENETIC TRANSMISSION

Although a review of the effect of hormones on brain development is beyond the scope of this chapter, it is important to note that hormones can have organizational as well as activational effects. Exposure to gonadal hormones during critical stages of neural development directs changes in brain morphology and function (e.g., sex-specific behavior in adulthood) and differentiation of dopaminergic neurons. Similarly, thyroid hormones are essential for the normal development of the CNS, and thyroid deficiency during critical stages of postnatal life severely impairs the growth and development of the brain, resulting in behavioral disturbances that may be permanent if replacement therapy is not instituted. Prenatal exposure in animals to endogenous or exogenous glucocorticoids or to stressful circumstances reduces offspring birth weight and may result in long-lasting changes in immune response, hypertension, hyperglycemia, hyperinsulinemia, cardiovascular function, and neuroendocrine responses and behavior, including attentional deficits, increased anxiety, and disturbed social behavior. Maternal deprivation in strains of rats with increased glucocorticoid response to stress has similarly been shown to lead to increased startle responses, anxiety-like behavior, increased alcohol preference, and difficulties with spatial learning in adulthood.

Epigenetic transmission occurs through changes in chromatin and DNA structure that do not involve changes in the sequence of DNA but which alter gene expression and phenotype. Maternal behavior can cause epigenetic alterations to steroid receptor genes and produce long-term changes influencing postpartum behavior. Cross-fostered rats show maternal care behaviors similar to those of their “adoptive” mother rather than those of their biologic parent. This change in hormone-influenced behavior is thought to involve estrogen and oxytocin receptor changes.

PSYCHONEUROENDOCRINOLOGY METHODOLOGY IN HUMANS

Human studies are often limited to examining the relationship between hormone concentrations or changes in concentration and psychiatric disease states, symptoms, neurotransmitter function, or response to treatment. Concentrations may be measured in plasma, urine, saliva, cerebrospinal fluid (CSF), or postmortem tissue and are sometimes used as indicators of regulatory neurotransmitter function in response to a given stimulus. For example, cortisol or prolactin response to d-fenfluramine has been used to assess serotonin activity and GH response to clonidine (Catapres) to assess dopaminergic function.

One example of a provocative psychoendocrine test used to assess the HPA system is the combined dexamethasone–CRH test, which assesses response to two hormonal stimuli, one inhibiting (dexamethasone [Decadron]) and the other stimulating (CRH), on cortisol secretion. Typically, 1.5 mg of dexamethasone is given in the evening, and plasma cortisol concentration is measured 16 hours later on the following day. An infusion of 100 μg of CRH is then given, and cortisol level and ACTH are measured again several times over the next 75 minutes. Abnormalities in this test are found in a variety of psychiatric illnesses, including bipolar disorder, major depression, schizophrenia, and PTSD, although the sensitivity or specificity for these disorders does not make the test a reliable diagnostic tool. Several studies or case reports have suggested an association between changes in suppression and outcome for these disorders.

Another method of studying the relationship of hormones to psychiatric disorders is the administration of hormones or other secretagogues (substances that cause other substances to be secreted) to experimentally correct an abnormal hormone concentration and examine the effects. Some secretagogues can be given orally to replace a parenterally administered hormone and be given multiple times during a day to mimic circadian rhythms or other variations in concentration when studying circadian effects.

Functional brain imaging studies can help localize the areas of changed activity produced by hormonal action affecting a variety of cognitive and behavioral activities.

HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Since the earliest conceptions of the stress response by Hans Selye and others, investigation of HPA function has occupied a central position in psychoendocrine research. CRH, ACTH, and cortisol are all elevated in response to a variety of physical and psychological stresses and serve as prime factors in the maintenance of homeostasis and the development of adaptive responses to novel or challenging stimuli. Allostatic load, an index of chronic stress-induced physiologic dysregulation, has been correlated with a number of adverse behavioral trajectories and outcomes. Glucocorticoids regulate glucose metabolism, blood pressure, immune response, lipid metabolism, glycogen deposition, and energy homeostasis for fight-or-flight response and are essential for embryonic development and neonatal survival. A normal glucocorticoid stress response helps to recover after the challenge and helps to store the experience for coping with future encounters, although sustained levels may impair some forms of memory. The hormonal response is dependent not only on the characteristics of the stressor itself but also on how the individual assesses and is able to cope with it. In primates, social status can influence adrenocortical profiles and, in turn, can be affected by exogenously induced changes in hormone concentration. Aside from generalized effects on arousal, distinct effects on sensory processing, stimulus habituation and sensitization, pain, sleep, and memory storage and retrieval also have been documented with CRH, ACTH, and cortisol (or corticosterone).

Exposure to chronic stress produces increased concentrations of CRH and arginine vasopressin (AVP) in the paraventricular nucleus (PVN) of the hypothalamus and, over time, leads to a reduction in CRH receptor number in the anterior pituitary. The release of CRH results in simultaneous activation of the locus coeruleus noradrenergic circuit, which functionally increases arousal and selective attention and decreases vegetative functions, such as appetite and sex drive. ACTH concentrations are increased in acute stress but diminish over time in chronic stress.

GRs are ubiquitously distributed throughout the body. At least two intracellular receptor subtypes bind corticosteroids: The mineralocorticoid receptor (MR) (or type I receptor) and the GR (or type II receptor). The human GR has an α and a β form, the α form showing high affinity for dexamethasone, a modest affinity for cortisol, and low affinity for aldosterone, deoxycortisol, and the sex steroids; and the β form acting as a negative regulator. MRs have high affinity but low capacity, whereas GRs have low affinity but high capacity. Owing to the difference in affinity, low corticosteroid levels generally result in a predominant MR occupation, with higher steroid levels shifting the balance in favor of the GR.

"Permissive actions" of MR activation before the onset of stress are tonically involved in the mediation of the initial stress response. When more GRs become occupied, local excitability may decrease or, in some cases, may increase on a short-term basis to inhibit or enhance the initial effects of stress-responsive hormones. Over time, continued stress produces increasing "allostatic load," the sustained effects of hypercortisolemia giving rise to hyperglycemia, increased visceral fat, elevated blood pressure, decreased bone density, hyperlipidemia, and changes in electrolytes and immune response. Interactions between MR and GR in the hippocampus may be relevant to understanding the regulation of stress response in depression and the efficacy of antidepressants. Studies of GR function have pointed to a relevant decrement in response to agonists in depressed patients, but MR function is generally preserved.

Three types of inhibitory feedback of glucocorticoids on CRH and ACTH have been characterized. Fast, rate-sensitive feedback occurs while plasma concentrations of the glucocorticoid are rising and regulate release rather than synthesis of CRH and ACTH. Intermediate, delayed feedback occurs from 1 to 2 hours after steroid administration, is dose sensitive and duration sensitive rather than rate sensitive, and inhibits the release of CRH and ACTH as well as the synthesis of CRH. Slow feedback is similar to intermediate feedback but occurs over a longer period of time (hours) and is distinguished by decreased synthesis of CRH and ACTH (and other POMC derivatives).

Glucocorticoid release is amplified, at least acutely, by serotonergic and cholinergic input and is inhibited by GABA and opioids. Catecholamines play a role in response to stress and interact with the limbic–hypothalamic–pituitary–adrenal axis. The acute addition of glucocorticoids can increase dopaminergic activity in certain areas of the brain, but chronic hypercortisolemia may decrease dopamine activity (depending on the region involved). Glucocorticoids may exert their influence on dopamine activities by functioning as a transcriptional regulator, by acting on promoter regions of dopamine receptors, and by modulating catecholamine biosynthesis.

Pathologic alterations in HPA function have been associated with a number of psychiatric disorders, including mood disorders, PTSD, dementias, and substance use disorders (SUDs). Disturbances of mood are found in more than 50% of patients with Cushing syndrome (characterized by elevated cortisol concentrations), with psychosis or suicidal thought apparent in more than 10% of cases studied. Cognitive impairments similar to those seen in major depressive disorder (MDD) are common and relate to the degree of hypercortisolemia present and a possible reduction in hippocampal size. In general, therapeutically induced reductions in cortisol levels result in a normalization of mood and mental status. Mifepristone (RU486) has been reported to ameliorate psychosis and depression in Cushing patients, and several studies have reported that it also alleviated psychosis or depression in psychotic depression not associated with Cushing syndrome. In Addison disease (characterized by adrenal insufficiency and diminished glucocorticoid output), apathy, social withdrawal, impaired sleep, and decreased concentration frequently accompany prominent fatigue. Replacement of glucocorticoid results in resolution of behavioral symptomatology, although correction of the associated electrolyte disturbances by itself does not.

Exogenous administration of synthetic corticosteroids is commonly associated with mild activation, but a higher dose and more sustained treatment may produce depression, mood lability, memory, attentional impairment, and sometimes psychosis. Alterations in HPA function associated with depression include elevated cortisol concentrations, failure to suppress cortisol in response to dexamethasone, increased adrenal size and sensitivity to ACTH, a blunted ACTH response to CRH, and elevated CRH concentrations in the brain. In addition to altered slow feedback, several groups have demonstrated decreased sensitivity to glucocorticoid fast feedback as well, and increased cortisol near sleep onset and on first awakening have been shown to be predictive of increased risk of future depression. The pattern of these abnormalities has not, thus far, led to a definitive theory of mechanism, and other elements, such as AVP, are important to understanding the change in homeostasis. The finding that corticosteroids have multiple regulatory effects on serotonergic function, particularly on the serotonin (5-hydroxytryptamine type 1A [5-HT$_{1A}$]) receptor, may also be relevant, as may be the state-dependent stimulant-like effects that glucocorticoids can exert on mesencephalic dopamine transmission.

Excessive glucocorticoid activity may contribute to the symptoms of psychotic mood disorders. Some mood stabilizers, such as lithium, carbamazepine (Tegretol), and valproate, inhibit the transcription activity of GRs and may exert some of their therapeutic effects in this way, and the development of CRH-1 antagonists as potential pharmacotherapies for depression and anxiety disorders, alone or in combination with current antidepressant medications, is currently underway. Cortisol response to CRH or ACTH is abnormal in some psychiatric illnesses, although studies in this area have been highly variable and confusing. For example, in one study, patients with PTSD exhibited low cortisol levels despite high CRH activity, while in another, cortisol response to ACTH was increased.

A number of studies have linked abnormalities in HPA activity, hippocampal volume, and certain memory functions, but it is not clear which is causal. One imaging study of identical twins discordant for PTSD showed similarly diminished hippocampal volume, but the treatment of the symptoms of PTSD with SSRIs is followed by an increase in hippocampal volume and improvement in memory. Genomic and nongenomic actions of cortisol in hippocampal cells promote enzymatic processes that can lead to cell death, but as the hippocampus mediates negative feedback of cortisol release, hippocampal damage may impair cortisol negative feedback. Increasing glucocorticoid levels by administration or other methods has decreased hippocampal volume in several (but not all) studies in non-human primates and other species. PTSD symptoms and cortisol at baseline predicted hippocampal size reduction later in one study, and a decrease in cortisol following the treatment of Cushing disease has been shown to reverse hippocampal atrophy.

In schizophrenia, difficulty suppressing cortisol after dexamethasone is associated with negative symptoms and cognitive impairment. Clozapine (Clozaril) improves cognitive functioning, possibly in part through preventing or reversing cortisol-induced hippocampal damage, and reverses stress-induced impairment of long term potentiation (LTP), a measure of synaptic plasticity important for the storage of information and memory, in the frontal cortex. The GR antagonist mifepristone also blocks cortisol-induced impairment of LTP.

Stress is often reported as a reason for relapse in substance-dependent individuals, and animal studies suggest that glucocorticoid administration is involved in drug self-administration. Glucocorticoid acute enhancement of dopamine activity likely contributes to the motivational changes involved with drug use. Alcohol usage and withdrawal produce profound changes in HPA regulation, pseudocushingoid features are a phenotypic feature of chronic alcohol intake, and HPA adaptation to alcohol withdrawal varies by family history of alcoholism. There is also suggestive evidence that alteration in HPA response to acute alcohol challenge may represent an endophenotype of genetic risk of dependence. CRH is involved not only in the HPA axis but also in extrahypothalamic systems that play a role in the relapse to alcohol and other drug use after stress.

Another disorder associated with a disturbance in glucocorticoid negative feedback is polydipsia. Polydipsic schizophrenic patients, particularly those with hyponatremia, show marked impairment in cortisol suppression of ACTH.

METABOLIC SYNDROME

Metabolic syndrome is a cluster of multiple metabolic risk factors, including elevated insulin levels and resistance, hyperglycemia, visceral obesity, hyperlipidemia, and hypertension. Glucocorticoids interfere with glucose transport and utilization. The insulin resistance and increased insulin concentrations that develop decrease lipid deployment and increase lipid accumulation. GRs are found in high concentrations in intra-abdominal fat tissue, accounting for the truncal obesity resembling that in Cushing disease. Elevated intracellular glucocorticoid tone is thought to be an etiology of metabolic syndrome. Selective inhibitors of 11β-hydroxysteroid dehydrogenase 1, which decrease cortisol production, are thus being tested as a therapeutic intervention. Stress can produce these changes, along with increased vascular resistance through effects on the somatic nervous system. Many patients with schizophrenia who exhibit increased cortisol and epinephrine have more central obesity, higher plasma cortisol, and an increased risk of diabetes, even when medication free. Many of the atypical antipsychotics and some of the other psychotropic medications also can cause hyperglycemia, hyperlipidemia, and visceral obesity, limiting their use. Reports of changes in HPA axis hormones with treatment by typical and atypical antipsychotics have been inconsistent. However, atypical antipsychotics may cause more glucose elevation after glucose challenge compared to typicals, putting patients at greater risk of developing diabetes.

PROOPIOMELANOCORTIN, MELANOCORTINS, MELANOCYTE-STIMULATING HORMONE, AND

MELATONIN

POMC is a prohormone from which several hormones called melanocortins are derived. These include ACTH (described above), melanocortins, and MSH.

Studies of rodent sexual behavior suggest that the activation of melanocortin receptors may be an avenue to treat women with hypoactive sexual desire, and the development of melanocortin medications for sexual disorders is underway. Blockade of the melanocortin-4 receptor decreases the reinforcing effects of cocaine, and melanocortins may be neuroprotective for ischemic injury, reducing hippocampal cell death, an area important in learning. Inactivating the melanocortin-5 receptor in rats also reduces pheromone-induced aggression.

MSH, an anterior pituitary peptide, controls the secretion of melatonin and melanin. Melanin is a pigment not only in hair, skin, and eyes but also in neurons in the substantia nigra and the locus coeruleus. Melatonin (described below) is a hormone that plays a major role in regulating the circadian rhythm. Phenothiazines increase pituitary MSH secretion and pigmentation in some patients. In a double-blind, cross-over trial in humans, an infusion of α-MSH resulted in a significant improvement in verbal memory but little change in mood. A dose-related biphasic effect on mood has been reported for MSH release–inhibiting factor. Recent data indicate that MSH interacts with leptin to counteract neuropeptide Y (NPY), decrease food intake, and increase energy expenditure. It may also antagonize the antidepressant effects and anxiolytic effects of NPY while also antagonizing the anxiogenic effects of the proinflammatory cytokine interleukin-1β. MSH inhibitors have been found to decrease dyskinetic movements in animals.

Melatonin is a pineal hormone that is derived from the serotonin molecule and controls photoperiodically mediated endocrine events (particularly those of the hypothalamic–pituitary–gonadal [HPG] axis). It also modulates immune function, mood, and reproductive performance; it is a potent antioxidant and free-radical scavenger and may have oncostatic effects. Melatonin has a depressive effect on CNS excitability and exerts neuroprotective effects against excitotoxicity. Melatonin has analgesic effects through its actions on opiate receptors and has regulatory effects on serotonin metabolism. Altered secretory patterns and levels of melatonin have been found in various psychiatric disorders, such as unipolar and bipolar depression, seasonal affective disorder (SAD), bulimia, anorexia, schizophrenia, panic disorder, and obsessive-compulsive disorder. Although suppression of melatonin is not necessary for the efficacy of light therapy in SAD, melatonin can be a useful therapeutic agent in the treatment of circadian phase disorders, such as jet lag, and intake of melatonin increases the speed of falling asleep as well as its duration and quality. A number of synthetic melatonin-like drugs have recently been or are being developed as hypnotic agents.

ENDOGENOUS OPIOIDS

Since the discovery of endogenous opioid receptors and their endogenous ligands in the early 1970s, research into the possible behavioral roles of such compounds has grown at a rapid pace. At least three different receptor systems for these ligands have been identified (μ, δ, and κ), and each of these has subtypes. Opioid receptors μ, δ, and κ are activated by the endogenous ligands β-endorphin, enkephalins, and dynorphin, respectively, among others. σ-Receptors, originally included because some opioids that suppressed coughing acted on them, are no longer considered opioid receptors. β-Endorphin is the principal opioid peptide prototype and, like ACTH, MSH, and β-lipotropin, is derived from POMC. Methionine enkephalin (met-enkephalin) and leucine enkephalin (leu-enkephalin) are two small pentapeptides that also possess direct opioid activity, met-enkephalin being contained in POMC and another precursor, proenkephalin, and leu-enkephalin being contained in the prohormones proenkephalin and prodynorphin. The best-documented function of endogenous opiates is analgesia and alteration of pain perception, but effects on stress, appetite regulation, learning and memory, motor activity, and immune function also appear to be of physiologic importance. CRF and endogenous opioids also interact to coregulate the locus coeruleus, a role important in early adaptation to stress.

Early enthusiasm for the idea that a dysfunctional opiate system was etiologically related to schizophrenia has waned in the face of contradictory findings. Increases in various endorphin compounds have been reported in plasma as well as in postmortem brain tissue of patients with schizophrenia, but studies of short- and long-term treatment with opioid antagonists show no consistent or reproducible effects on psychopathology. However, hypersecretion of opioids in the CNS of patients with PTSD has been postulated to be an adaptive response to a traumatic experience, and CSF β-endorphin concentration is inversely related to intrusive and avoidant symptoms of PTSD. Naltrexone (Vivitrol; Revia), an opioid receptor antagonist, has decreased symptoms in autistic children and can improve functioning, with decreases in social withdrawal, stereotypy, and abnormal speech being directly related to decreases in β-endorphin levels.

In animal models, a number of stressors, including those that are purely psychological, induce opiate-mediated effects such as analgesia and hypomotility that are reversed by the opiate antagonist naloxone (Narcan). Several studies have found that concentrations of plasma β-endorphin in humans are correlated with measures of stress elicited by surgery, exercise, parachuting, or pain. Short-term administration of opioid agonists also increases eating, whereas antagonists reduce food intake by as much as 30%, diminish the intake of fats and highly palatable foods, and increase caloric expenditure. Thus far, however, their long-term use in obesity and eating disorders has not proven clinically useful. Some studies of opioid antagonist treatment have found certain binge parameters (e.g., duration) to be reduced in bulimia, but no studies have demonstrated weight loss in obese subjects. Naltrexone is helpful as an adjunct in the treatment of alcohol as well as opioid dependence, reducing drinking, craving, the high derived from drinking alcohol, and the likelihood that sampling alcohol would precipitate a relapse. In addition to the μ agonist methadone, buprenorphine, a partial μ agonist, has been helpful for opioid dependence, probably both because of its alleviation of withdrawal and because of its blockade of opioid-induced euphoria.

It is well known that exogenous opioids (e.g., heroin and morphine) can induce a euphoric mood state and that exercise increases the release of endogenous opioids and is associated with mood enhancement; these observations, together with findings that exercise-induced mood enhancement is blocked by naloxone, suggest that endogenous opioids are also involved in the mediation of mood. Such conclusions must be moderated, however, by the recognition that additional specific and nonspecific effects on other neurochemical systems are possible contributors to exercise-related mood effects.

HYPOTHALAMIC–PITUITARY–GONADAL AXIS

GnRH is a decapeptide that was sequenced and synthesized by Andrew Schally and colleagues in 1971. GnRH administration results in the rapid release of LH and FSH from the pituitary in healthy subjects and, in some pathologic states, such as acromegaly, an abnormal release of GH or prolactin. The cell bodies of GnRH are located principally over the optic chiasm in the arcuate area, with projections to the median eminence and in the lamina terminalis. GnRH release is stimulated by norepinephrine and is inhibited through negative feedback of gonadal steroids. Administration of GnRH can result in a depressive-like state, characterized by hot flashes, anxiety, insomnia, decreased libido, and fatigue in euthymic subjects, but it is not known whether this is a direct effect of the agent or is caused by the hypoestrogenic state that is produced when GnRH is given continuously. A GnRH analog has been found to have some efficacy in the treatment of paraphilia by decreasing testosterone.

The gonadal hormones (progesterone, androstenedione, testosterone, E_2, and others) are steroids that are secreted principally by the ovary and testis, but significant amounts of androgens arise from the adrenal cortex as well. The prostate gland and adipose tissue are also involved in the synthesis and storage of dihydrotestosterone and contribute to individual variance in sexual function and behavior.

The timing and presence of gonadal hormones play a critical role in the development of sexual dimorphisms in the brain. Developmentally, these hormones direct the organization of many sexually dimorphic CNS structures and functions, such as the size of the hypothalamic nuclei (INAH3) and corpus callosum, the neuronal density in the temporal cortex, the organization of language ability, and the responsiveness in Broca area. Women with congenital adrenal hyperplasia, a deficiency of the enzyme 21-hydroxylase leading to high exposure to adrenal androgens in pre- and postnatal life, have been found to be more aggressive and less interested in “traditional female roles” than female control subjects. Sexual dimorphisms may also reflect acute and reversible actions of relative steroid concentrations (e.g., higher estrogen levels transiently increase CNS sensitivity to serotonin). The importance of timing in the exposure to sex steroids is highlighted by studies of administration in gender identity disordered adults. These individuals perform on cognitive tests according to their physical gender and not to their perceived gender. Treatment with sex steroids produces substantial cross-sex changes but no changes in cognitive performance.

Testosterone

Testosterone is the primary androgenic steroid, having androgenic (i.e., facilitating male gonadal development) and anabolic (i.e., facilitating linear body growth and somatic growth) functions. Testosterone is important for sexual desire in men and women. In males, muscle mass and strength, sexual activity, desire, thoughts, and intensity of sexual feelings are dependent on normal testosterone levels, but these functions are not clearly augmented by supplementing testosterone in those with normal androgen levels. The addition of small amounts of testosterone to normal hormonal replacement in postmenopausal women has, however, proven to be as beneficial as its use in hypogonadal men. Testosterone has both genomic and nongenomic actions, including acting directly at the cell membrane or modulating the activity of other membrane receptors or second messengers, and regulating the actions of a wide range of neurotransmitters.

Testosterone administration has been shown to result in increased violence and aggression in animals, and testosterone level tends to be correlated with aggression in humans, but anecdotal reports of increased aggression with testosterone treatment have not been uniformly substantiated in human scientific investigations. Reports may be confounded by factors such as past history and social factors, which are particularly important determinants of the effects of hormones in primates and in humans. For instance, in the cynomolgus monkey, administration of testosterone increases dominant behavior in dominant monkeys and submissive behavior in submissive monkeys; in hypogonadal men, it improves mood and decreases irritability. Psychological tests such as the Point Subtraction Aggression Paradigm have been developed to measure aggression in a human laboratory setting and support the clinically observed association between increased testosterone and aggression, although personality characteristics are confounding factors. Free testosterone in the CSF has been associated with measures of aggression, sensation seeking and monotony avoidance, suspiciousness, and reduced socialization, and testosterone-induced aggression in mice has been associated with a decrease in brain allopregnanolone. Abnormal testosterone levels have been inconsistently reported in a variety of disorders, including schizophrenia, PTSD, depression, and anorexia. Studies of testosterone treatment in depression have generally been inconclusive, although two randomized, placebo-controlled trials found intramuscular (IM) therapy effective in eugonadal men with late-life depression and testosterone gel supplementation efficacious in refractory depression. Testosterone may play a role in pre-menstrual syndrome, as concentrations are higher in those with the disorder. Testosterone has also been reported to improve mood and fatigue in HIV-positive men. A recent trial in women with treatment-resistant depression, however, found no benefit.

Anabolic steroids are synthetic derivatives of testosterone modified to enhance their anabolic actions, such as muscle growth, rather than their androgenic actions. Varying effects of anabolic-androgenic steroids on a wide variety of moods have been noted anecdotally. In one prospective placebo-controlled study of anabolic-androgenic steroid administration in normal subjects, positive mood symptoms, including euphoria, increased energy, and sexual arousal were reported, in addition to increases in negative mood symptoms of irritability, mood swings, violent feelings, anger, and hostility. In addition to a variety of adverse physical effects, anabolic steroids can cause a variety of adverse psychiatric effects, including aggressive behavior, mood and psychotic disturbances, and psychological dependence, particularly when taken in high doses.

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) and DHEA-S are adrenal androgens secreted in response to ACTH and represent the most abundant circulating steroids. DHEA is also a neurosteroid that is synthesized in situ in the brain. DHEA has many physiologic effects, including a reduction in neuronal damage from glucocorticoid excess and oxidative stress. Behavioral interest has centered on its possible involvement in memory, mood, and a number of psychiatric disorders. *Adrenarche* is the prepubertal onset of adrenal production of DHEA-S and may play a role in human maturation by increasing the activity of the amygdala and hippocampus and promoting synaptogenesis in the cerebral cortex. DHEA has been shown to act as an excitatory neurosteroid and to enhance memory retention in mice, but studies of DHEA administration in humans have not consistently shown any improvement in cognition. Several trials of DHEA administration point to an improvement in well-being, mood, energy, libido, and functional status in depressed individuals. Administration of DHEA to women with adrenal insufficiency (e.g., Addison disease) has repeatedly been demonstrated to enhance mood, energy, and sexual function; effects in men remain to be assessed. Mood, fatigue, and libido improved in HIV-positive patients treated with DHEA in one study, and DHEA and DHEA-S have been found to be inversely correlated with the severity of attention deficit-hyperactivity disorder (ADHD). Women diagnosed with fibromyalgia have significantly decreased DHEA-S levels, but supplementation does not improve outcomes. Several cases of possible DHEA-induced mania have been reported, and DHEA has been reported to be inversely related to extrapyramidal symptoms (EPS) in schizophrenics treated with antipsychotics. DHEA administration in these cases improves EPS.

Double-blind treatment studies have shown antidepressant effects of DHEA in patients with major depression, midlife-onset dysthymia, and schizophrenia, although beneficial effects on memory have not been reliably demonstrated. A small, double-blind trial of DHEA treatment for Alzheimer disease failed to reveal significant benefit, although a near-significant improvement in cognitive function was seen after 3 months of treatment.

Animal studies suggest that DHEA may be involved in eating behavior, aggressiveness, and anxiety as well, with its effects resulting from its transformation into estrogen, testosterone, or androsterone from its antiglucocorticoid activity or from direct effects on $GABA_A$, n-methyl-D-aspartate (NMDA), and σ-receptors. Because of the putative antiglucocorticoid effects, the ratio of cortisol to DHEA levels may be particularly important in understanding adaptive responses to stress. Both cortisol and DHEA appear to be involved in fear conditioning, with the cortisol/DHEA ratio hypothesized to be an index of the degree to which an individual is buffered against the negative effects of stress. This ratio has been found to be related to some measures of psychopathology and response to treatment, predicting the persistence of the first episode of major depression and being related to the degree of depression, anxiety, and hostility in schizophrenics and response to antipsychotic treatment. PTSD patients have higher DHEA levels and lower cortisol/DHEA ratios related to symptom severity, suggesting a role in PTSD recovery. Fear-potentiated startle is larger in individuals with high as compared to low cortisol/DHEA-S ratios and is positively associated with cortisol and negatively with DHEA-S. Greater DHEA response to ACTH is related to lower PTSD ratings and the cortisol/DHEA ratio to negative mood symptoms. A genetic variation in an ACTH receptor promoter has been found to influence DHEA secretion in response to dexamethasone and may underlie some individual differences in stress response.

Estrogen and Progesterone

Sex differences in the prevalence or expression of psychopathology or response to treatment may be caused by differences in the concentrations of hormones or gender-related CNS differences in brain morphology and function. Mood and some other psychiatric disturbances are particularly likely to occur during times of sex hormone changes in women, such as the postpartum period, premenstrually, and perimenopause. The primary estrogens are estradiol (E_2), estrone (E_1), and estriol (E_3), with E_2 being the major secretory product of the ovaries. Two different estrogen receptors have been identified (α and β), each with different anatomical distributions and physiologic effects. Estrogens can influence neural activity in the hypothalamus and limbic system directly through the modulation of neuronal excitability and have complex multiphasic effects on nigrostriatal dopamine receptor sensitivity. Estrogens also enhance dopamine synthesis and release, modify basal firing rates, and can lead to stereotypical behavior in rodents. Accordingly, there is evidence that the antipsychotic effects of psychiatric drugs may change over the menstrual cycle and that the risk of tardive dyskinesia is partly dependent on estrogen concentrations. However, studies of symptom changes in schizophrenic women show significant differences for anxiety–depression and withdrawal–retardation subscales but not for psychotic subscales across the menstrual cycle. Nevertheless, lower levels of estrogen are associated with episodes of acute psychosis in both women and men and with more severe negative symptomatology as well as poorer cognitive function. Estrogen pretreatment attenuates anticholinergic drug-induced problems with attention.

Several studies have suggested that gonadal steroids modulate spatial cognition and verbal memory and are involved in impeding age-related neuronal degeneration. There is also some evidence that estrogen administration may decrease the risk and delay the onset of dementia of the Alzheimer type in postmenopausal women, but acute treatment in dementia has been ineffective in reducing symptoms.

Estrogen has mood-enhancing properties and can also increase sensitivity to serotonin, possibly by inhibiting MAO; in animal studies, long-term estrogen treatment results in a decrease in 5-HT_1 and an increase in 5-HT_2 receptors. In oophorectomized women, significant reductions in tritiated imipramine binding sites (which modulate presynaptic serotonin uptake) were restored with estrogen treatment. Severe postpartum depression has been successfully treated with sublingual 17-β-estradiol, as have depressive disorders in perimenopausal women in a large, randomized, double-blind trial. Prophylactic estrogen administration has been reported to prevent the recurrence of postpartum depression.

Associations between response to antidepressant treatment and age group in women have been found. Low-dose estrogen augmentation of antidepressant medication for perimenopausal women is reported to improve mood, and poorer response to selective serotonin releasing inhibitor (SSRI) treatment in older women can be eliminated by hormone replacement therapy. Inadequate response to SSRIs may be due to a chronic hypoestrogenic state, as serotonin receptor binding appears to be estrogen dependent. Tamoxifen (Nolvadex), a SERM used to treat breast cancer, showed beneficial effects on mania in one study. The greater sensitivity of women to certain kinds of stress may also be attributed in part to differences in tissue sensitivity. Brain norepinephrine system activation, for example, may be stronger in women because of the differential postsynaptic sensitivity of locus coeruleus neurons to CRH. Many of estrogen's psychiatric effects also could be mediated through its stimulation of brain-derived neurotrophic factor (BDNF) or NPY through the estrogen–BDNF–NPY cascade (see Neuropeptide Y).

Progesterone, the primary progestin, is produced by the corpus luteum of the ovary. Although progesterone itself may be anxiogenic, metabolites of progesterone (allopregnanolone and pregnenolone) appear to have anxiolytic and hypnotic properties via GABA_A agonistic activity. Progesterone is colocalized with serotonin in cells of the median raphe and causes increased serotonin uptake and turnover in the brain in several species. Progesterone, which has antiestrogen effects, such as downregulating estrogen receptors and increasing MAO activity, is often associated with dysphoric mood. The ratio of progestin to estrogen in oral contraceptives has been associated with negative mood change, although this effect varies with depression history, and meta-analyses have not shown a clear increase in depressive symptoms with contraceptive use overall. Independently, progesterone interactions with dopamine have been hypothesized as serving a possible etiologic role in schizophrenia.

The association of these hormones with serotonin is hypothetically relevant to mood change in premenstrual and postpartum mood disturbances. Women with a history of depression have higher FSH and LH and lower E_2 levels and are at risk of beginning perimenopause at a younger age. Similarly, the 2:1 female-to-male ratio in depression prevalence may speculatively be related to the rapid changes in hormone levels in menarche. Premenstrual dysphoric disorder is a disorder in which a constellation of symptoms resembling MDD (in some respects) occurs in most menstrual cycles, appearing in the luteal phase and disappearing within a few days of the onset of menses. No definitive abnormalities in estrogen or progesterone levels have been demonstrated in women with premenstrual dysphoric disorder, but decreased serotonin uptake with premenstrual decreases in steroid levels have been correlated with the severity of symptoms in some studies. Progesterone downregulates the estrogen receptor, and it has been suggested that, despite high circulating concentrations of estrogen, the luteal phase is a period of functional estrogen withdrawal, with concomitant effects on the serotonergic system. Recent evidence indicates that the abrupt decline of progesterone and allopregnanolone in the luteal phase results in increased production of the α_4 subunit of $GABA_A$ and changes in receptor sensitivity that could account for the typical behavioral symptoms noted. This effect is correlated with the insensitivity of the GABA receptor to modulation by the benzodiazepine class of tranquilizers (and hence is anxiogenic). SSRIs, particularly fluoxetine (Prozac), have demonstrated efficacy, and as many as 50% of women may respond to fluoxetine administered only in the second half of each cycle. Alprazolam (Xanax), a $GABA_A$ agonist, has been found to be more effective than placebo in several studies for the treatment of premenstrual dysphoric disorder. In women with severe symptoms that are not responsive to these treatments, the long-term use of a GnRH agonist to abolish menstrual cycling with added estrogen–progestin may be therapeutic.

The menstrual phase also has been associated with aspects of substance abuse. Although reports vary, craving for cigarettes and tobacco withdrawal appears to vary with the menstrual phase (worse in the luteal phase). Women show greater heart rate and pleasurable drug effects after cocaine administration during the follicular phase but report that cocaine improves dysphoric mood during the luteal phase.

The bulk of the psychological symptoms associated with menopause is actually reported during perimenopause rather than after the complete cessation of menses. Reported symptoms include worry, fatigue, crying spells, mood swings, diminished ability to cope, and diminished libido or intensity of orgasm. Estrogen replacement alone may be beneficial, but combination androgen–estrogen replacement may be superior for reinstating energy, a sense of well-being, and libido. In women with an intact uterus, the addition of progestin is necessary to protect against endometrial hyperplasia but can attenuate the beneficial effects of estrogen on mood.

The postpartum period appears to be a particularly risky time for the emergence or relapse of psychiatric illnesses. Women with bipolar disorder appear to be particularly sensitive to alterations in gonadal steroid levels. A high risk of relapse during the postpartum period has been observed and appears to be maintained over subsequent pregnancies; evidence for a familial preponderance of the puerperal trigger also exists, suggesting a genetic contribution. During pregnancy, a number of mechanisms play a role in dampening the response to stress in order to promote maternal care and the survival of the offspring. Hormones such as oxytocin and prolactin produce inhibitory effects on the HPA axis, decreased excitatory activity, and a more positive mood state. The reversal of many of these effects may contribute to the vulnerability of women to postpartum psychiatric illnesses. Lactation has the potential to dampen some postpartum changes and has been associated with decreased maternal postpartum depression.

PREGNENOLONE AND ALLOPREGNANOLONE

Neuroactive steroids, such as pregnenolone and allopregnanolone (allo), modulate activity at GABA_A, NMDA, σ-1, 5-HT_3, nicotinic, kainate, oxytocin, and glycine receptors, among others. Pregnenolone is a neurosteroid synthesized from cholesterol in the brain and is partially metabolized to all subsequent steroids. It, and especially its sulfate, pregnenolone sulfate, appear to have memory-enhancing properties in animal studies. Pregnenolone increases the rate and extent of the formation of microtubules, which are important in neuronal plasticity and function. Progesterone counteracts this effect. Pregnenolone sulfate is an excitatory neurosteroid and has GABA inhibitory effects.

Allo is a neurosteroid derived from progesterone with high concentrations in the CNS. It acts as a $GABA_A$ receptor agonist, decreases CRH concentrations in the hypothalamus, and reduces the anxiety evoked by CRH in rats. Testosterone-induced aggression in mice is thought to be mediated by downregulation in allo, and normalization of allo with progesterone and estrogen prevents aggression. SSRIs increase brain allo levels in rodents. Social isolation also downregulates allo and increases aggression. Fluoxetine reduces both allo downregulation and aggression. CSF levels of allo in humans have been correlated with clinical improvement over the first 8 to 10 weeks of SSRI treatment, an effect that appears to be independent of the serotonin reuptake inhibition. Allo increases in response to ethanol administration and may play a role in ethanol withdrawal through modulation of $GABA_A$. Administration of allo also has been shown to reduce anxiety and hyperlocomotion associated with benzodiazepine withdrawal in animals. Allo is currently unavailable for clinical use, but studies have already commenced on clinical treatment with allo or with related compounds. Brexanolone is an FDA-approved neurosteroid analog that has been shown to have efficacy in the treatment of moderate to severe postpartum depression, although utilization has been limited by its expense and the need to be administered through infusion.

PROLACTIN

Since its identification in 1970, the anterior pituitary hormone prolactin has been examined as a potential index of dopamine activity, dopamine receptor sensitivity, and antipsychotic drug concentration in studies of CNS function in psychiatric patients and as a correlate of stress responsivity. Prolactin signaling is mediated by the transmembrane prolactin receptor, PRL-R, which is expressed in a wide variety of tissues. The secretion of prolactin is under direct inhibitory regulation by dopamine neurons located in the tuberoinfundibular section of the hypothalamus and is, therefore, increased by classical antipsychotic medications. Prolactin also inhibits its own secretion by means of a short-loop feedback circuit to the hypothalamus. In addition, a great number of prolactin-releasing or -modifying factors have been identified, including estrogen, serotonin (particularly through the 5-HT_2 and 5-HT_3 receptors), norepinephrine, opioids, TRH, T_4, histamine, glutamate, cortisol, CRH, and oxytocin, with interaction effects possible. For example, estrogen may promote the serotonin-stimulated release of prolactin.

Prolactin is primarily involved in reproductive functions but also in weight and metabolism control. During maturation, prolactin secretion participates in gonadal development, whereas, in adults, prolactin contributes to the regulation of the behavioral aspects of reproduction and infant care, including estrogen-dependent sexual receptivity and breastfeeding. In female rats, prolactin secretion is strongly stimulated with exposure to pups. In women, basal prolactin levels are elevated in the postpartum period before weaning, and prolactin release is stimulated by suckling. Hyperprolactinemia is associated with low testosterone in men and reduced libido in men and women. In rodents, prolactin is increased along with corticosterone in response to such stressful stimuli as immobilization, hypoglycemia, surgery, and cold exposure and may be specifically associated with the use of passive coping in the face of a stressor. Prolactin promotes various stress-related behaviors in rats, depending on the condition, such as increasing object-directed exploration while decreasing other exploration.

Hyperprolactinemic patients often complain of depression, decreased libido, stress intolerance, anxiety, and increased irritability. These behavioral symptoms usually resolve in parallel with decrements in serum prolactin when surgical or pharmacologic treatments are used. In psychotic patients, prolactin concentrations and prolactin-related sexual disturbances have been positively correlated with the severity of tardive dyskinesia. Prolactin levels are also positively correlated with negative symptoms.

HYPOTHALAMIC–PITUITARY–THYROID AXIS

Thyroid hormones are involved in the regulation of nearly every organ system, particularly those integral to the metabolism of food and the regulation of temperature, and are responsible for the optimal development and function of all body tissues. Moreover, rates of secretion and metabolism of all other major hormones (cortisol, gonadal hormones, and insulin) and catecholamines depend on thyroid status. The thyroid gland secretes two thyroid hormones: T_3 and T_4. T_3 is the more potent of the two, and most of the T_3 circulating in the blood is created by the peripheral metabolism of T_4. The brain relies on its own conversion of T_4 to T_3 rather than on circulating T_3. The hypothalamus secretes TRH into the capillaries of the pituitary portal venous system, and the pituitary responds with the synthesis and secretion of TSH, which stimulates thyroid cells. Negative feedback regulation occurs when T_3 and T_4 act in the pituitary and hypothalamus to inhibit TSH and TRH, respectively. Finally, a corticotropin-release–inhibiting factor (CRIF) has been identified in the rat that inhibits the synthesis and secretion of ACTH. This peptide, prepro-TRH 178–199, is derived from the prohormone TRH and may play a role in integrating the regulation of the HPA and HPT axes. The expression of genes that encode for thyroid hormone receptors, such as TRα and TRβ*,* plays a major role in the regulation of neuronal differentiation and the action of immediate early genes. As in the case of steroids, thyroid hormones regulate the transcription of a variety of genes through binding to thyroid response elements (TREs) in regulatory sequence elements and may also be critical to understanding sex-dependent neuronal signaling.

There is general agreement that central noradrenergic systems are primarily stimulatory to TSH secretion and that central dopamine neurons inhibit TSH release. Thyroid hormones, in turn, are important regulators of central adrenoceptor function, generally decreasing presynaptic noradrenaline release and increasing postsynaptic β-adrenergic receptor number. Hypothyroidism is conversely associated with a decreased β-receptor number. Changes in serotonin function are also apparent, with T_3 increasing 5-HT in the frontal cortex and inducing downregulation of 5-HT_{1A} autoreceptors. These changes in neurotransmitter release and receptors in response to thyroid hormones parallel the alteration in α- and β-receptor sensitivity associated with pharmacologic and electroconvulsive antidepressant treatments and may explain the therapeutic efficacy of supplemental thyroid hormone in treatment-resistant depression. Alternatively, the therapeutic benefit may be secondary to the alteration of gene expression and remodeling of synaptic connectivity. In addition to its prime endocrine function, TRH has direct effects on neuronal excitability, behavior, and neurotransmitter regulation, particularly on central cholinergic systems located in the septohippocampal band and on mesolimbic and nigrostriatal dopamine systems. In lower animals, TRH possesses mild stimulant properties. Initial reports of its mood-elevating effects in healthy human subjects led to a number of projects investigating its short- and long-term antidepressant effects in clinical populations. Despite some initial enthusiasm, the degree of mood alteration does not seem to be great, nor is its occurrence reliable.

Given these observations, it is not surprising that alterations in behavioral function have been observed in patients with primary thyroid gland dysfunction, beginning with the earliest reports in the medical literature. It has been noted that thyroid disorders may induce virtually any psychiatric symptom or syndrome, although regular associations of specific syndromes and thyroid conditions are not consistently found. Hyperthyroidism is commonly associated with fatigue, irritability, insomnia, anxiety, restlessness, weight loss, and emotional lability; marked impairment in concentration and memory may also be evident. Such states can progress into delirium or mania, or they can be episodic in nature. On occasion, a true psychosis develops, with paranoia being a particularly common presenting feature. In some cases, psychomotor retardation, apathy, and withdrawal rather than agitation and anxiety are the presenting features. Symptoms of mania also have been reported after rapid normalization of thyroid status in hypothyroid individuals and may covary with thyroid levels in individuals with episodic endocrine dysfunction. In general, behavioral abnormalities resolve with normalization of thyroid function and are responsive symptomatically to traditional psychopharmacologic regimens. Long-term residual complaints of fatigue, cognitive impairment, and emotional distress have been reported in some individuals even after remission of the precipitating thyroid dysfunction, and there is evidence for an increased risk of dementia over time. Caution should be exerted, however, regarding the use of MAOIs or tricyclic antidepressant (TCA) medications in hyperthyroid states because of possible synergistic cardiotoxicity. In several case reports, haloperidol (Haldol) has been linked to increasing thyrotoxicity, and hyperthyroidism has been associated with an enhancement of the neurotoxic effects of antipsychotic medications.

The psychiatric symptoms of chronic hypothyroidism are generally well recognized. Most classically, fatigue, decreased libido, memory impairment, and irritability are noted, but a true secondary psychotic disorder or dementia-like state also can develop. In milder, subclinical states of hypothyroidism, the absence of gross signs accompanying endocrine dysfunction may result in its being overlooked as a possible cause of a mental disorder. Accordingly, the evaluation of the basal TSH concentration or the TSH response to TRH infusion is necessary to arrive at the proper diagnosis. Hypothyroidism impairs neurogenesis in the hippocampus, and this impairment is associated with rat models of depression. Thyroid hormone administration corrects the impairment and reverses the depression.

A blunted response of TSH to TRH infusion has been found in a significant percentage of patients with a variety of disorders, including eating disorders, panic disorder, alcoholism, schizophrenia, and, most commonly, MDD, and probably reflects a transient hyperthyroxinemia. No evidence of TRH hypersecretion has been shown. Large-scale studies suggest that such subjects are, in fact, euthyroid, and the predictive sensitivity of the test is low. Thyroid autoimmunity may play a role in some psychiatric illnesses. Antithyroid antibodies are found more frequently in women with depression than in control subjects and in patients with bipolar disorder and may contribute to relative treatment resistance as well as to postpartum behavioral disturbance. The frequency of thyroid antibodies may also be higher in certain nonpsychiatric diseases with prominent psychiatric symptoms, such as fibromyalgia and rheumatoid arthritis. Patients with major depression also have been found to have low levels of CSF transthyretin, a protein involved in thyroid transport. Basal T_3 level has been inversely related to time to episode recurrence, and basal TSH positively correlated with the overall severity of depressed mood in an unselected inpatient population. Depressed patients who show an improvement in mood after one night of sleep deprivation also appear to have lower T_3 uptake at baseline and greater nocturnal TSH release. Thyroid receptor alterations can produce symptoms of ADHD in animals, and genetic resistance to thyroid hormone has been associated with ADHD symptoms in humans. Thyroid receptor coactivators also may play a role in increased vulnerability to a number of psychiatric disorders, including depression and psychosis.

Most antidepressant therapies have some influence on thyroid concentrations at baseline; T_4 and T_3 concentrations have been correlated with antidepressant response, as have antidepressant-induced changes in thyroid hormones as well as changes induced by electroconvulsive therapy (ECT). Lithium increases antithyroid antibodies and inhibits iodine uptake into the thyroid, iodination of tyrosine, the release of T_3 and T_4 from the thyroid, and peripheral breakdown of thyroid hormones. It also regulates *TR* gene expression, blocks the thyroid-stimulating effects of TSH through interference with adenylate cyclase, and may, in certain circumstances, precipitate rebound thyrotoxicosis. Approximately 30% of patients receiving lithium have an elevated TSH level during treatment, and approximately one-sixth of these patients go on to develop frank hypothyroidism. Attention to subtle alteration in thyroid status induced by lithium treatment is important in the clinical evaluation of symptomatic complaints, such as fatigue, memory impairment, and anhedonia; a specific association between lower serum T_4 and mood instability during lithium maintenance suggests even subclinical changes may be clinically relevant. Carbamazepine, an anticonvulsant shown to have antimanic properties akin to lithium, also decreases peripheral thyroid hormone concentrations while increasing TSH. Administration of T_3 accelerates clinical response to TCAs and is sometimes helpful in patients with treatment-resistant depression, whereas adjunctive T_4 contributes to decreasing cycling in patients with rapid-cycling bipolar I disorder. Supraphysiologic dosing is sometimes required, with 200 to 500 μg per day being given as an adjunct in treatment-resistant depression and intractable bipolar disorder. Administration of mirtazapine (Remeron), a mixed-action antidepressant, increases free T_3 levels and decreases free T_4. Higher T_3 concentrations predicted improvements in depression in one study.

PARATHYROID HORMONE

Parathyroid hormone (PTH) was originally isolated as an endocrine factor having effects on bone, gut, and kidney and contributing to calcium and phosphorus homeostasis. However, the frequent and often profound neuropsychiatric changes that can result from altered parathyroid gland function are consistent with other central actions of PTH that have been described in recent years. Hyperparathyroidism can cause lethargy, stupor, coma, depression, delirium, psychosis, primarily visual hallucinations, or anxiety. Hypoparathyroidism can cause cognitive impairment, psychosis, depression, or anxiety by alterations in calcium and magnesium levels. PTH administration can impair the active uptake and release of norepinephrine and dopamine and result in adrenergic-like effects (not blocked by β-adrenergic antagonists), learning and memory problems, and a state of hyperalgesia.

Lithium treatment can raise the concentrations of serum calcium and may increase PTH over a period of months to years by direct stimulation of PTH secretion and through a shift in the set point for inhibition of PTH secretion by calcium. When such effects are associated with somatic or behavioral changes, discontinuation of lithium should result in rapid symptomatic improvement. When this does not happen, a parathyroid adenoma is sometimes discovered fortuitously. Primary hyperparathyroidism most commonly occurs secondary to a single parathyroid adenoma, the removal of which almost invariably results in lysis of behavioral symptoms, regardless of severity or chronicity. Animal studies suggest that long-term lithium administration can stimulate the development of extant parathyroid tumors but does not induce tumors in normal parathyroid tissue. Thus, reinstitution of lithium treatment after surgical removal of the tumor should be possible.

GROWTH HORMONE

Somatotropin or GH, a hormone required for normal growth, is synthesized and released by the anterior pituitary gland. Dopamine, serotonin acting at the 5-HT$_{1D}$ receptor, and norepinephrine acting at the α_2-adrenergic receptor appear to play a role in its release. GH acutely stimulates lipolysis and ketogenesis, which are important in the adaptation to stress, and prevents hypoglycemia. Most psychiatric studies of the regulation of GH have used strategies similar to those described for prolactin. Accordingly, studies of GH response to various provocative stimuli, such as GHRH or psychotherapeutic drugs, have been seen as a means to evaluate central neurotransmitter function. Augmentation of GH secretion in response to GHRH, LH-releasing hormone (LHRH), or TRH in patients with schizophrenia or dementia of the Alzheimer type has been interpreted as reflecting an alteration in catecholamine and, possibly, prostaglandin regulation, which facilitate the secretion of human GH. In general, however, there is a large variation in GH response to GHRH; a blunted response has been variably linked to the length of illness, presence of negative symptoms, and platelet MAO activity, but the validity of the conclusions drawn from this test is controversial.

The stress responsiveness of somatotrophs is well established but species dependent, with increases in circulating GH noted in humans and inhibition of secretion noted in rodents. In humans, the direction of the GH stress response may depend on the persistence of the stressor. GH appears to be relatively more responsive to exercise and hypoglycemic stress than to psychological stress. However, GH has been reported to increase in response to psychological stress in anxious subjects, perhaps due to hyperactivity of the noradrenergic system. Case reports have documented reversible GH deficiencies and marked growth retardation and delay of puberty secondary to a stressful experience. Administration of GH to individuals with GH deficiency has a beneficial effect on cognitive function in addition to its more obvious somatic effects. A significant proportion of adult-onset patients with GH deficiency are depressed, and GH therapy significantly improves their depression scores. Some prepubertal as well as adult patients with diagnoses of MDD show hyposecretion of GHRH during an insulin tolerance test, a deficit that has been interpreted as reflecting alterations in cholinergic and serotonergic mechanisms. Blunted response to 5-HT_{1D} agonists also has been found. Panic disorder patients may have a blunted GH response to clonidine (Catapres), an α_2-adrenergic agonist, that does not normalize with antidepressant treatment. A number of GH abnormalities also have been noted in patients with anorexia nervosa, but secondary factors, such as weight loss, may be responsible for alterations in endocrine release in depression and eating disorders. At least one study has reported that GHRH stimulates food consumption in patients with anorexia nervosa and attenuates elevated food consumption in patients with bulimia. Administration of GH to elderly men results in an increase in lean body mass, but controlled trials have been unable to replicate anecdotal reports of improved mental clarity, muscle strength, or vigor. Recent evidence indicates that a novel GH secretagogue (GHS), ghrelin, may represent an important alternative regulatory influence over food intake and sleep patterns.

Many GHS can be administered orally, in contrast to GH, which must be injected on a daily basis. In addition, they may be used to fine-tune body concentrations in a way that daily injections cannot. GHB, a potent GHS, has been used to mimic the physiologic secretory pattern of GH and as a way to increase SWS in patients with fibromyalgia and, secondarily, to a reduction in pain and fatigue. The use of the GHS GHB also has been used by bodybuilders as a way of increasing muscle mass, but respiratory depression and sedation, and dependence with severe withdrawal effects may result.

SOMATOSTATIN

Somatostatin (SRIF) is a hypothalamic tetradecapeptide that is located principally in the nerve endings of the median eminence and in neurosecretory neurons located in the PVN. SRIF inhibits the anterior pituitary secretion of ACTH, thyrotropin, GH, and prolactin, alters the release of catecholamine neurotransmitters, and stimulates serotonin release. A number of receptor subtypes have been cloned, and receptor-specific ligands have been developed. SRIF was so named because of its action in inhibiting the release of immunoreactive GH, a function that is subserved by SRIF-2 receptors.

In rats, SRIF delays the extinction of active avoidance behavior and antagonizes amnesia induced by electric shock. Alterations in the concentration of SRIF have been associated with a number of conditions in which cognitive dysfunction is present, including Huntington disease, Parkinson disease, multiple sclerosis, and Alzheimer disease. Decreases in SRIF are highly correlated with decreases in acetylcholinesterase, suggesting a close relationship between the cholinergic and somatostatinergic systems. Decreased concentrations of SRIF in the CSF are inconsistently found in patients with depression, and central injection of SRIF in rats causes decreased slow-wave and rapid-eye movement sleep, altered appetite, and locomotor activity, impaired cognition, and decreased sensitivity to pain. Early stressful experiences also have been related to sustained elevations of CRH and somatostatin in the CSF of adult primates. Altered somatostatin concentrations have been reported in a number of other illnesses and with treatment, but the physiologic relevance of these changes is still unclear. Somatostatin receptors 2 and 4 have been specifically implicated in SUDs.

ARGININE VASOPRESSIN

AVP (or antidiuretic hormone [ADH]) is a posterior pituitary hormone that maintains plasma osmolarity through the regulation of renal water excretion and stimulates hepatic glycogenolysis. AVP release is triggered by pain, emotional stress, dehydration, increased plasma osmolarity, or decreases in blood volume and acts synergistically with CRH to control ACTH release. AVP potentiates the stimulatory effect of CRF. An AVP receptor antagonist blocks ACTH release, norepinephrine release, and hyperthermic response to stress and attenuates some stress-related behaviors. AVP receptor blockade does not impair motor or cognitive processes or produce tolerance, as do many other anxiolytics.

Animal and normal human studies of AVP administration (or longer-acting synthetic analog compounds) have indicated that the hormone may enhance the consolidation and retrieval of memory, particularly that associated with aversive learning. AVP has been shown to prevent the loss of tolerance to the incoordinating, sedative–hypnotic, and hypothermic effects of alcohol after cessation of ingestion and to delay the loss of sexual behavior after castration.

Altered AVP function has been reported in depression and in eating disorders. Anorexic and bulimic patients show hypersecretion of centrally directed AVP, and patients with bulimia nervosa or depression may have an attenuated AVP response to hypertonic saline. Vasopressin delays the extinction of behaviors acquired during aversive conditioning and may be related to an obsessional preoccupation with the aversive consequences of eating and weight gain. An inverse relationship between AVP concentration and motor activity in depression and an increased number of vasopressin and oxytocin neurons also have been reported in the hypothalamus of depressed patients. Although dexamethasone suppression of ACTH and cortisol release is attenuated in depressed patients, suppression of ACTH and cortisol release in response to vasopressin is not.

Profound alterations in fluid ingestion and excretion have been observed in psychiatric patients. Polydipsia occurs in 10% to 15% of hospitalized psychiatric patients and is unrelated to diagnosis; in many cases, the syndrome is secondary to inappropriate secretion of AVP, which occurs as a feature of the altered behavioral state itself and resolves with treatment or, conversely, is precipitated by a variety of antidepressant or antipsychotic agents. In contrast, fluoxetine treatment for depression decreases the CSF vasopressin levels. Alprazolam, an inhibitor of CRH secretion, inhibits the vasopressin-stimulated release of ACTH and cortisol.

Several subtypes of AVP receptors and been discovered, including $V_{1a}R$, $V_{1b}R$, and V_2R. $V_{1a}R$ knockout (KO) mice show impairments in spatial learning, and both $V_{1a}R$ and $V_{1b}R$ KO mice show impairments in prepulse inhibition and social behavior. AVP $V_{1a}R$ KO mice have reduced social recognition. With transgenic technology, this gene, when introduced into the nonmonogamous mouse, increased a behavior associated with monogamy. AVP antagonists prevent bonding in the monogamous prairie vole. Animal studies show that centrally released AVP produces anxiogenic and depression-like actions, including generating passive coping strategies in stressful situations. That AVP modulates the stress response is shown by the ability of the $V_{1a/b}$ receptor antagonist to normalize the usually abnormal dexamethasone–CRH test in rats bred for high anxiety (HAB). Serotonin increases the release of AVP, but SSRIs reduce AVP secretion or normalize AVP overactivity in HAB rats, resulting in the normalization of the dexamethasone–CRH test and less depression-like behavior in response to stress. Animal studies of the role of AVP in social behavior suggest that receptor variations may be involved in such disorders as schizophrenia and autism. In fact, several studies have found an association between an AVP receptor gene and autism and social behavior in a nonclinical population.

OXYTOCIN

Oxytocin is a posterior pituitary hormone that is involved in osmoregulation, the milk ejection reflex, food intake, and female maternal and sexual behaviors and has many effects reciprocal to those of vasopressin. Convergent evidence, using a range of methodologies, indicates that oxytocin inhibits food and sodium intake. Oxytocin binding in the hypothalamus is increased by estrogen and glucocorticoids and in estrogen-primed women. Oxytocin also can act as a neuromodulator of limbic dopamine concentrations and thus may be involved in the adaptation to substances of abuse, and it can act as a mediator of the effect of CRH on ACTH. Oxytocin has anxiolytic activity.

Many of oxytocin's behavioral effects are affiliative, and it promotes a variety of reproductive (grooming, arousal, lordosis, orgasm, nesting, and birthing) and maternal behaviors (breastfeeding and mother–infant bonding). Infusion of oxytocin in female subjects of monogamous species facilitates pair bonding in the absence of mating, and administration of an oxytocin antagonist prevents pair bonding. It has been called the *amnestic neuropeptide* owing to its ability to attenuate memory consolidation and retrieval. Patients with autism and anorexia have been reported to have reduced levels of oxytocin, but depressed patients do not differ from healthy controls in basal levels. Autistic children also do not show the expected increase in oxytocin with age. In adults with autism, oxytocin infusion reduces repetitive behaviors. In one animal study, chronic administration of phencyclidine (PCP), which lowers hypothalamic oxytocin, also decreased social interaction. An association between an oxytocin receptor gene and autism has recently been identified. Oxytocin interacts with the mesolimbic dopamine system and is believed to facilitate the acquisition of drug use disorders, particularly of some of the "party drugs," such as 3,4 methylenedioxymethamphetamine and gamma hydroxybutyrate (GHB), which are often used to promote social behavior. Variants in the oxytocin receptor gene, particularly rs53576, have been shown to correlate with measures of empathy and exogenous administration of oxytocin to increase affiliative behavior in humans.

NEUROPEPTIDE Y

NPY is closely linked with stress response and with the action of a number of steroid hormones. NPY is widely distributed throughout the CNS and is one of the most conserved peptides in evolution, suggesting an important role in the regulation of basic physiologic functions, including learning and memory. NPY and NPY-related peptides bind to at least five receptors, which are widely distributed but relatively concentrated in the hypothalamus, the hippocampus, and several other limbic regions. NPY is synthesized in the arcuate nucleus of the hypothalamus. Immunoreactive NPY is found in the serotonin-containing raphe nucleus, and it has been implicated in the modulation of emotional processing. Marijuana use appears to elevate the expression of NPY-1 receptor mRNA levels, perhaps explaining some of the drug's effects. NPY has been found to increase feeding, particularly carbohydrate ingestion, and to counteract leptin effects in a variety of animal models, possibly through its effects on inhibition of fear and anxiety circuits. It has a mutually inhibitory relationship with insulin, and its release is stimulated by stress and corticosteroids and associated with norepinephrine release.

NPY has been studied for its potential anxiolytic, antinociceptive, antihypertensive, and memory-enhancing effects and for a possible role in seizure disorders, schizophrenia, and depression. Treatments for depression, such as some antidepressants, lithium (Eskalith), and ECT, increase NPY concentrations in a number of brain areas in rats, while significantly low levels of NPY have been found in the temporal cortices of patients with schizophrenia. Greater NPY release during stress is associated with less psychological distress in humans and the modulation of the activity of GABAergic neurons. Neuroactive steroids, in turn, regulate NPY transmission. NPY appears to influence alcohol consumption and alcohol and morphine withdrawal effects. Reduced levels of NPY are found in discrete brain regions of alcohol-preferring rats, and polymorphisms of the NPY gene are associated with alcohol dependence and with alcohol withdrawal seizures in humans. Polymorphisms in the genes for the NPY peptide and for a promoter region also have been found to be associated with depression in some individuals.

GALANIN

Galanin is a 29 amino acid inhibitory peptide that is stimulated in a coordinated fashion with gonadal steroid release. Its documented actions include increased release of GH and inhibition of insulin release, locus coeruleus noradrenergic firing, and acetylcholine release, as well as impairment of memory, control of food intake, nociception, energy expenditure, and the mediation of some emotional responses. Studies are underway using galanin receptor agonists and antagonists and galanin receptor KO mice to explore its role in mediating anxiety- and depression-related behavior and in decreasing opiate withdrawal and drug dependence overall. Inhibition of GALR1 and GALR3 and activation of GALR2 appear to attenuate depressive symptoms, suggesting galanin as a possible novel antidepressant drug target. Spexin and kisspeptin share an ancestral origin with galanin and may be similarly involved in emotion and pain regulation, as well as in energy homeostasis.

INSULIN

Insulin is a protein hormone secreted by the β cells of the pancreas in response to elevations of glucose and amino acids; insulin receptors occur in high density in the hippocampus and are believed to help neurons to metabolize glucose by controlling the transport across cell membranes. Some atypical antipsychotics impair response to insulin and raise blood glucose, increasing the risk of developing diabetes (see Metabolic Syndrome). Psychotic stress itself may impair insulin sensitivity. Those antidepressants that predominantly increase catecholamine activity, such as many of the TCAs, also reduce sensitivity to insulin. Those that increase serotonergic function, such as the SSRIs, increase sensitivity to insulin and are preferred in the treatment of depression comorbid with diabetes. However, insulin may play a more active role in psychiatric symptoms as increasing evidence indicates that insulin may be integrally involved in learning, memory, and mood. Depression is frequent in patients with diabetes, as are indices of impaired hormonal response to stress, but it is not known whether these findings represent direct effects of the disease or are secondary, nonspecific effects. Higher fasting insulin levels also have been associated with better psychopathology scores in schizophrenic patients.

LEPTIN/GHRELIN/GLUCAGON-LIKE PEPTIDE

Leptin is a protein hormone synthesized and secreted in a pulsatile fashion by adipose tissue and involved in the regulation of food intake. Obesity is associated with leptin resistance, principally its metabolic actions, because sympathetic effects are preserved. Leptin also affects the HPG axis, inhibits insulin-induced steroidogenesis and human chorionic gonadotropin-induced testosterone secretion, and may play a role in menstruation, pregnancy, lactation, puberty, and amenorrhea due to weight loss in anorexia nervosa. Leptin stimulates hematopoiesis, T-cell activation, phagocytosis, and cytokine production and decreases susceptibility to infection. Mediators of leptin action include orexigenic neuropeptides, such as NPY, galanin, and galanin-like peptide, melanin-concentrating hormone (MCH), and anorexigenic neuropeptides, such as CRH and α-MSH hormone, as well as gut microbiota. Weight gain produced by some atypical antipsychotics may be mediated in part through increases in leptin. Patients with major depression have lower leptin levels, and these levels are inversely correlated with depression severity. However, higher leptin levels have been found in subjects exposed to trauma with hyperarousal, and these levels are related to hypervigilance. Because these relationships were correlations, the causal relationship is not known. Increased leptin may be an attempt at adaptation, as postulated for changes in opioids and neuroactive steroids in PTSD.

Ghrelin is an orexigenic peptide released in the stomach that is involved in energy regulation. Studies have shown that its release is sensitive to a number of physical and psychological stresses and, as such, may modulate coping mechanisms and central reward pathways through brain-mediated receptor signaling. Increased blood levels have been reported in both restricting and binge-eating/purging subtypes of anorexia nervosa.

Glucagon-like peptide (GLP-1) is another gut peptide involved in appetite suppression that has also shown some effects on central control of stress response and emotional regulation.

CHOLECYSTOKININ

Cholecystokinin (CCK) is a peptide neurotransmitter originally isolated from the gut. In addition to its presence in the pancreas and the gastrointestinal (GI) tract, CCK is found in high concentrations in the cerebral cortex, limbic system, and hypothalamus. CCK is involved in the regulation of such behavioral functions as inhibition of intake of solid and liquid food, production of satiety, pain relief (probably from modulation of the endogenous opioid system), cardiovascular and respiratory function, neurotoxicity, and seizures, sexual and reproductive behaviors, and memory. Of the two identified receptor subtypes, CCK type A (CCK-A) is found primarily in the periphery and in some discrete brain areas, whereas CCK type B (CCK-B) is plentiful in the brain. The primary form of CCK, CCK-8S (a sulfated octapeptide), coexists with dopamine in the VTA and substantia nigra, and its interactions with dopamine are context and location specific. CCK stimulates the synthesis of NGF and plays a neuroprotective role. CCK also modulates HPA activity.

Of particular interest to psychiatry is the colocalization of CCK with dopamine in mesolimbic and mesocortical, but not in nigrostriatal systems. CCK contributes to the modulation of dopamine-mediated behavior and might be dysregulated in psychiatric syndromes thought to involve altered dopamine transmission. CCK-A receptor antagonists have been proposed for the treatment of schizophrenia, and initial evidence suggests that CCK agonists may be useful for decreasing the severity of parkinsonian symptoms. Cerulein, a mixed CCK-A and CCK-B agonist has weak, neuroleptic-like effects on prepulse inhibition in schizophrenic patients. Evidence is stronger for a role of CCK-B receptor antagonists in the treatment of anxiety. CCK has anxiogenic effects in some animal models, and several small-scale human studies have demonstrated that the administration of CCK-4 or pentagastrin can induce panic attacks and can increase neurosteroid release in a significant percentage of healthy volunteers as well as in anxiety disorder patients, even in the absence of arousal or environmental stress. Panic attacks in subjects with preexisting panic disorder can be elicited at doses of CCK-4 that do not reliably induce panic in healthy subjects, indicating enhanced sensitivity. Not only can selective CCK-B antagonists completely abolish the anxiogenic effects of CCK-4, but in an animal model of anxiety used to evaluate the efficacy of benzodiazepines, CCK-B antagonists also demonstrated independent anxiolytic properties. However, CCK overactivity may be involved in submissive behavior in animal models, and CCK receptor expression is higher in suicide victims.

Modulation of mesolimbic dopamine-related behavior, including exploratory and rewarded behaviors, may underlie CCK’s effects on substance use. Central CCK activity has been linked with a preference for drugs of abuse, such as cocaine or alcohol, and polymorphisms of the CCK gene may be one of the risk factors for smoking. This suggests a potential role for CCK receptor antagonists in the treatment of drug dependence.

GASTRIN AND GASTRIN-RELEASING PEPTIDE

Gastrin is a peptide hormone closely related to CCK that stimulates the secretion of gastric acid by the stomach. Pentagastrin is a synthetic polypeptide with effects similar to those of gastrin. It is a CCK agonist and produces anxiety and panic in patients with anxiety disorders and to a lesser extent in those without anxiety disorders. It increases ACTH and cortisol release. Gastrin-releasing peptide (GRP), as its name implies, stimulates gastrin release but has a number of other actions, including interacting with GABA, dopamine, and GRs. GRP appears to enhance memory storage, and a GRP receptor antagonist impairs emotionally motivated memory tasks in rats. GRP-receptor-deficient mice show increased locomotor activity and changes in social behavior.

NEUROTENSIN

Neurotensin is a tridecapeptide that appears to play a role in neuroendocrine regulation and coordination as a signaling molecule. Gonadal and adrenal steroids and thyroid hormones alter neurotensin levels in the hypothalamus, preoptic area, and arcuate nucleus. Neurotensin has a close neuroanatomical relation with serotonin and dopaminergic pathways and is involved in the control of anterior pituitary activity, stimulating the release of prolactin and TSH, as well as in the regulation of a subpopulation of serotonergic neurons in the dorsal raphe and frontal cortex and GABAergic and glutamatergic neurons. Stimulation of serotonin neurons may be responsible for its analgesic effects and reduction of the stress response, whereas the effects on dopamine suggest a possible antipsychotic role. Subgroups of drug-free schizophrenic patients have low neurotensin CSF concentrations and altered neurotensin receptor binding in the entorhinal cortex. Psychotogenic drugs (e.g., methamphetamine) inhibit the release of striatal neurotensin via an inhibitory effect of the dopamine type 1 (D_1) receptor. Most antipsychotic drugs increase neurotensin concentrations in the nucleus accumbens and caudate nucleus; schizophrenic patients with decreased CSF neurotensin show an increase compared to baseline values after antipsychotic drug treatment and clinical improvement. Because of neurotensin’s association with the nigrostriatal dopamine and the serotonin systems, it is suspected of playing a role in movement disorders caused by antipsychotic drugs. Central administration of neurotensin in rats produces motor effects seen in animal models of parkinsonian and dystonic reactions (catalepsy) and tardive dyskinesia. Neurotensin may exert an antipsychotic action through intramembrane receptor interactions that reduce the affinity of the dopamine type 2 (D_2) agonist binding site. Overexpression of neurotensin 1 receptors in rats results in decreased activation of the mesolimbic dopamine system, similar to that produced by atypical antipsychotics but without changing prepulse inhibition or locomotor behavior, as atypical antipsychotic drugs do. This suggests that neurotensin receptor agonists may be candidates for the treatment of psychosis and attenuate dopamine-induced motor behaviors.

Involvement in the development of drug dependence also has been hypothesized. Blocking the effects of neurotensin with antiserum or a receptor antagonist enhances dopamine release in the nucleus accumbens, and neurotensin itself blocks stimulant-induced motor activity. However, doses that block hyperlocomotion do not attenuate the self-administration of cocaine and even enhance conditioned place preference, an animal model of rewarding effects. Neurotensin's modulating effects on dopamine activity may depend on stimulus intensity, enhancing the rewarding properties of a subthreshold stimulus from intracranial self-stimulation (ICSS), as do psychostimulants, but decreasing maximal stimulation rate, as do antipsychotic drugs. Acute administration of stimulants increases neurotensin in the nucleus accumbens, but with chronic administration, levels return to normal. Ibogaine, a hallucinogen used in indigenous religious ceremonies, has been shown to interrupt cocaine and methamphetamine abuse in patients and may act similarly to ICSS, increasing neurotensin concentrations in the nucleus accumbens when given alone but attenuating cocaine-induced increases in neurotensin. Neurotensin also mimics many of the effects of alcohol, chronic alcohol downregulates neurotensin receptors, and lower concentrations of neurotensin have been found in the frontal cortices of alcohol-preferring rats.

FUTURE DIRECTIONS: ENDOCRINE VARIABLES IN THE DIAGNOSIS AND TREATMENT OF PSYCHIATRIC DISORDERS

Although it is clear that alterations in endocrine regulation are involved in the pathophysiology and treatment responses of many psychiatric disorders, incorporating these findings into clinical diagnostic assessment, and decision making remains problematic. Questions about state/trait differences and the role of confounding variables plague nearly all observations, and most of the findings to date are based on small numbers of subjects studied under experimental conditions. Large-scale longitudinal or cost-effectiveness studies are rare, despite indications that baseline alterations in glucocorticoid regulation and thyroid status (two of the best-studied abnormalities) may actually be useful in subtyping psychiatric disorders and in the prediction of outcome. Although the dexamethasone suppression test (DST) was perhaps prematurely put forward as a diagnostic aid, the fact remains that alterations in HPA/stress regulation underlie a number of psychiatric diagnoses and may serve as complementary independent variables in defining treatment response and course of illness to the classical behavioral categories that have thus far defined current practice. Studying genetic polymorphisms in factors regulating hormonal response may help us better understand the influence of hormonal variability on the illness and also possible underlying differences in the nature of the illness reflected in these genetic subtypes. The incorporation of endocrine variables into the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) would have been premature, but the routine assessment of endocrine status in clinical trials and epidemiologic surveys is long overdue. Incorporation of biologic variables into psychiatric diagnosis and treatment decision making requires prospective proof of concept studies that unequivocally demonstrate the clinical superiority of such assessments over that of behavioral variables alone. Unfortunately, no such data exist at the present time.

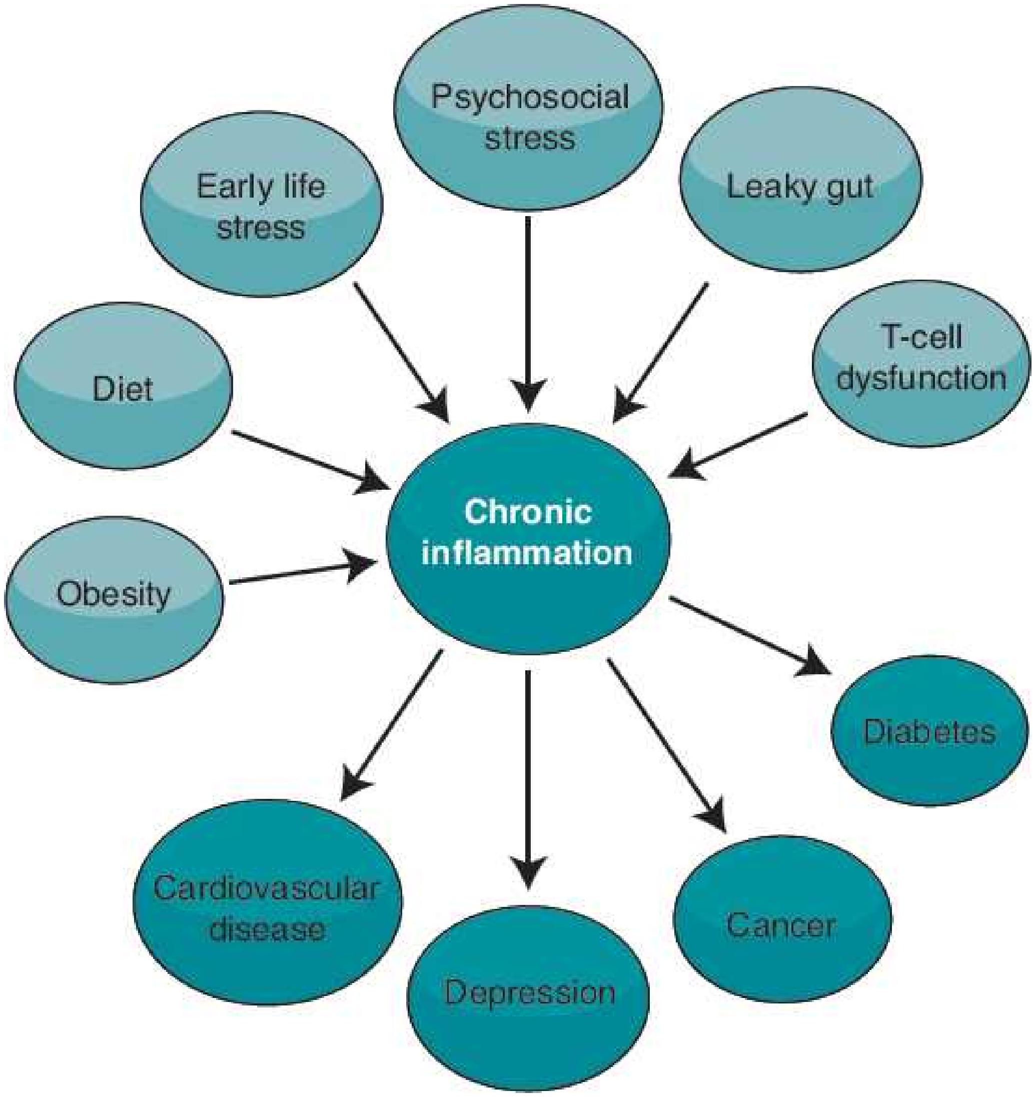
▲ 1.13 Immune–Brain Interactions in Psychiatry

EBRAHIM HAROON, M.D., ANDREW H. MILLER, M.D., AND CHARLES L. RAISON, M.D.

The immunologic capacity is essential to all multicellular organisms. The relationship between the immune and central nervous systems (CNS) may underlie successful adaptations to environmental challenges. Increasingly, immune brain communication can be a cause of many psychiatric and medical disorders and is the result of multiple lifestyles and individual risk factors. Figure 1.13–1 provides an overview of these risk factors. However, for a long time, the brain was considered an immune-privileged organ as it existed outside the reaches of the body's immune system. Indeed, the blood–brain (BBB) and blood–cerebrospinal fluid (CSF) barriers separated the brain from the rest of the body, allowing only a few essential molecules or cells to pass through their tight walls. Consequently, immune molecules or cells have limited access to the CNS.

Instead, the brain employs its own immune system with lymphatics, lymphocytes in the meninges and choroid plexus, and various subsets of macrophage-like cells found in border regions and the brain parenchyma. However, despite the protection provided by the tight BBB, the brain immune system does not function autonomously from the peripheral immune system. Upheaval in the body's immune system impacts the brain and modifies its functioning. The brain, in turn, shapes and prepares the body's immune system for current and anticipated dangers. The brain has co-opted cellular and molecular elements of its immune system to regulate its development and modulate synaptic plasticity. This chapter will discuss the basic elements of this immune–brain communication and how this newly acquired knowledge can help foster newer therapeutic advances in psychiatry.



Psychosocial stress
Early life stress
Leaky gut
Diet

(See eBook for color images.) (Reprinted from Haroon E, Raison C, Miller A. Psychoneuroimmunology meets neuropsychopharmacology: Translational implications of the impact of inflammation on behavior. *Neuropsychopharmacology* 2012;37:137–162. doi:10.1038/npp.2011.205.)

COMPONENTS OF THE IMMUNE SYSTEM

The immune system performs myriad functions, including:

1. protecting the body from the invasion of foreign pathogens, such as viruses, bacteria, fungi, and parasites,
2. detecting and eliminating cells that have become neoplastically transformed,
3. surveying, controlling, and maintaining the various symbiotic and commensal microbiota, notably in the gut,
4. sculpting of brain circuitry, and
5. regulating neurodevelopment and neuronal communication.

These functions are accomplished through specialized sensors (receptors) on immune and glial cell surfaces that recognize pathogenic molecules from invading organisms or neoplastic cells. The cells communicate via a rich intercellular communication network that involves direct cell-to-cell interactions and signaling between cells of the immune system by soluble factors called cytokines. Intriguingly, immune signaling molecules also communicate with brain cells via cytokine receptors on glial cells and some neurons, orchestrating a complex neurobehavioral response to any threat (physical or psychosocial).

Table 1.13–1.
Divisions of the Immune System: Innate versus Acquired

Lines of Defense	Innate	Acquired
Physiochemical barriers	Skin, mucous membranes	Cutaneous and mucosal immune systems
Cells	Phagocytes (macrophages, neutrophils, and natural killer cells)	Lymphocytes (B and T cells)
Soluble mediators that affect other cells	Macrophage-derived cytokines, i.e., IL-1, IL-6, TNF, IFN-a	Lymphocyte-derived cytokines, i.e., IL-2, IL-4, IL-10, IFN-g
Memory	Trained	Yes
Circulating molecules	Complement, acute-phase reactants	Antibodies

IL, interleukin; IFN-a, interferon-alpha; IFN-g, interferon-gamma; TNF, tumor necrosis factor.

Arms of the Immune System—Innate and Adaptive Immunity

Table 1.13–1 delineates the functional differentiation of the two arms of the immune system, that is, innate or natural immunity and adaptive or acquired immunity. Immune cells originate from stem cells in the bone marrow but differentiate into myeloid and lymphoid stem cell lines. The myeloid family gives rise to erythrocytes, platelets, and mononuclear phagocytic cells, and the lymphoid family yields T and B lymphocytes and natural killer (NK) cells.

Key differences and overlaps exist between innate and adaptive immune systems. The components of innate immunity act rapidly but are relatively nonspecific against pathogens or infected cells. On the other hand, the adaptive immune system is highly specific, carrying an “adaptive immune memory” that often lasts a lifetime. However, recent data have indicated that the innate immune system may also carry the recent memory of an encountered pathogen—a phenomenon called “trained innate immune memory.” Trained immunity involves creating a short-term “memory” of a pathogen by modifying innate immune cells’ epigenome, genome, and, ultimately, function.

Thus, trained immunity lasts up to several months, in contrast to the adaptive immune memory, which may last a lifetime. Furthermore, trained immunity does not create antibodies in preparation for a second encounter, unlike its adaptive counterpart. In other words, trained immunity is akin to recent memory, while adaptive immunity is akin to long-term memory. Therefore, innate immunity (trained or acute) is considered evolutionarily more primitive and less specialized than the T and B lymphocyte–mediated adaptive/acquired immunity. Intriguingly, lymphocytic cells, such as NK cells, act as innate immune cells. Operationally, however, all the above nodes of immunity interact and cooperate. Most notably, the immune system exhibits a high level of biologic redundancy, with several molecules converging on the same functional target, ostensibly as a fail-safe mechanism in the face of threat or danger.

Innate Immune System

Innate Immune Surveillance. The innate immune system is usually the first point of contact with internal or external threats. The cells mediating innate immunity are maintained at a constant background level of activation, partly by exposure to microbial components from the gut. These cells do not require prior activation and recognize invading pathogens without delay. Thus, they provide an important first line of defense against infectious agents during the early stages of an immune response. Mononuclear phagocytic cells and NK cells are examples of innate immune cells. NK cells are a specialized but important component of innate immunity. These cells originate from the lymphoblastic heritage-like adaptive immune cells but act as innate cells. They can destroy virally infected cells by binding to them and releasing cytolytic factors, including perforin. NK cells also can recognize and destroy neoplastically transformed host cells, especially those of hematopoietic origin, thus protecting against some cancers. Figure 1.13–2 depicts the hematopoietic origins of different immune cells.

Mononuclear phagocytic cells include the following:

1. Monocytes (circulating in the blood)

2. Macrophages (monocytic cells entering tissues from circulation)
3. Microglia (the macrophage equivalent in the brain)
4. Dendritic cells (immune cells residing in tissues)
5. Reticular cells (immune-capable fibroblasts residing in reticuloendothelial organs [spleen, lymph nodes, and lymphoid organs])

Of note, the reticuloendothelial organs may represent the crossing point at which immune information is exchanged between the innate and adaptive systems. These cells originate from the lymphoblastic heritage like adaptive immune cells but act as innate cells. They can destroy virally infected cells by binding to them and releasing cytolytic factors, including perforin. NK cells can also recognize and destroy neoplastically transformed host cells, especially those of hematopoietic origin, thus protecting against some cancers.

Threat Detection and Immune Signaling. Figure 1.13–3 summarizes the key events that take place during innate immune activation—of relevance to psychiatry. Once a threat is recognized, the innate system sends alarm signals to all other components of the immune and nervous systems. Immune molecules and proteins are keys to coordinating the system-wide responses to immune stimulation. The most important factors will be discussed below.

Surface Pattern Recognition Receptors. Innate immune cells are part of the immune surveillance system that survey circulating antigens and mobilize rapid immune responses upon discovering pathologic products. Innate cells recognize extracellular pathogens (e.g., bacteria and parasites) through relatively simple molecular pattern recognition receptors (e.g., toll-like receptors, or TLRs). TLRs recognize two types of pathogenic molecular patterns. The first involves evolutionarily conserved molecular patterns of infectious agents, called pathogen-associated molecular patterns (PAMPs). The second refers to the recognition of deoxyribonucleic acid (DNA) and other debris from dying or neoplastic cells, known as danger-associated molecular patterns (DAMPs). Thus, the immune response induced by DAMPs is referred to as sterile inflammation and can be provoked by biochemicals leaking from dying or distressed cells, including adenosine triphosphate (ATP), DNA, heat shock proteins

(HSPs), and high-mobility group box 1 (HMGB1). Then, these cells rapidly neutralize the threat by engulfing and degrading pathogens or dead cells.

Intracellular Signaling Cascades. Activation of TLRs by pathogens (and by some cytokines) triggers intracellular signaling cascades—akin to second messenger systems in neurons. These intracellular signaling cascades include nuclear factor-kappa-B (NF-kB) and a distinct subtype of mitogen-activated protein kinase (MAPK) known as p38 MAPK. Both NF-kB and MAPK play a sentinel role in initiating the innate immune response.

Inflammasomes. Sterile inflammatory responses to noninfective but toxic stimuli (dead, neoplastic cells, or products of stress and distress) are mediated by inflammasomes, which are cytosolic protein complexes in the myeloid cells that respond to microbial and sterile inflammatory stimuli. Just-in-time assembly of inflammasome machinery leads to activation of the enzyme caspase 1, which cleaves the inactive precursors of cytokines such as interleukin-1 (IL-1) beta and interleukin (IL)-18 into active forms that can drive the inflammatory response. Inflammasomes act in concert with TLRs but focus on responding to debris from dying cells or distressed cells (sterile inflammation). Indeed, studies suggest that the release of DAMPs such as adenosine from ATP of stressed cells may explain how psychological stress activates inflammation—in the absence of an infectious stimulus. These studies have revealed that adenosine and glutamate released by stressed neurons trigger activation of the inflammasome. Obesity is a well-known cause of chronic inflammation. DAMPs released from the formation and death of adipocytes lead to chronic innate immune activation in obesity. While beyond the scope of this chapter, inflammasome activation in monocytes and macrophages by SARS-CoV-2 viral particles results in much of the tissue damage in COVID-19–associated lung dysfunction.

FIGURE 1.13–3. Locally cytokines act on endothelial and tissue stromal cells. Tissue stromal cells produce chemotactic factors, recruiting other immune cells to the site of injury. The endothelial cells produce adhesion molecules, enhancing immune cell margination and diapedesis. In the brain, proinflammatory cytokines—including interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)—activate the hypothalamic–pituitary–adrenal (HPA) axis and induce behavioral changes that subserve the metabolic demands of fever and inflammation. The proinflammatory cytokines also induce the liver to produce acute phase proteins. CAM, cellular adhesion molecule; IFN, interferon; NF-κB, nuclear factor-kappa-B; PGE, prostaglandin E; TLR, toll-like receptor. (Reprinted with permission from Cowles MK, Miller AH. Stress,

cytokines and depressive illness. In: Squire LR, ed. *The New Encyclopedia of Neuroscience*. Elsevier: Academic Press; 2009, 519–527.)

Cytokines. Cytokines are large molecular weight proteins that serve as the primary long-distance signaling molecules of the immune system. Some of their myriad functions are illustrated in Table 1.13–2. Activated mononuclear cells release proinflammatory cytokines, including tumor necrosis factor (TNF), IL-1, and IL-6. TNF and IL-1 are the principal mediators of the response to gram-negative bacteria and are among the earliest cytokines released in the inflammatory cascade, followed by IL-6. TNF and IL-1 are endogenous pyrogens capable of inducing fever by increasing the synthesis of prostaglandins by cytokine-stimulated hypothalamic cells. TNF also leads to cachexia, characterized by the wasting of muscle cells and appetite suppression. Activated mononuclear cells also release type I interferons (e.g., interferon [IFN]-alpha) with direct antiviral properties.

Acute Phase Response Proteins. Acute Phase Response Proteins (APP) synthesized primarily in the liver, limit tissue damage, isolate, and destroy invading pathogens, and set repair functions in motion. APPs are divided into positive and negative acute-phase proteins. Negative acute-phase proteins are those molecules whose production is decreased to make way for the synthesis of positive APPs. Negative acute-phase proteins include albumin, transferrin, and retinol-binding protein and are often used to measure the extent of chronic inflammation (e.g., following cachexia). Positive APPs aid in inflammatory activity and include the following:

Table 1.13–2.
Cytokine Mediators of Innate Immunity

Cytokines and Subunits	Principal Cell Source	Principal Cellular Targets and Biologic Effects
Interleukin-6 (IL-6)	Macrophages, DCs, endothelial cells, T cells	*Liver:* Synthesis of acute-phase proteins, *B cells:* Proliferation of antibody-producing cells, *T cells:* Th17 differentiation
Interleukin-2 (IL-2)	T cells	T cells: Proliferation and differentiation into effector and memory cells; promotes regulatory T cell development, survival, and function, *NK cells:* Proliferation, activation
Interleukin-4 (IL-4)	CD4 $^+$ T cells (Th2), mast cells	*B cells:* Isotype switching to IgE, IgG4 (in humans; IgG1 in mice), *T cells:* Th2 differentiation, proliferation, *Macrophages:* Alternative activation and inhibition of IFN-g-mediated classical activation
Interleukin-27 (IL-27)	Macrophages, DCs	*T cells:* Enhancement of Th1 differentiation; inhibition of Th17 differentiation
Granulocyte–monocyte CSF (GM-CSF)	T cells, macrophages, endothelial cells, fibroblasts	*Immature and committed progenitors, mature macrophages:* Induced maturation of granulocytes and monocytes, macrophage activation
Granulocyte-CSF (G-CSF, CSF3)	Macrophages, fibroblasts, endothelial cells	*Committed hematopoietic progenitors:* Maturation of granulocytes
IFN-a (type I IFN; multiple proteins)	Plasmacytoid DCs, macrophages	*All cells:* Antiviral state, increased class I MHC expression, *NK cells:* Activation
IFN-g (type II IFN)	T cells (Th1,	*Macrophages:* Classical activation

	CD8 $^{+}$T cells), NK cells, ILC1s	(increased microbicidal functions), *B cells:* Isotype switching to opsonizing and complement-fixing IgG subclasses (in mice, not humans), *T cells:* Th1 differentiation, *Various cells:* Increased expression of class I and class II MHC molecules, increased antigen processing and presentation to T cells
Interleukin-10 (IL-10)	Macrophages, T cells (mainly regulatory T cells)	*Macrophages:* DCs: Inhibition of expression of IL-12, co-stimulators, and class II MHC
Tumor necrosis factor (TNF, also called TNF-alpha; TNFSF2)	Macrophages, NK cells, T cells	*Endothelial cells:* Activation (inflammation, coagulation), *Neutrophils:* Activation, *Hypothalamus:* Fever, *Muscle, fat:* Catabolism (cachexia)
Interleukin-1 beta (IL-1β)	Macrophages, DCs, fibroblasts, endothelial cells, keratinocyte; major type of biologically active IL-1	*Endothelial cells:* Activation (inflammation, coagulation), *Hypothalamus:* Fever, *Liver:* Synthesis of acute-phase proteins, *T cells:* Th17 differentiation
IL-1 receptor antagonist (IL-1RA)	Macrophages	*Various cells:* Competitive antagonist of IL-1
Interleukin-17A (IL-17A), Interleukin-17F (IL-17F)	CD4 $^{+}$T cells (Th17), ILC3s	*Epithelial cells, macrophages, and other cell types:* Increased chemokine and cytokine production; GM-CSF and G-CSF production

Transforming growth factor-beta (TGF-β)	T cells (mainly Tregs), macrophages, other cell types	*T cells:* Inhibition of proliferation and effector functions; differentiation of Th17 and Treg, *B cells:* Inhibition of proliferation; IgA production, *Macrophages:* Inhibition of activation; stimulation of angiogenic factors, *Fibroblasts:* Increased collagen synthesis
MCP (Monocyte chemoattractant protein)-1, (CCL2)	Many cells	*Mixed leukocyte:* Recruitment
IL-8, (CXCL8)	Many cells	*Neutrophil:* Recruitment
Fractalkine, (CX3CL1)	Many cells	*T cell, NK cell, and monocyte:* Recruitment

CCL2, CXCL8, CXC3CL1, chemokine nomenclature for MCP-1, IL-8 and Fractalkine, respectively; DC, dendritic cells; IFN, interferon; IFN-a, interferon-alpha; IFN-g, interferon-gamma; Ig, immunoglobulin; MHC, major histocompatibility complex; NK, natural killer cells; Th, T helper cells.

1. Protease inhibitors: for example, alpha 1 antitrypsin, alpha 1 antichymotrypsin
2. Coagulation proteins: for example, fibrinogen, prothrombin
3. Complement proteins: for example, C2, C3, C4, C5, etc.
4. Transport proteins: for example, haptoglobin
5. Inflammatory proteins: for example, C-reactive protein (CRP), serum amyloid A (SAA)

The combination of liver-derived plasma proteins induced by TNF and IL-1 with those induced by IL-6 constitutes the acute-phase response (see Fig. 1.13–3). Notably, the synthesis of CRP in the liver is increased by the action of IL-6 on hepatocytes. Thus, plasma CRP is a well-regarded measure of overall inflammatory activation. It is standardized across clinical laboratories and is well known to predict the risk of acute (pneumonitis) and chronic inflammation (cardiovascular disease, autoimmune disorders).

Complement Factors. Complement factor proteins, also produced by the liver, represent another important component of the innate immune response. These functionally linked proteins interact with each other in an orderly manner to subserve innate immune functions, including cell lysis, opsonization, attracting inflammatory cells (chemotaxis), stimulating immune cells to release chemical mediators of inflammation, and neutralization of antigen–antibody complexes to prevent tissue damage. Of note, complement proteins tag cells for identification and destruction by phagocytic cells. For instance, complement proteins such as the C4A-complement shape neuronal pruning of synapses by microglial phagocytosis during development. Aberrant phagocytic signals leading to excess pruning are believed to play an etiologic role in some cases of autism and schizophrenia. Nascent evidence indicates that activation of immunologic mechanisms via maternal or fetal infection may worsen pathology associated with aberrant complement activation.

Adaptive Immunity

T and B lymphocytes are the crowning achievements of the evolution of immune cell specialization and account for the diversity, specificity, and adaptive functionality within the immune system. The adaptive immune response includes three phases, that is, a recognition phase, an activation phase, and an effector phase of antigen elimination.

Recognition Phase. During the recognition phase, the presence of an infectious agent, antigen, or neoplastically transformed cell is sensed using specialized receptors for antigens on the surfaces of B and T lymphocytes. The receptors for an antigen on a particular B or T cell are identical and unique to their descendants (clones). A family of lymphocytes with identical antigen receptor specificity is called a clonal line. Thus, diversity in antigen recognition is derived from the vast number of different B- and T-cell clonal lines present in each individual. When an antigen is detected, the corresponding clonal line is selected and activated. Of note, the surface receptors on lymphocytes are highly specialized and customized to each pathogen or dying cell and are typed using their surface protein expression—referred to as a cluster of differentiation (CD). Intriguingly, the reticuloendothelial organs are conceptualized as librarians holding vast libraries of clonal lines, ready for activation. Several antigen-presenting innate cells traffic into the sinusoids of these organs via lymphatic channels and come into proximity with the lymphocytes. Thus, antigen recognition by lymphocytes may occur in a paracrine manner in the reticuloendothelial organs such as the spleen, thymus, and lymph nodes. Of note, the miseducation of lymphocytes at this interface may also trigger some leukemias.

Activation Phase. The activation phase includes the proliferation and mobilization of the immune cells relevant to eradicating the infectious agent. The binding of foreign antigens alone is usually insufficient to produce B- and T-cell activation—an accessory signal is required. Important accessory signals are generated by the IL group of cytokines secreted by T helper (Th) lymphocytic cells acting in concert with antigen-presenting cells (APCs), such as macrophages and dendritic cells. The Th cells and APCs stimulate each other in a reverberating manner to mount and amplify the immune response. APCs secrete IL-1 and other cytokines that stimulate Th cells to secrete a host of cytokines, including IFN-gamma, which further increase the activity of APCs, ultimately improving their antigen-presenting capacity. Thus, cytokines involved in the acquired immune response often simultaneously serve multiple functions. Binding to antigen in the presence of stimulatory cytokines results in activating intracellular systems regulating cell growth, division, and proliferation of T and B lymphocytes. Activation also results in the clonal expansion of immune cells with the identical high-affinity specificity for the foreign antigen. In addition, some progenies undergo further differentiation during clonal expansion into mature effector cells, such as antibody-secreting plasma B cells and cytotoxic CD8+ T lymphocytes (CTLs) that participate in cell-mediated immunity.

In contrast, some descendants of activated B or T cells become memory cells primed for activation upon future stimulation by the same antigen. Thus, reexposure to the same antigen elicits a more rapid and robust secondary immune response (thus the name acquired immunity) than the first or primary immune response to that antigen. Notably, memory cells may live for many years providing long-lasting acquired immunity, as demonstrated by individuals who have received a vaccine or had their first contact with a specific infectious agent during infancy. Similarly, exaggerated immune memory may play a part in hypersensitivity reactions.

Effector Phase. During the effector phase, the pathogen is neutralized and eliminated. Acquired immune responses employ humoral (antibody-mediated) and cell-mediated (CTLs) processes to neutralize a threat. Antibodies secreted from B cells are principal effectors of humoral immunity. Humoral immunity is especially effective in combating extracellular pathogens, such as bacteria and parasites. Cell-mediated immunity using CTLs is used to kill target cells directly. In contrast to humoral immunity, cell-mediated (CTL-based) immunity effectively protects against viral and intracellular bacterial infection and, as with NK cells, may provide some protection against tumor cells. The T cells also release macrophage-activating cytokines such as IFN-gamma that enhance the antimicrobial functions of macrophages, including microglia. Regulation of the acquired immune response is another important component of the effector phase. It includes CD4+CD25+ regulatory T cells (also known as CD4 cells), which are immunosuppressive and restrict immune responses to self-antigens. In addition, the inhibitory costimulatory molecule called programmed death-1 (PD-1) and its ligands have been shown to play an important role in regulating/suppressing T-cell activation. Indeed, loss of PD-1 has been associated with an autoimmune diathesis in laboratory animals. PD-1 depletion has also been proposed as a mechanism leading to “cytokine storm” in conditions such as SARS-CoV-2 infections.

Integration with the Innate Immune System. B and T cells also recruit, enhance, and direct innate immune mechanisms to neutralize the threat posed by specific antigens. For example, circulating antibodies can neutralize pathogens by binding to and coating the pathogens (opsonization). Pathogens that are opsonized are made susceptible to lysis by complement factors and phagocytosis. NK cells and phagocytic cells (such as neutrophils and macrophages) have receptors for the Fc fragment (fragment crystallizable region) of antibodies. Furthermore, complement proteins bind to and are activated by the Fc fragments of some types of antibodies. Thus, antibodies can link effector cells and cytolytic proteins of innate immunity with pathogens, lending a level of specificity that is not inherent in the effector arms of the innate immune processes themselves.

Cytokines Synchronize Innate and Acquired Immunity. Cytokines are the primary signaling molecules that convey immune information between different components of the immune system. Cytokines can be broadly divided into categories based on initiating, regulating, and maintaining the immune response. Hence, some cytokines mediate innate immunity and inflammation, others regulate acquired immunity, and the remaining control proliferation and differentiation of immature immune cells (see Table 1.13–2). Although structurally distinct, these cytokines overlap in function and act together to govern the dynamic events of immunity.

Regulatory T Cells. Within the acquired immune response, significant interest has been paid to two varieties of Th cells (CD 4+ T cells) known as Th1 and Th2. Th1 cells produce cytokines such as IL-2 and IFN-gamma that promote T-cell proliferation and activity and promote inflammatory responses that are especially relevant for protection against intracellular pathogens. Th2 cells produce cytokines such as IL-4 that promote antibody production and provide protection against parasites. In addition, Th2-type T-regulatory cells dampen immune activation both via direct cell-to-cell effects and via the production of anti-inflammatory cytokines, especially IL-10. Exaggerated Th2 responses have been closely associated with allergic and hypersensitivity reactions and asthma. A third subset of Th17 cells, developmentally distinct from Th1 or Th2 cells, also has been identified. These cells produce the cytokine IL-17, which has recently been linked to autoimmune (psoriasis) and allergic conditions once thought to be more closely involved with Th1 or Th2 dysregulation. More recently, two additional subsets of effector cells have been described including, Th9 cells, which secrete IL-9 and seem to be predominantly proinflammatory, and Th22 cells, which secrete IL-22 and can have either pro- or anti-inflammatory effects.

IMMUNE–BRAIN COMMUNICATION

The CNS and immune system interact and modulate each other in health and disease. This complex interplay of immune–brain communication is illustrated in Figure 1.13–4. While both systems defend against threats, each offers unique evolutionary advantages. For example, the immune system offers a specialized network to neutralize threats, but its operational domain is at the closest proximity and immediacy of the threat. On the other hand, as a superior prediction machine, the brain can anticipate and prepare the immune system for a future threat. Similarly, the immune system can control behavior in a manner that promotes healing and recovery. In the CNS, resident immune cells (microglia) are found mostly in the parenchyma, while trafficking immune cells are stationed in specialized niches inside the brain—including meninges and choroid plexus, ready to be called into action when indicated. Astrocytes participate in immune responses only after priming by microglial cells, as happens during aging or brain infections. The BBB separates the cerebral blood vessels from brain tissue and tightly regulates the flow of peripheral immune molecules into the CNS. Under usual circumstances, direct between the blood and the CNS can occur only at specific locations. The blood–brain interchange typically occurs in fenestrated capillaries found in circumventricular organs (CVOs). The recently discovered brain lymphatic (glymphatic) system facilitates the movement of fluid and small molecules between the CSF and interstitial fluid. The glymphatic system is one possible route for cytokines from the meningeal compartment to the brain. Thus, the CSF, carrying cytokines (from the peripheral circulation) in the subarachnoid space, can enter the Virchow–Robin spaces, dive deep along with the perivascular spaces, and then diffuse into the brain parenchyma. Subsequently, the cytokines may interact with cytokine receptor–expressing neurons, glia, and stroma in the brain parenchyma. However, how cytokines cross the arachnoid mater to reach the subarachnoid space during homeostasis remains unanswered.

Neuronal activity can alter the immunologic response within the brain. Microglia, the brain's resident immune cells, respond to cues from ongoing neuronal activity. Neural activity is accompanied by the spillover of neurotransmitters that escape from the synapse. Microglia sense these spillover neurotransmitters using surface receptors. The activation of these receptors modifies the function and phenotype of microglial cells. In addition, brain activity can also stimulate epithelial cells in the CVOs by increasing the release of chemotactic molecules, changing the permeability of the BBB, and promoting the recruitment of immune cells from peripheral circulation into the brain.

Comparisons of immune–brain communication pathology in stress-induced psychiatric disorders such as depression and post-traumatic stress disorder (PTSD) reveal a more complex picture that defies simplistic explanations. There is sufficient evidence linking peripheral and central immune changes in unipolar and bipolar affective disorders (see later sections in this chapter). Emerging data indicates that this process may be less connected in PTSD. This will be discussed in the section on PTSD.

Immune Receptors on Neurons

Both immune and neurologic systems detect and neutralize threats and maintain homeostasis. Both systems perceive internal and external environments and use specific receptors to monitor ambient stimuli. For example, both sensory afferent fibers of the autonomic nervous system (vagal afferents) and peripheral sensory neurons in the dorsal root ganglia display immune receptors (TLRs and cytokine receptors) and transmit immunologic signals to the brain. Peripheral neurons become more sensitive to pain and itch stimuli when these immune receptors are stimulated, resulting in behavioral modifications. For example, avoidance behavior occurs when an organism protects itself from injury, danger, or infection by avoiding a substance or circumstance deemed harmful by immune-associated sensory cues.

Neurochemical Receptors on Immune Cells

In addition to signaling neural pathways, peripheral immune cells express receptors for a wide range of chemicals regulated by or produced from several body tissues, as shown in Table 1.13–3. The adrenergic receptor expressed on T and B cells was one of the first receptors to be identified in lymphocytes. Following that, receptors for various small molecule neurotransmitters such as noradrenaline (NE), dopamine (DA), acetylcholine (ACh), serotonin (5HT), and glutamate were recognized on immune cells including microglia. Neurotransmitter receptors on immune cells, like those in the CNS, are found in the cell surface and, in most cases, are linked to G proteins and second-messenger pathways. The impact of CNS chemicals and hormones on the immune system varies depending on which step of the immune response is involved (recognition, activation, or effector). For example, norepinephrine has been shown to boost immune activity during recognition but suppress response during the effector phase. As a result, while persistent stress is linked to increased baseline inflammation, it also reduces the body’s ability to fight infections and develop a strong immunologic response to immunizations. These data suggest that the time of exposure as well as the dose are critical.

Lymphoid Tissue Nerve Innervation

One of the first indications of immune–brain communication was the discovery of the sympathetic nervous system (SNS) innervation of immunologic tissues. SNS fibers have been found in reticuloendothelial organs (bone marrow, thymus, spleen, and lymph nodes) involved in lymphocyte growth, education (e.g., self–nonself-discrimination), and function. The superior cervical and stellate ganglia, for example, supply sympathetic fibers to the thymus, whereas the mesenteric and celiac plexuses supply sympathetic input to the spleen. Furthermore, the sympathetic supply to the bone marrow is derived from the spinal cord level corresponding to the bone’s position. Efferent input from the vagal or recurrent laryngeal nerves normally provides parasympathetic counter-regulation. Sympathetic nerve fibers usually enter lymphoid tissues in tandem with vascular supply. These fibers are widely known for modulating vascular tone by controlling the contractility of the smooth muscles that line the arteries. Nevertheless, penetrating nerve fibers also terminate near developing lymphocytes and macrophages. By altering blood flow into lymphoid organs and locally releasing neurotransmitters like NE and neuropeptides, SNS fibers can modulate immune cell functions.

FIGURE 1.13–4. In the context of psychosocial stress, catecholamines (such as noradrenaline) released by activated sympathetic nervous system fibers stimulate bone marrow production and the release of myeloid cells (for example, monocytes) that enter the periphery where they encounter stress-induced damage-associated molecular patterns (DAMPs), bacteria and bacterial products such as microbial-associated molecular patterns (MAMPs) leaked from the gut. These DAMPs and MAMPs subsequently activate inflammatory signaling pathways such as nuclear factor-kappa-B (NF-κB) and the NOD-, LRR- and pyrin domain-containing protein 3 (NLRP3) inflammasome. Stimulation of NLRP3 in turn activates caspase 1, which leads to the production of mature interleukin-1-beta (IL-1β) and IL-18 while also cleaving the glucocorticoid receptor contributing to glucocorticoid resistance. Activation of NF-κB stimulates the release of other proinflammatory cytokines including tumor necrosis factor (TNF) and IL-6, which together with IL-1β and IL-18 can access the brain through humoral and neural routes. Psychosocial stress can also lead to the activation of microglia to an M1 proinflammatory phenotype, which releases CC-chemokine ligand 2 (CCL2) that in turn attracts

activated myeloid cells to the brain via a cellular route. Once in the brain, activated macrophages can perpetuate central inflammatory responses. ASC, apoptosis-associated speck-like protein containing a CARD; HMGB1, high mobility group box 1; HSP, heat shock protein; LPS, lipopolysaccharide; TLR, Toll-like receptor. Table 1.13–3.
Neurotransmitters, Hormones, and Peptides— Targeting Immune cells

Neurotransmitters	Hormones	Peptides
Dopamine	Corticosteroids–glucocorticoids	ACTH
Glutamate, receptors, and transporters	Mineralocorticoids	Alpha-MSH
Norepinephrine	Estrogen	AVP
Serotonin	Progesterone	Calcitonin
Histamine	Testosterone	CRH
Acetylcholine	GHRH	IGF-1
GABA	GnRH	Melatonin
	Growth hormone	NPY
	Opioids (endorphins, enkephalins)	PTH
	Thyroid hormone	Somatostatin
	Prolactin	Substance P
		TRH
		TSH VIP
		CGRP

Receptors for the above molecules have been identified on the immune cells, indicating their impact on the immune system.

ACTH, adrenocorticotropin; alpha-MSH, alpha-melanocyte-stimulating hormone; AVP, arginine vasopressin; CGRP, calcitonin gene–related peptide; CRH, corticotrophin-releasing hormone; GABA, gamma amino butyrate; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-like growth factor-1; NPY, neuropeptide Y; PTH, parathyroid hormone; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; VIP, vasoactive intestinal peptide.

Microscale Correlates of Inflammatory Activation on the Brain

Table 1.13–4 illustrates a selected list of key neurotransmitters of relevance to psychiatry. We will provide an abbreviated discussion of selected contents of the table below.

Table 1.13–4.
Immunologic Effects of Representative Neurotransmitters

Neurotransmitters	Immune Markers	Preclinical	Human
Serotonin	TNF and IL-1	Increased 5HTT (number and activity)	
	TNF		Increased brain stem 5HTT
SSRI (paroxetine)	IFN-alpha		Attenuate severity of depression
Dopamine			
Dopamine	IFN-alpha	*Primates, microdialysis:* Decrease in DA secretion, rescued by DA supplementation	
Dopamine	IL-6	*Rodents, microdialysis:* Decreased DA	
	IFN-alpha		Decreased presynaptic DA function on PET, Decreased basal ganglia activity on fMRI
	IL-6		CSF BH4 negatively correlated
DA promoting medications	CRP >1 mg/L		Improvement in Depressive Symptoms with

			bupropion, stimulants
Glutamate			
Glutamate	IFN-alpha		Increases in MRS glutamate signals
Glutamate	CRP >3 mg/L		Increases in MRS glutamate signals
Glutamate	KYNA/QUIN		Negatively Correlated with MRS glutamate in depression
Ketamine	LPS	*Rodents:* Pre-administration of Ketamine blocked sickness symptoms	
Ketamine	IL-6, CRP, kynurenine		Predictors of clinical response
GABA			
GABA	IL-18		Predicted depression severity
Acetyl choline			
Acetyl choline	Anti-inflammatory		Predicted increase in heart rate variability
	KYNA	*Rodents:*	Increased KYNA

Increased KYNA cognitive deficits by decreasing a7nAChR	related to experimental stress in schizophrenic subjects

a7nAChR: alpha-7-nicotinic acetyl choline receptors; DA: dopamine; HTT: serotonin reuptake transporters; KYNA: kynurenic acid; LPS: lipopolysaccharide bacterial endotoxin; MRS: magnetic resonance spectroscopy; and QUIN; quinolinic acid.

Norepinephrine. The effects of immune molecules on NE have been extensively studied. NE binding to beta-adrenergic receptors is a key mechanism by which stress activates immune cells. Beta-adrenoceptor blockade therapy may be useful in controlling the aberrant behavior of immune cells in medical disorders. Thus, for example, administration of beta-blockers before cancer therapy may be helpful to mitigate the risk of metastasis.

Serotonin. Innate immune cytokines, including TNF and IL-1, have also been shown to increase the expression and function of synaptic reuptake pumps for serotonin (and NE) via stimulation of p38 MAPK-linked pathways. The relevance of this mechanism to depression is highlighted by a recent human study showing that increased circulating levels of TNF were associated with increased brainstem serotonin reuptake availability. Conversely, etanercept, an antagonist to TNF, lowered brainstem serotonin transporter availability and improved symptoms of depression. Finally, treatment with the serotonin reuptake inhibitor, paroxetine, has been shown to attenuate the behavioral consequences of IFN-alpha administration, further highlighting the importance of effects on serotonin metabolism in cytokine-induced mood disturbances.

Dopamine. In addition to the effects of chronic cytokine exposure on noradrenergic and serotonergic transmission, it has been reported that chronic administration of IL-2 or IFN-alpha significantly alters DA metabolism while also leading to depression. For example, induction of inflammation in nonhuman primates (using IFN-alpha) led to decreases in DA metabolism in the basal ganglia, which was associated with depression-like behavior and responded to local L-Dopa administration via reverse microdialysis. These data parallel data from rodent studies, which demonstrated decreased DA in the nucleus accumbens following intraperitoneal injections of IL-6. Furthermore, chronic (i.e., 4 to 6 weeks) IFN-alpha treatment led to anhedonia, depression, and fatigue that correlated with reduced basal ganglia activation on functional magnetic resonance imaging (MRI) in response to motivational signals and decreased presynaptic striatal DA function. Several recent studies have investigated the mechanisms that underlie DA deficits. The pteridine derivative tetrahydrobiopterin (BH4) is an essential cofactor in synthesizing key monoamines relevant to psychopharmacology, including DA, NE, and serotonin. By diverting scarce BH4 to catalyze the generation of reactive oxygen and nitrogen species, inflammatory cytokines (such as IFN-gamma, TNF, and IL-6) decrease the production of key monoamines such as DA. For example, CSF concentrations of BH4 correlate negatively with CSF IL-6 levels among patients treated with IFN-alpha. Notably, plasma phenylalanine to tyrosine ratio (an indirect measure of BH4 activity) correlates with CSF concentrations of DA and severity of depressive symptoms following IFN-alpha–treatment. Targeting the DA system in inflammation using bupropion or stimulants decreases inflammation-induced anhedonic symptoms in human and preclinical models.

Glutamate. Although initial interest in the impact of inflammation focused on the monoamines (i.e., serotonin, NE, DA), studies also implicate changes in glutamate transmission as being relevant to the behavioral effects of cytokines. For example, increased levels of glutamate in the basal ganglia and dorsal anterior cingulate cortex (dACC) have been observed in patients receiving IFN-alpha, and higher levels of glutamate in these brain regions correlated with an increase in depressive symptoms. Glutamate exerts a paradoxical effect on neural plasticity and survival by promoting both neuronal health and toxicity. It may do so via its location-specific effects on glutamate receptors. Stimulation of synaptic N-methyl D-aspartate (NMDA) receptors enhances synaptic growth and survival, while stimulation of extrasynaptic NMDA receptors can promote cell death. The underlying mechanisms of toxicity include both receptor overstimulation and decreased synthesis of brain-derived neurotrophic factor (BDNF). Finally, increased extrasynaptic glutamate may stimulate presynaptic metabotropic glutamate receptors (mGluR) that inhibit the release of glutamate in the synapse, further impacting synaptic dysfunction. In this context, activated immune cells, including microglia and trafficking macrophages, are plentiful sources of extracellular/extrasynaptic glutamate in the brain. Activated immune cells have high antioxidant requirements due to accelerated mitochondrial metabolism and increased synthesis of reactive oxygen species. The release of glutamate by immune cells may be increased via system xC-, which extrudes glutamate molecules in exchange for cysteine to synthesize the antioxidant glutathione. In addition, the above cells release glutamate into the extrasynaptic space due to inflammation- and quinolinic acid (QA)-induced glial toxicity (discussed in the following sections). Moreover, immune-associated dysfunction of astrocytic glutamate reuptake pumps leads to decreased clearance and inefficient containment of glutamate, resulting in its “spillover” into the extracellular space. Increases in brain glutamate measures have been associated with increased neuropathology in neuroimmune disorders such as MS and HIV, depression-like behavioral changes following IFN-alpha, and among depressed individuals with high inflammation. Thus, there is significant evidence supporting immune-associated dysregulation of glutamate in depression and other neuropsychiatric disorders. In addition, glutamate dysregulation may also be bound to the activation of the kynurenine (KYN) pathway.

Kynurenine Pathway Molecules with Glutamate-Like Effects. KYNs are inflammatory molecules that bridge peripheral inflammation with neurobehavioral outcomes. When induced by cytokines like IFN-gamma or TNF, the enzyme indoleamine 2,3-dioxygenase (IDO) produces KYN from tryptophan in immune cells. KYN then undergoes a series of biotransformations resulting in glutamate-modifying metabolites like QA and kynurenic acid (KYNA). QA affects glutamate toxicity by decreasing the expression of astrocyte glutamate reuptake pumps, stimulating astrocytic glutamate release, and activating extrasynaptic NMDA receptors. KYNA, on the other hand, decreases the activation of NMDA receptors by allosterically modulating their glycine-binding sites. Antagonistic actions of KYNA on nicotinic acetylcholine receptors type-7 (nAChR7), which are linked to cognitive deficits in schizophrenia, also reduce presynaptic glutamate release. QA levels rise during inflammatory activation because inflammatory molecules selectively activate the QA pathway. Exaggerated NMDA activity in preclinical models and increased severity of depressive symptoms and suicidal behavior in depressed humans have been linked to concurrent increases in QA and decreases in KYNA. In the brain, QA is produced by microglia, while astrocytes and oligodendrocytes produce KYNA. This compartmentalization of their synthesis could play a role in the QA/KYNA imbalance.

During inflammation, more than 95% of free tryptophan is metabolized via the KYN pathway, with the remainder being utilized to produce serotonin and melatonin. Based on this finding, some researchers proposed that diverting tryptophan into the KYN pathway could result in tryptophan depletion, leading to depression. However, the ability of cells to retain tryptophan availability even in circumstances of significant tryptophan depletion and the preservation of high plasma levels of tryptophan even after continuous IDO activation has argued against this idea. IFN alpha and gamma and TNF stimulate IDO, resulting in large reductions in plasma tryptophan levels and increases in KYN metabolites in the blood. The only study examining the link between IFN-alpha-induced alterations in CSF metabolites and the onset of depression revealed that the cytokine did not affect central tryptophan levels while dramatically increasing KYN and QA levels in the CSF. The capacity of KYNs to easily pass the BBB via specific amino acid transporters is their most prominent property. As a result, KYN molecules directly link inflammation to excitatory neurotransmission and brain alterations that might cause neuropsychiatric symptoms.

Notably, changes in the KYN pathway have been targeted for neuropsychiatric treatment. Inhibitors of the KYN pathway are being developed to treat medical conditions, including cancer, that could be repurposed to treat psychiatric problems. Interestingly, blocking glutamate receptors with ketamine or inhibiting IDO activity protects mice from lipopolysaccharides (LPS)- or stress-induced depressive-like behavior but leaves the inflammatory response intact. These results indicate that increased activation of glutamate receptors by glutamate and/or QA may be a common pathway through which inflammation causes depressive-like behavior.

Macroscale Neural Correlates of Inflammatory Activation on the Brain

Studies utilizing positron emission tomography (PET) and MRI prove that peripheral cytokine activity can induce centrally mediated behavioral changes. These and other imaging modalities provide a means by which various behavioral alterations can be associated with changes in the functioning of specific brain regions. Studies on IFN-alpha, an innate immune cytokine used to treat infectious disorders and cancer, have extensively contributed to our understanding of the brain response to peripheral immune stimulation. IFN-alpha induces substantial behavioral abnormalities, including major depression in up to 50% of patients, depending on the amount and duration of therapy. Thus, IFN-alpha is a potent and reliable inducer of peripheral inflammation and its behavioral correlates (depression, anhedonia, fatigue, and cognitive impairments). During a functional MRI task of visuospatial attention, in comparison to controls, patients administered IFN-alpha exhibited significantly greater activation of the dACC that was correlated with the number of errors during task performance. Interestingly, increased dACC activity during cognitive tasks has also been demonstrated in patients vulnerable to mood disorders, such as those with high trait anxiety, neuroticism, or OCD. In addition, IFN-alpha leads to basal ganglia hypermetabolism measured using PET-uptake of 18-fluorodeoxyglucose), which was positively correlated with the severity of fatigue. In addition, impairments in DA metabolism mediated the development of fatigue following IFN-alpha. Of note, recent studies have provided further support to the selective targeting of reward circuitry by increased inflammation among depressed subjects. Using magnetic resonance spectroscopy (MRS), increased peripheral inflammation was also associated with increased glutamate signals in the dACC and basal ganglia regions among two independent cohorts (depressed patients and subjects treated with IFN-alpha) that was associated with severity of depression, anhedonia, and psychomotor slowing. Subsequently, we demonstrated that these increases in MRS glutamate signals were associated with greater incoherence in spontaneous brain oxygen level–dependent fluctuations on resting-state functional MRI and impaired functional connectivity between the basal ganglia and medial prefrontal regions. Similarly, studies from other groups have demonstrated similar brain and behavioral targets of inflammation.

SOCIAL ADVERSITY, ENVIRONMENTAL THREATS, AND THE IMMUNE SYSTEM

While stress was once thought to be linked to immune suppression, evidence over the last several decades suggests that this conclusion oversimplifies the complexities of the mammalian immune response to environmental perturbation. It is widely accepted that stress can activate certain aspects of the immune system, particularly the innate inflammatory response (see Fig. 1.13–4). Most factors that increase the risk of depression in today's environment also raise levels of peripheral inflammatory biomarkers, and many factors that improve emotional well-being have been found to reduce inflammation. A succession of animal and human studies demonstrating that stressful stimuli can impact the development of immune-related disorders such as infectious diseases, cancer, and autoimmune disorders sparked interest in the effects of the broader environment on the immune system. These findings demonstrate that peripheral T- and monocytic cell functioning—specifically the homing of these cells to the meninges of the brain in response to psychosocial stress—is required for learning in rodents in a process that drives hippocampal BDNF production via an IL-4–dependent mechanism.

Stress (Acute/Mild)

Data from laboratory animals suggest that brief or mild stressors might help animals adjust to new situations. In mouse models, brief/mild stress preceding antigen challenge resulted in an increased immunologic response. Acute stress boosts leukocyte activity by boosting leukocyte recruitment from the bone marrow into the bloodstream, infiltration into the pathology site, and proliferation at the infection site. Similar variations in NK cells and CD8 cytotoxic cell activity have been observed during stress. Acute stress appears to decrease regulatory and other suppressor T cells, according to new research. A rise in activated immune cells in the blood has been observed following acute stress such as parachute jumping, arithmetic problem solving, and confrontational human interactions. However, immunologic activation caused by acute stress is promptly decreased following the resolution of the stress. Notably, increased sympathetic activity is responsible for the acute effects of stress on the immune system, but increased parasympathetic activity is responsible for its suppression following stress resolution.

Severe/Chronic Stress

Chronic stress has been linked to immunosuppressive effects, despite its ability to increase proinflammatory responses. Chronic or severe stress is linked to increased health risks, frequently accompanied by proinflammatory alterations. In mouse models, chronic unexpected stress (predator stress, restraint stress) promotes inflammatory cell mobilization and functional activity of macrophages. These stressors work by increasing the release of DAMPs such as ATP, which activate inflammasomes leading to the release of IL-1.

Health Consequences of Chronic Stress

Allergies: Chronic stress, unlike acute stress, shifts the balance between the proinflammatory Th1 and the anti-inflammatory Th2 phenotypes, favoring the latter at the expense of the former. Thus, acute/mild stress in animals and humans may increase the in vitro production of the Th1 cytokine IFN-gamma without increasing the Th2 cytokine IL-4. In contrast, chronic/severe stressors tend to suppress IFN-gamma and IL-2 by Th1 cells, while not affecting or increasing the Th2 cytokines IL-4 and IL-10. This shift from Th1 to Th2 may also increase the susceptibility to allergic or hypersensitivity reactions, where Th2 responses play an important role. Chronic stressors in humans lead to a decrease in NK cell activity and lymphocyte proliferation in response to mitogen, and a decrease in monocyte sensitivity to endogenous cortisol. Furthermore, stress from a caregiver or an examination hinders the body’s ability to function or mount effective immunity against pathogens or immunization.

Th17 cells orchestrate tissue inflammation in autoimmune disorders (multiple sclerosis) by inducing proinflammatory cytokines (IL-6, IL-1, and TNF) and chemokines which recruit Th1 cells to the target tissue (monocyte chemoattractant protein [MCP]-1). Although functional T-regulatory cells accumulate in the target tissue, they are not efficacious during the inflammatory phase due to the overwhelming amounts of proinflammatory cytokines, such as IL-6, which protect effector and cytotoxic T cells from the suppressive effects of Treg cells. Therefore, boosting Treg cells and controlling tissue inflammation may provide the most effective strategy for controlling tissue inflammation and treating autoimmune diseases.

RELEVANCE OF IMMUNE–CNS INTERACTIONS TO PATHOLOGY AND TREATMENTS IN PSYCHIATRY

Major Depression

For many years, major depression was considered a quintessential example of how stress-related disorders may decrease immunocompetence. More recently, however, it has become evident that stress also activates inflammatory pathways, even while suppressing measures of acquired immunity. Thus, chronic stress-induced inflammatory activity may lead to depression and suppress *in vitro* functional assays, such as lymphocyte proliferation and NK cell activity. Nevertheless, despite potential negative impacts on health in the modern world, depressive behavior (with its attendant reduction in exploratory behavior) may represent an adaptive redeployment of limited metabolic energy reserves to innate immunity at the expense of adaptive immunity to promote survival across environmental challenges faced by hominids during evolution. Figure 1.13–5 depicts the key neural targets of inflammatory molecules in the etiopathogenesis of depressive disorders.

FIGURE 1.13–5. Once in the brain, the inflammatory response can affect metabolic and molecular pathways influencing neurotransmitter systems that can ultimately affect neurocircuits that regulate behavior, especially behaviors relevant to decreased motivation (anhedonia), avoidance, and alarm (anxiety), which characterize several neuropsychiatric disorders including depression. On a molecular level, proinflammatory cytokines including type I and II interferons (IFNs), interleukin-1 beta (IL-1β), and tumor necrosis factor (TNF) can reduce the availability of monoamines—serotonin (5-HT), dopamine (DA) and noradrenaline (NE)—by increasing the expression and function of the presynaptic reuptake pumps (transporters) for 5-HT, DA, and NE through activation of mitogen-activated protein kinase (MAPK) pathways and by reducing monoamine synthesis through decreasing enzymatic co-factors such as tetrahydrobiopterin (BH4), which is highly sensitive to cytokine-induced oxidative stress and is involved in the production of nitric oxide (NO) by NO synthase (NOS). Many cytokines, including IFN-gamma, IL-1 beta, and TNF, can also decrease relevant monoamine precursors by activating the enzyme indoleamine 2,3-dioxygenase (IDO), which breaks down tryptophan, the primary precursor for serotonin, into kynurenine. Activated microglia can convert kynurenine into quinolinic acid (QUIN), which binds to the *N*-methyl-D-aspartate receptor (NMDAR), a glutamate (Glu) receptor, and together with cytokine-induced reduction in astrocytic Glu reuptake and stimulation of astrocyte Glu release, in part by induction of reactive oxygen species (ROS) and reactive nitrogen species (RNS), can lead to excessive Glu, an excitatory amino acid neurotransmitter. Excessive Glu, especially when binding to extrasynaptic NMDARs, can in turn lead to decreased brain-derived neurotrophic factor (BDNF) and excitotoxicity. Inflammation effects on growth factors such as BDNF in the dentate gyrus of the hippocampus can also affect fundamental aspects of neuronal integrity including neurogenesis, long-term potentiation, and dendritic sprouting, ultimately affecting learning and memory. Cytokine effects on neurotransmitter systems, especially DA, can inhibit several aspects of reward motivation and anhedonia in corticostriatal circuits

involving the basal ganglia, ventromedial prefrontal cortex (vmPFC), and subgenual and dorsal anterior cingulate cortex (sgACC and dACC, respectively), while also activating circuits regulating anxiety, arousal, alarm and fear including the amygdala, hippocampus, dACC, and insula. BH2, dihydrobiopterin; DAT, dopamine transporter; EAAT2, excitatory amino acid transporter 2; NET, noradrenaline transporter; NF-κB, nuclear factor-kappa-B; SERT, serotonin transporter; TH, tyrosine hydroxylase; TPH, tryptophan hydroxylase. Inflammation and Depression—Cross-Sectional Associations. As evidenced by multiple meta-analyses, individuals with depressive disorders demonstrate elevated levels of several pro- and anti-inflammatory cytokines, including IL-2, IL-5, IL-6, IL-7, IL-8, IL-10, IL-12, IL-13, IFN-gamma, CRP, and TNF. From this diverse set of inflammatory cytokines, the most robust and consistent associations between depression and inflammatory biomarkers have been observed for CRP, IL-6, IL-1, and TNF. Of note, the elevation of anti-inflammatory cytokines may occur to counteract the proinflammatory bias.

Inflammation and Depression—Longitudinal Associations. There is support for the conclusion that chronic inflammatory activation increases the risk of depression. Medical disorders associated with chronic inflammation, such as autoimmune disorders (rheumatoid arthritis, multiple sclerosis, lupus), infectious disorders (HIV, hepatitis, cytomegalovirus), vascular disorders (stroke, ischemic disease), and metabolic disorders (diabetes, obesity) are all associated with substantial increases in the frequency of depression. These findings were validated and supported by results from a large-scale population-based cohort study in Denmark, using survival analysis adjusted for age, birth year, and gender. The risk of mood disorders increased by 45% following diagnosis of autoimmune disorders and 62% following hospitalization for infectious diseases. Immune-stimulating treatments such as IFN-alpha are well-known inducers of depression. Multiple studies, including a recent meta-analysis, have indicated that antidepressant pretreatment may reduce the risk of developing depression in IFN-alpha–treated subjects. Finally, increased CRP and IL-6 also predicted the development of depression prospectively, with some variability across studies.

Caveats in Interpreting Inflammation–Depression Associations. Despite these associations, it is difficult to conclude whether inflammation is universally associated with depression or if depression is a neuroinflammatory disorder like multiple sclerosis. It appears that not all subjects with depression have increased levels of inflammatory cytokines, and not all subjects with elevated plasma cytokines develop depression. Inflammation is more likely to be linked to pathophysiology in a subset of depressed subjects with increased individual vulnerabilities or biologic predispositions to inflammation-induced depression. Another factor impacting this association involves confounding factors such as obesity, elevated blood pressure, and diabetes, which are common among depressed subjects. It is unclear if such associations between inflammation and depression exist after controlling for these confounding factors. For example, one study that controlled for waist circumference and blood pressure could not replicate the previously reported associations between depression and increased inflammatory markers in the plasma. Intriguingly, some studies have reported high correlations between plasma and CSF levels of inflammatory markers such as CRP, TNF, and IL-6, only among untreated depressed individuals after controlling for confounding factors, including obesity as reflected by body mass index (BMI). Furthermore, a meta-analysis of 69 studies also reported an increase in IL-6 and TNF concentrations in the CSF of depressed patients.

Association Between Inflammation and Domains of Depressive Symptoms. The extreme heterogeneity in the diagnosis of depression has severely hampered the search for biomarkers related to its development, progression, and treatment response. One recent approach has been to narrow the diagnostic entity by breaking it down into subsyndromal symptom domains. Some key domains of interest relevant to inflammation's effects on the brain and behavior include anhedonia, anxiety, suicidality, cognitive symptoms, and sleep—although these symptom domains may extend into diagnostic categories other than depression in a "transdiagnostic manner." Indeed, as noted above, increased inflammation has been reliably associated with effects on neurotransmitter systems and brain regions and circuits that regulate motivation and motor activity as well as anxiety, arousal, and alarm. The specificity of these effects suggests a narrower influence of inflammation on the wider universe of symptoms exhibited by patients with mood and anxiety disorders. Indeed, in a recent paper examining the relationship between inflammation and specific symptoms of depression in 56,351 subjects from 15 population-based cohort studies, anhedonia, fatigue, and sleep problems were reliably associated with inflammation. These data are very consistent with what we know about how inflammation affects the brain. Nevertheless, a detailed review of this approach is beyond the scope of this chapter, but the readers are referred to exhaustive reviews on these topics.

Inflammatory Biomarkers as Predictors of Responses to Conventional Antidepressant Treatments. Identifying biomarkers that can predict treatment response is crucial in clinical practice if relevant lab testing is low cost and not time intensive. Ideally, these biomarkers would help categorize patients into subgroups (depressed subjects with varying biomarker profiles) and suggest the best treatment options for subjects who are unresponsive to traditional antidepressant drugs. In summary, current evidence suggests a negative relationship between increased inflammation and clinical response to classical antidepressant therapy, notwithstanding encouraging data using ketamine and ECT (to be discussed later). Some commonly studied markers are examined below.

TUMOR NECROSIS FACTOR. The lack of response to antidepressant treatment among TNF-gene knockout mice suggested that antidepressants require some TNF to be effective. This preclinical finding has not been fully supported in human studies. Responders to antidepressant treatment with escitalopram had lower baseline TNF levels than nonresponders to healthy controls. SSRI-resistant depressive subjects demonstrated significantly higher levels of IL-6 and TNF in the plasma. In a recent study using 98 depressed subjects who had failed several antidepressant trials, we reported that subjects who failed three or more treatment trials demonstrated significantly higher TNF, sTNFR2, and IL-6 than subjects who failed fewer treatment trials. In addition, plasma levels of the three markers predicted treatment trial failures with significant accuracy (AUC >0.7). Increased TNF activation has generally formed the basis for targeting the immune system in depression using TNF-blocking monoclonal antibodies such as infliximab.

INTERLEUKIN-6. IL-6 has been consistently linked to treatment resistance in depression since early 2000. Compared to healthy controls, depressed patients who did not respond to SSRI therapy had higher baseline levels of IL-6 and TNF. Surprisingly, inflammatory markers such as IL-6 predict a good response to ketamine. An earlier report indicated that ketamine responders exhibited higher plasma IL-6 levels than nonresponders. Intriguingly, preclinical treatment-resistant depression models tended to indicate comparable findings. Similarly, a more recent larger analysis with more structured control of confounding factors appeared to support this conclusion from previous studies. In this study, baseline IL-6 predicted a greater reduction in depressive symptoms at the end of the study. More recently, another study has demonstrated that elevated KYN metabolites also predicted a positive response to ketamine, indicating that ketamine benefits may be more pronounced among patients with inflammatory activation. Along similar lines, higher baseline IL-6 levels predicted greater response to a course of ECT, an effect that was moderated by female sex. Intriguingly, early treatment increases in IL-6 and CRP during treatment fell to normal levels at the end of the study. In summary, circulating levels of IL-6 predict treatment response depending upon the type of treatment, with elevated IL-6 being associated with the nonresponse to SSRIs or SNRIs and positive response to ketamine and ECT.

INTERLEUKIN-8. IL-8 is a chemokine and proinflammatory cytokine that has demonstrated association with the severity of anxiety and depression scores, especially among females. Recent data indicate that baseline levels of IL-8 predicted treatment response to an index course of ECT, specifically in females. For instance, female responders to a course of ECT treatments demonstrated lower IL-8 levels at baseline. However, unlike IL-6, decreases in IL-8 from baseline to end-of-treatment were negatively correlated with the percentage of symptom improvement only among females. Thus, IL-8 may be a sex-specific marker of treatment response to ECT in major depression. Another study reported that IL-8 predicted response to ketamine among female depressives.

C-REACTIVE PROTEIN. A secondary analysis from the GENDEP study (a multicenter, partially randomized open-label pharmacogenetics study) examined the impact of baseline CRP in predicting treatment response among depressed patients randomized to escitalopram or nortriptyline for

12 weeks. Baseline CRP levels predicted treatment outcomes for antidepressants differently. Patients with CRP > 1 mg/L responded more favorably to nortriptyline treatment than escitalopram. Similar findings were reported from the COMED trial, where a CRP > 1 predicted a poor response to escitalopram and a good response to escitalopram plus bupropion. Another more recent study indicated that baseline peripheral CRP levels were higher among depressed subjects who were treatment resistant than those who responded.

INTERLEUKIN-1. Two genotypes of the single-nucleotide polymorphisms (GG genotype) of the IL-1 gene were associated with nonremission after 6 weeks of antidepressant treatment. In addition, an increase in the number of G-alleles in both SNPs (G-, GG) was associated with decreases in the responsiveness of the amygdala and ACC to emotional stimulation.

KYNURENINE PATHWAY. A postmortem study reported that microglia in the anterior cingulate cortex of acutely depressed, suicidal patients expressed greater QA levels. These increases in QA and its downstream effects on NMDA receptor modulation have provided a molecular basis to examine ketamine (a noncompetitive NMDA receptor antagonist) as an antidepressant therapy among depressed subjects with elevated inflammation. Intriguingly, initial data have also linked KYNs to the outcome of ketamine therapy for depression. A recent analysis has indicated that KYN pathway toxicity may underlie some neurocognitive deficits following Covid-19 infections.

In conclusion, increases in peripheral inflammatory markers may likely be useful biomarkers to identify subgroups of patients with differential responses to treatments. However, the choice of immunologic biomarkers will be limited by the nonavailability of standardized assay techniques for all immune biomarkers other than CRP. In addition, the high variability in the concentrations of these markers over time and redundancy in functional activity may impact the interpretation of immune measures. Nevertheless, it is possible to use CRP as a baseline screening tool to stratify inflammatory risk among depressed subjects—as routinely done in other disciplines such as cardiology.

Anti-Inflammatory Therapies for Depressive Disorders

NONSTEROIDAL ANTI-INFLAMMATORY AGENTS. Inhibition of enzymes such as cyclooxygenase-1 and 2 (COX-1 and COX-2, respectively) using nonsteroidal anti-inflammatory agents (NSAIDs) have been evaluated as potential treatments for depression. Both COX enzymes lead to the synthesis of prostaglandins that promote inflammation while protecting gastrointestinal and vascular smooth muscles. NSAIDs are classified into nonselective agents, including aspirin that acts on COX-1 and COX-2 and celecoxib that are selective COX-2 inhibitors.

NSAID Monotherapy. Despite initial enthusiasm, monotherapy with NSAIDs has so far yielded mixed results. The earliest study in this area reported that Australian men who had used aspirin in the past 5 years but not at the time of the study had 40% higher odds of experiencing depressive symptoms. Thus, the authors concluded that aspirin failed to protect against developing depression. However, aspirin was likely prescribed to target chronic medical conditions associated with increased inflammation and depression. A later study indicated that a combined intake of statins and aspirin reduced the risk of depression. However, statins, via their anti-inflammatory effects, may have confounded the immunoprotective effect of aspirin. Another study indicated a relationship between aspirin intake and reduced frequency of depression among older males with high levels of homocysteine in the plasma—signifying increased vascular inflammation. A study of depressed older individuals from an Alzheimer disease (AD) prevention trial comparing celecoxib 200 mg twice a day or naproxen sodium 220 mg twice a day with a placebo indicated that neither celecoxib nor naproxen group experienced significant remission of depressive symptoms. Data from individuals receiving ibuprofen, naproxen, and celecoxib for the treatment of osteoarthritis experienced a significant reduction in the intensity of depressive symptoms. However, the limitation of disability and pain from osteoarthritis may likely have contributed to improvements in depression scores. More importantly, the benefits of NSAIDs are often outweighed by the risks of renal, gastrointestinal, and cardiovascular side effects. Notably, cardiovascular toxicity following treatment with rofecoxib (Vioxx) was noted as early as 2 months following the initiation of treatment. In this context, a very large study published recently found no protective effect of aspirin in depression.

NSAID Augmentation Therapy. The efficacy of NSAIDs as augmentation agents to antidepressant therapy has also been mired in mixed results. An early study used a double-blind, placebo-controlled randomized design to compare celecoxib plus reboxetine (antidepressant), reboxetine alone, and placebo. While both the reboxetine alone and reboxetine plus celecoxib groups achieved a reduction in symptom severity, the substantial number of subjects dropping out of the celecoxib group implied intolerance to the side effects of this medication. Subsequently, two studies indicated positive benefits with 6-week celecoxib augmentation of fluoxetine. However, another study using the same universe of subjects indicated that the augmentation effect of celecoxib peaked at 4 weeks and waned off at 8 weeks. The authors concluded that celecoxib may accelerate response to SSRIs. Using baseline inflammatory markers such as PET labeling of translocator protein density on the glial cells predicts better response to celecoxib in depressed individuals. However, a recent, well-conducted study indicated that augmentation with celecoxib was no better than a placebo in augmenting the antidepressant efficacy of vortioxetine. Thus, the overall efficacy of NSAID monotherapy or augmentation is not well supported by current data. Several factors, including the selection of patients without increased inflammation, global outcome variables such as changes in depression rating scale scores, and using drugs with off-target effects, were implicated in trial failures. A large population-based study from Korea reported that a combination of NSAIDs with antidepressants increased the risk of intracranial hemorrhage with a hazard ratio of 1.6 (95% confidence interval = 1.3 to 1.85), raising serious concerns about NSAID augmentation.

CYTOKINE INHIBITION. Given the link between some depressions and inflammatory cytokines, recent research has focused on examining the antidepressant efficacy of cytokine-blocking agents. TNF-antagonist such as infliximab were among the earliest to arrive on the scene. In 2013, 60 medically stable patients with treatment-resistant major depression were treated with three infusions of the TNF antagonist infliximab (5 mg/kg) or placebo (n = 30 in each group) at baseline, weeks 2, and 6 of a 12-week trial. While the overall change in depression severity scores using Hamilton Depression Rating Scale did not differ between treatment groups, there was a treatment by time by group interaction, whereby subjects with a high baseline CRP level >5 mg/L exhibited a clinically meaningful response in favor of infliximab. In addition, baseline TNF and its receptors were significantly higher in infliximab responders versus nonresponders. Intriguingly, the extent of adverse events and dropouts was very few in contrast to studies with NSAIDs. This article pointed out several factors of relevance. While providing proof-of-concept evidence linking TNF-antagonism and antidepressant activity, the authors stressed significant caution in interpreting the results. Some of the limitations included the small sample available for exploratory analysis, limited generalizability of CRP >5 mg/L to most depressed patients in clinical practice, and the global measure of depression outcome that was used. Of note, the use of TNF-antagonists (infliximab, adalimumab, etanercept) to treat medical disorders such as psoriasis has also resulted in substantial improvement of comorbid depressive symptoms. These findings are subject to cautionary interpretation as the improvement in depression may have resulted from improvement in disability and suffering from disease activity. Treatment with TNF antagonists increases the risk of opportunistic infections such as tuberculosis, histoplasmosis, and bacterial sepsis. Recently, siltuximab (chimeric monoclonal antibody against IL-6) for multicentric Castleman disease and sirukumab (human monoclonal antibody against IL-6) for the treatment of rheumatoid arthritis were evaluated for their antidepressant effects in these medically ill cohorts. Treatment with the above two IL-6 antagonists reduced the prevalence of depression and anhedonia in this analysis, though limited by the confounding effects of primary medical conditions and their treatment. Finally, a recent trial of infliximab for bipolar depressed patients (see below) found similar effects on anhedonia but without a clear relationship with baseline inflammation. Nevertheless, a history of childhood maltreatment, which has been reliably associated with inflammation, was found to be predictive of response.

KETAMINE. A detailed discussion of ketamine is available in other chapters of this textbook. Its relevance to inflammatory activation is a source of interest for this chapter. Earlier sections outlined changes in immune markers with ketamine therapy. Despite long-standing knowledge that ketamine is an antagonist at the NMDA receptor site, it is far from clear if its mechanisms are limited to NMDA blockade. Notably, ketamine reduces IDO activation and decreases the KYN/tryptophan ratio in the

CNS. Ketamine also stimulates the mammalian target of rapamycin (mTOR), which plays a major role in maintaining synaptogenesis. Intriguingly, ketamine has also been shown to reduce IL-6, TNF, and IL-1 levels in preclinical depression models. Furthermore, ketamine has been shown to reduce levels of NF-kB, the transcription factor that promotes inflammation in depression.

MINOCYCLINE. Minocycline is a microglial inhibitor and exerts anti-inflammatory effects in the brain by inhibiting the production of proinflammatory cytokines and reactive oxygen species released by microglia in the brain. In addition, minocycline is well known to decrease IDO activity and reduce the synthesis of neurotoxic KYN metabolites by microglial cells. An early study reported that oral intake of minocycline 100 mg twice a day significantly reduced depression severity in a group of subjects with HIV infection. Subsequently, minocycline 150 mg/day in combination with antidepressants was reported as effective and well tolerated in the treatment of unipolar psychotic depression. However, despite evidence of the efficacy of minocycline in depressed patients with a CRP >3 mg/L, oral minocycline at similar doses was not found to reduce TSPO labeling in major depressive disorder. Several recent studies have evaluated the efficacy of minocycline in treating depression and other mental disorders with disappointing results (to be discussed under bipolar disorders). Similarly, recent large-scale efforts to examine the effect of minocycline in treating bipolar depression have not yielded meaningful results.

Antidepressant Effect on Cytokines

PRECLINICAL. *In vitro* analyses of human blood samples have yielded variable findings that are difficult to interpret, depending on the antidepressant used. Venlafaxine decreased IL-6 and sertraline increased IFN-alpha and IL-6, both associated with decreases in NF-kB activity. Both imipramine and fluoxetine decreased the release of TNF and IL-1 by rat glial cells subjected to immune stimulation using in vitro application of LPS mediated by decreases in NF-kB activity. Amitriptyline led to decreases in serum levels of IL-1 and TNF in preclinical peritonitis models by decreasing nitric oxide production. Paradoxically, citalopram increased the production of IL-1, IL-6, TNF, and IL-22; mirtazapine increased IL-1, TNF, and IL-22; and escitalopram decreased IL-17 production by immune-stimulated T and B lymphocytes from depressed individuals. Reviews on this area attributed the high variability to the type of drug used and the method of immune stimulation used. However, it does appear that antidepressants as a class may converge on the intracellular immune signal transduction pathways mediated by NF-kB.

CLINICAL STUDIES. Measures of plasma inflammatory markers from clinical samples of treated depressed subjects have also added to our understanding. An early meta-analysis failed to support a universal relationship between antidepressants and immune markers. Instead, there was a class-specific effect with SSRIs impacting IL-6 and both SSRIs and TCAs impacting IL-1. A recent meta-analysis of 35 longitudinal clinical studies using plasma measures of cytokines reported net decreases in IL-6 levels resulting from antidepressant treatment.

Schizophrenia

Innate Immune Changes in Schizophrenia. Increased inflammation is generally not associated with the development of positive psychotic symptoms such as those encountered in schizophrenia. Studies using circulating immune marker assays do not help distinguish schizophrenia from affective disorders. A meta-analysis of over 85,000 people found modest but reliable increases in CRP among schizophrenic subjects. Furthermore, CRP levels were moderately increased in persons with SZ independent of antipsychotics or the course of the illness (first episode vs. progressive illness), and an increase in peripheral CRP levels paralleled the increase in severity of positive symptoms but not negative symptoms. However, a more inclusive meta-analysis reported that elevated plasma levels of two cytokines (IL-6, TNF), one soluble cytokine receptor (sIL-2R), and one cytokine receptor antagonist (IL-1RA) were increased in acute schizophrenia, bipolar mania, and major depression. Finally, a recent meta-analysis confirmed the relationship between increases in inflammatory markers (IL-6, IL-8, and IGg/albumin ratio) in the CSF of patients with schizophrenia and affective disorders. These authors pointed to the difficulty in arriving at a firm conclusion due to bias and poor control of confounding factors. However, another meta-analysis controlling for variability and confounders indicated moderate effects for IL-6, IFN-gamma, and IL-17 (Hedges g 0.3 to 0.6 for mean differences). Finally, a meta-analysis of studies examining translocator protein (TSPO)-PET binding in schizophrenia reported moderate elevations in TSPO tracer binding in grey matter relative to other brain tissue in schizophrenia when using binding potential as an outcome measure, but no difference when the volume of distribution is the outcome measure. Thus, variability in marker estimations, bias in sample selection, and poor selection of confounding factors cloud the picture. However, studies of first-episode psychosis have yielded more consistent findings. A recent meta-analysis using 3,453 drug-naive first episode versus 4,152 control subjects reported that elevated IL-6, IL-8, and TNF were seen among first-episode psychotic subjects. Given the rarity of reports on first-episode subjects, this approach of pooling across multiple studies may be the most pragmatic approach.

Adaptive Immune Changes in Schizophrenia. A detailed discussion of the adaptive immune cell change in schizophrenia is beyond the scope of this chapter. The findings are often variable and contradictory. However, all these studies underline that alterations in T and B lymphocytes and other adaptive immune cells may be integral to the pathology of some patients with schizophrenia. An increasing cytotoxic, proinflammatory bias (as opposed to regulatory T-cell activity) is noted in the peripheral blood of susceptible individuals. Intriguingly, the pathology of B lymphocytes may be related to the expression of autoimmune encephalitis linked to psychotic symptoms. In addition, transcriptional profiling of postmortem brain specimens from individuals with schizophrenia indicated that genes associated with innate immune (cytokine, chemokines), postsynaptic signaling, and glutamate pathways were enriched. Other studies have reported upregulated expression of microglial activation, cytotoxic lymphocyte infiltration, and IgG deposition.

Maternal Immune Activation. While human studies have demonstrated the statistical link between exposure to maternal inflammation in schizophrenia, animal studies have revealed that exposure to chronic maternal inflammation is associated with persisting brain morphology and functional changes in the offspring. For example, various immune stimuli (activating both antiviral and antibacterial immunity) administered to pregnant lab animals result in aberrant developmental trajectories comparable to schizophrenia in the offspring. These behavioral deficits include deficient social interaction, repetitive and stereotyped behaviors, poor working memory, impaired executive functioning, and impaired sensorimotor gating as assessed via prepulse inhibition. In addition, some pathogenic viruses may act by triggering cell-death cascades in dopaminergic neurons, resulting in fluctuating DA levels and behavioral symptoms of schizophrenia. Multiple epidemiologic studies have linked *in utero* exposure to infectious pathologies with the development of schizophrenia later in life. Prenatal infections that have been associated with schizophrenia include rubella, influenza, and toxoplasmosis. Similarly, obstetric complications, gestational diabetes, and severe physical or psychosocial stressors (e.g., famine, war, psychological trauma, maternal depression) can increase maternal inflammation, which in turn predicts the development of schizophrenia. Maternal cytokines, including IL-8, are also significantly increased in pregnancies leading to the development of schizophrenia. For example, fetal exposure to increases in IL-8 was associated with significant increases in ventricular CSF, significant decreases in left entorhinal cortex volumes, and significant decreases in right posterior cingulate volumes among subjects who developed schizophrenia later in life. In addition, elevations in maternal TNF have also been linked to the later development of schizophrenia. Intriguingly, strategies to block inflammatory cytokines such as IL-1, IL-6, and TNF reduced the risk of behavioral and cortical deficits associated with schizophrenia-like behavior in laboratory animal models. Similar results have been obtained by strategies that increase the synthesis and release of the anti-inflammatory cytokine IL-10 in animal models using poly IC. Thus, schizophrenic disorders in some subjects may represent the outcome of immune activation and inflammatory pathologies in the developing brain.

Autoimmune Psychosis. A study using the Danish National Registry reported that previous history of autoimmune disorders increased the risk of later schizophrenia by 29% and a history of hospitalization for infection increased the risk to 60%. Furthermore, when autoimmunity was combined with infection, the risk of subsequent schizophrenia increased by 125%, even after controlling for confounding factors. In this context, the role played by autoimmunity in promoting risk for psychosis has been emphasized. More specifically, pathologic activation of neurotransmitter receptors by adaptive immune response has offered a possible avenue to study immune dysregulation in psychosis. The most dramatic presentation involves the clinical and laboratory features suggestive of autoimmune

NMDA receptor encephalitis. Autoimmune encephalitis is best diagnosed in the presence of clear neurologic features, including seizures, cognitive dysfunction, or movement disorders. In addition, these patients have pathogenic antibodies that target surface epitopes on synaptic and related proteins—principally the NMDA receptor system, voltage-gated potassium channel (VGKC)-system, leucine-rich-glioma inactivated (LGI)-1, and contactin-associated protein-like (CASPR)-2 systems. A detailed description of these syndromes and pathologies is provided elsewhere. Identification of receptor-specific antibodies on activated lymphocytes and characteristic protein bands in the CSF may be of diagnostic value. MRI findings, including medial temporal hyperintensities on T2-FLAIR images and increased or decreased uptake of FDG-PET in temporal and parietal regions, have also been reported. Finally, EEG changes, including diffuse slowing, intermittent rhythmic delta or theta activity, or overt epileptogenic activity, have been used in the diagnostic workup of these disorders.

Even though the study of neuroimaging and EEG markers indicates a specific vulnerability of medial temporal regions in the disease process, clinical evaluation remains the cornerstone in the diagnosis of these disorders. If the antibody activity is associated with an occult tumor (such as a thymoma), its removal may help alleviate the symptoms. In addition, immunotherapies such as plasma exchange, immunoadsorption, or intravenous immunoglobulins have all been tried with varying levels of success. Immunosuppressive therapies such as high-dose steroids, methotrexate, or azathioprine have also been used in acute treatment. Anti-CD20 agents that reduce B lymphocyte activity, such as rituximab, have also met with some success. Finally, there may be a role for the modulation of the IL-27 system by altering the function of Th27 cells.

Immune Therapies for Schizophrenia. The reader is referred to extensive meta-analyses and reviews on this area. This section will provide a summary of this burgeoning area of research. In general, most studies have found modest benefits of add-on anti-inflammatory agents in treating psychotic disorders. However, sophisticated meta-regression analyses indicated that smaller studies with limited samples exerted substantially larger effect sizes, diminishing the confidence of pooled estimates

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS. Two initial studies that used high doses of aspirin (1,000 mg/day) for 3 to 4 months demonstrated modest efficacy with an effect size of ~0.30. However, this is an area that raises significant risk versus benefit concerns. Furthermore, aspirin may not readily cross the BBB and is well known to have off-target effects in reducing hypothalamic–pituitary–adrenal (HPA) axis activity. The studies that used celecoxib 400 mg/day for 5 to 11 weeks yielded low effect sizes (0.15) in the treatment of schizophrenia. Thus, the use of NSAIDs is not well supported in the literature.

ESSENTIAL FATTY ACIDS. In addition to neuroprotective effects, omega-3 fatty acids such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) have moderate anti-inflammatory effects on IL-1, TNF, and IFN-gamma. Daily doses of fatty acid with the EPA doses ranging from 0.5 to 4 g combined with DHA doses of 0.4 to 2.2 g have been studied for durations of 8 weeks up to 2 years. Most studies point to mild benefits with an effect size of 0.23. Nevertheless, some subjects may likely benefit from the addition of essential fatty acids.

ESTROGENS. It is well known that estrogens modulate immune activation through a variety of mechanisms. Some proposed mechanisms include increasing antioxidant capacity, improving glucose homeostasis, and possibly decreasing DA dysregulation. Estrogen doses ranging from 0.05 mg per day to 2 mg per day have been tried with some benefit. Pooled effect sizes have ranged in the 0.5 range among both female-only and bisexual groups. However, other risks from chronic estrogen therapy, such as increases in cancer risk, may need to be balanced against the benefits.

MINOCYCLINE. Minocycline has been reported to have benefit in some studies. However, a large study reported substantially negative results, limiting the confidence in prescribing minocycline. In addition, given its antibiotic characteristics, adverse effects on the microbiome have led to concerns about its widespread use. Therefore, much more evidence is necessary before recommending the use of minocycline.

N-ACETYLCYSTEINE. N-acetylcysteine (NAC) is a well-studied antioxidant molecule that may have a modulatory effect on inflammation, oxidative stress, and glutamate metabolism and can potentially cross the BBB.

Doses in the range of 600 to 3,600 mg/day have been used for periods ranging from a few weeks to a year. Its efficacy in chronic schizophrenia is similar to other immunomodulatory interventions with effect sizes in the ~0.4 range. A greater utility may be seen in first-episode schizophrenia. However, we note that there are few studies of first-episode subjects, and more data will need to be acquired before confidently prescribing this agent.

DRUGS TO TREAT METABOLIC SYNDROME. Metabolic syndrome and diabetes are commonly associated with increases in proinflammatory activity. Targeting metabolic dysregulation using regulators of glucose metabolism has been proposed as a viable strategy to reduce immune activation in some psychotic patients. Pioglitazone is a peroxisome proliferator-activated receptor (PPAR)-gamma inhibitor with anti-inflammatory activity and glucose-regulating effects. Pioglitazone has been shown to demonstrate beneficial effects on the course of schizophrenia in one study. Similar experiences with modulators of insulin sensitivity, such as metformin, have also been reported. Finally, modulators of lipid metabolism, such as statins, have also targeted inflammatory activation in some cases. Limited trial data indicate that statins may confer modest benefits in targeting schizophrenic symptoms. One should note that metabolic syndrome, diabetes, and lipid dysregulation are all common among schizophrenic subjects where the mainstay treatment, atypical antipsychotics, are well known for their contribution to these pathologies. Thus, it is highly likely that subjects will be exposed to these medications at some point during their lifetimes.

Bipolar Disorder

The link between immune activation and bipolar disorder has generally followed research on the links between inflammation and major depression. Several studies on major depression have included both unipolar and bipolar depressions. Accordingly, the increases in circulating inflammatory markers, activation of the KYN pathway, and inflammation-associated dysregulation in glutamate and DA systems have been all reported in bipolar disorders. However, this notion may have been oversimplified, and differences may exist in the pathophysiology of these two disorders.

Bipolar versus Unipolar Differences. For example, both unipolar and bipolar subjects may experience greater increases in inflammatory Th1 with concurrent decreases in anti-inflammatory Th2 and Th17 cells. However, while the T-cell imbalance persisted in MDD, they may be temporarily restored in BD until the next relapse. Indeed, gene expression studies indicate that increased expression of inflammatory genes precedes the onset of clinical symptoms but subsides following symptomatic remission in BD (as opposed to unipolar depression). The precise mechanism that underlies these differences is not clear. However, the common risk in proinflammatory gene activation shared by both MDD and BD may be related to environmental factors such as childhood adversity, age of onset, duration of illness, and frequency of episodes.

Staging or Neuroprogressive Models. Each recurrence or relapse of bipolar disease increases the risk of subsequent episodes, each with greater severity, a poorer likelihood of remission, and greater cognitive/neurologic dysfunction—a process referred to as kindling. This empirical model is referred to as the “staging or neuroprogressive model.” Immune dysfunction has been invoked as a possible etiologic factor in promoting kindling. Intriguingly, much of the data supporting the neuroprogressive model has been focused on innate immune factors. Two recent meta-analyses examined the association between plasma CRP and bipolar disorder. The first study reported that plasma CRP concentrations were substantially elevated during acute manic episodes and moderately during euthymia but not depressed periods. The second study reported increases in plasma CRP to be elevated during all three phases of illness—mania, depression, and euthymia. Increased circulating levels of inflammatory markers, including TNF, IL-6, soluble receptor antibodies for IL-1 (IL-1RA), and sIL-2R, have been associated with acute bipolar symptoms in some but not all studies. One recent study reported that circulating TNF markers may partially mediate the association between prior severe mood episodes and executive dysfunction in BD.

Allostasis and Neuroprogression. It has been proposed that chronic immune activation following repeated episodes of BD may result from increasing “allostatic load.” Briefly, allostatic load represents a buildup of the adaptive costs of chronic, recurrent stress. More work remains to be done to understand how recurrent episodes increase the allostatic load, contribute to brain pathology, and promote cognitive dysfunction.

Immune System and Bipolar Psychopharmacology. Several immunotherapies have been examined in clinical trials. However, the data should be interpreted very cautiously due to the small number of studies, small sample, and diversity of agents used. A summary is presented below.

N-ACETYLCYSTEINE. A major pathway to neuroprogression may involve the activation of oxidative stress by immune molecules. As a co-adjuvant agent, NAC has shown positive results in all phases of bipolar disorder, including acute treatments. An earlier study demonstrated that NAC treatment resulted in ~8 point reduction in the Montgomery–Asberg rating scale for depression. Subsequent studies have reported conflicting results. A recent study comparing NAC, NAC plus aspirin, aspirin, and placebo reported a better response rate for NAC plus aspirin than other groups. This area opens a promising new therapeutic target for the treatment of bipolar disorders.

CYTOKINE ANTAGONISTS. A major recent study examined the effect of adjunctive intravenous infliximab for treating bipolar depression with high inflammation. The elevated inflammatory load was defined using plasma CRP (>5 mg/L) or “phenotypic” inflammation (history of obesity, diabetes type I/2, inflammatory bowel disease, rheumatologic disorder, cigarette smoking, or migraine headaches). This study reported a negative result for infliximab compared with placebo. However, an association between infliximab responders and early life stress was reported demonstrating subgroup effects within the larger cohort. This study reinforced the value of narrowly defining inflammation based on immune markers. Of note, a recent meta-analysis that summarized this nascent area of research indicated that cytokine antagonists as a group were moderately beneficial through targeted group selection.

OMEGA-3 FATTY ACIDS (DHA/EPA). Despite initial enthusiasm, several controlled studies investigating the use of omega-3 fatty acids in BD have trended negatively. While meta-analyses have indicated modest effect sizes, follow-up meta-regression studies indicated that studies with small samples strongly influenced the pooled effect size. Notably, studies using small samples or open-label design have demonstrated significant effects. To date, most of the studies have examined the efficacy of omega-3 fatty acids in the depressed phase of bipolar disorder. Thus, these findings require replication in larger samples.

MINOCYCLINE. An earlier meta-analysis reported a significant pooled effect size for the use of minocycline to treat bipolar depression. Subsequently, a large-scale study was conducted to examine the effects of anti-inflammatory agents in bipolar depression. The study compared varying combinations of aspirin 81 mg twice a day, minocycline 200 mg twice a day, and placebo. The aspirin plus minocycline group demonstrated significant improvement in clinical endpoints along with a significant three-way interaction between the two drugs and plasma IL-6. While these effects indicate possible beneficial effects of minocycline, these authors clarified that the effect of remission might have been primarily driven by aspirin, as both arms with aspirin benefited most. However, a large-scale study described earlier did not indicate the benefit of either celecoxib or minocycline or their combination. Thus, more investigation is required to enable clinicians to determine risk-benefit considerations.

PIOGLITAZONE. Proof-of-concept studies have indicated an antidepressant efficacy of pioglitazone in the acute treatment of bipolar depression. However, larger clinical trials may be necessary to establish the risk benefit of pioglitazone, which has a substantial side effect burden.

Anti-Inflammatory Effects of BD Treatments. Antimanic medications such as lithium are known to exert a variety of anti-inflammatory effects. Some of the anti-inflammatory effects attributed to lithium include attenuation of COX-2, inhibition in the synthesis of IL-1, and inhibition of NF k-B. The latter effect is believed to be mediated via the effects of lithium on glycogen synthase kinase (GSK)-3 beta. Furthermore, lithium may also decrease microglial activation and expression of TLR-4. In addition, valproate may also inhibit the same site—TLR-4.

Conclusion. So far, the psychopharmacologic trials of anti-inflammatory agents to treat bipolar disorder have progressed in tandem with the advances in our understanding of the staging model. In general, moderate effect sizes ~0.4 have been reported suggesting moderate antidepressant effects across a wide range of anti-inflammatory medications. However, most studies did not stratify patients based on inflammation. Thus, more studies are required to address the utility of immune-modifying agents on bipolar mania and upon the course of illness specifically in the context of increased inflammation.

Autism

Immune dysregulation in autism is believed to result from a confluence of prenatal and postnatal risk factors. Maternal immune activation (MIA) resulting from maternal infections and presence of maternally derived antibrain autoantibodies found in ~20% of mothers constitute some of the prenatal risk. The postnatal environment on the other hand is characterized by somewhat distinct profiles of immune dysregulation, inflammation, and endogenous autoantibodies.

Autism has been associated with several immune abnormalities, including unbalanced Th1/Th2 cytokine production, reduced NK and T-cell activation, and increased TNF and IL-12, especially in patients with comorbid gastrointestinal symptoms. In addition, patients with autism exhibit increased autoimmune-based genes, including HLA-DR-Bβ1*04 and the complement C4B null allele. More recent meta-analytic studies in autism spectrum disorders report increased circulating concentrations of IL-1, IL-6, IL-8, IFN-gamma, and MCP-1 and reduced anti-inflammatory cytokine TGF-beta. Still, while a convincing case can be made for a significant immune component to autism, the relationship of immune abnormalities to the neurobehavioral symptoms of the disease remains controversial. In this context, recent epidemiologic studies have not substantiated the claim that childhood vaccines trigger autism, and immune-based therapies for autism have not been reliably effective. However, a large epidemiologic study from Denmark found that *in utero* exposure to maternal influenza infection was associated with a twofold increased risk of autism, while prolonged episodes of maternal fever increased the risk by threefold. Similarly, maternal autoimmune diseases have been shown to increase the risk of autism in children by 34%.

Animal studies also support the possibility that inflammatory activation either in utero or early in life may increase the risk for autism. For example, exposure of pregnant macaques to low-dose LPS resulted in significantly increased brain volume in the affected offspring, a finding repeatedly observed in human children with autism. As stated earlier, it is increasingly recognized that immune processes play central roles in brain development. Perhaps the most striking example of the power of immune processes to guide and disrupt neural development in ways relevant to autism comes from a mouse model of MIA that produces various behaviors in offspring relevant to autism in humans. Prenatal immune stimulation reduced the number of circulating anti-inflammatory Th2 type T-regulatory cells while increasing IL-6 and IL-17 production by Th1 type cells. Transplantation of immunologically normal bone marrow cells into MIA offspring whose native immune cells had been ablated using irradiation reversed autism-like behavioral changes.

Other Disorders

Far less attention has been given to the role of immunity in general, particularly inflammation in the pathogenesis of neuropsychiatric conditions other than major depression, bipolar disorder, schizophrenia, and autism. Nonetheless, increasing evidence suggests that increased inflammation is a hallmark of nearly all types of psychiatric disturbance. Indeed, it is intriguing that no currently defined psychiatric condition has been reliably associated with reduced levels of inflammatory biomarkers.

Post-Traumatic Stress Disorder. Given the well-characterized relationship between stress and the immune system, it is easy to extrapolate that a similar relationship would exist between PTSD and inflammatory activation. Compared with healthy controls, PTSD patients had significantly higher IL-1, IL-2, IL-6, IFN-gamma, and TNF-alpha with moderate to strong pooled effect sizes. Less strong associations were noted between PTSD and CRP and WBC counts. Intriguingly, these studies noted no relationship between PTSD and adaptive immune system or anti-inflammatory cytokines. Individuals exposed to childhood trauma had significantly elevated baseline peripheral levels of CRP, IL-6, and TNF-alpha. Subgroup analyses for specific types of traumas (sexual, physical, or emotional abuse) revealed that the type of trauma impacts individual inflammatory markers differentially. Age, BMI, and gender had no moderating effects. A large-scale study reported that plasma CRP might be prospectively associated with PTSD symptom emergence, suggesting that inflammation may predispose to PTSD. A more recent study highlighted a bidirectional genetic association between PTSD and CRP, also suggesting a potential role of socioeconomic status in the interplay between childhood support and inflammatory processes with respect to PTSD risk. Despite considerable heterogeneity, these recent studies have reported an association between PTSD and peripheral inflammation cross-sectionally and longitudinally. In addition, immune stimulation using endotoxin is associated with a more robust inflammatory response in subjects with PTSD, mediated via increased expression of NF-kB. The role of immune factors in fear learning and fear extinction mechanisms has been of recent interest. It has been demonstrated that inflammation-associated impairment in synaptic plasticity of fear extinction circuitry may underlie the behavioral dysfunction in PTSD. Much more work remains to be done to clarify these hypotheses. In addition, increased inflammation has been associated with decreased connectivity between reward-related brain regions and anhedonia in trauma-exposed women with PTSD symptoms, further emphasizing the consistency of effects of inflammation on the brain across disorders and related to motivation.

Comparing stress-related disorders such as depression and PTSD indicate that stress-induced immune pathophysiology is complex, heterogeneous, and defies simplistic explanations. Data from the two well-known stress-related disorders, that is, depression and PTSD, has shown differential associations between peripheral and central neuroimmune activation profiles. Despite well-documented increases in peripheral inflammation in PTSD, decreased binding of TSPO in prefrontal–limbic regions and decreased in microglial activation markers in postmortem brain specimens in transcriptomic analysis point to a delinking the central–peripheral immune responses. Thus, it is likely that the microglial response varies with the underlying psychopathologic syndromes.

OCD. Pediatric autoimmune neuropsychiatric syndromes associated with streptococcal infections (PANDAS) such as Sydenham chorea result from antineuronal antibodies induced by group A beta-hemolytic streptococcal infection. Children with Sydenham chorea frequently exhibit obsessive-compulsive symptoms, and sudden onset of OCD, tics, emotional lability, hyperactivity, and ADHD have been described among children following infection with group A beta-hemolytic streptococcus. Moreover, children with repeated streptococcal infections exhibit higher distal choreiform movements and behaviors consistent with ADHD. Interestingly, recent data suggest that OCD more generally may also be associated with increased levels of several cytokines, including TNF, IL-6, and IL-1.

Neuro-Covid

NEUROLOGIC SYMPTOMS

Pathology. Severe pathologies induced by SARS-CoV-2 are the result of an exaggerated host immune response than the extent of the infection. The host immune response can include an exaggerated activity of both innate and adaptive immune systems, although increased innate activity has been decisively linked to acute mortality from COVID-19. Specific neurologic syndromes consistently reported include anosmia, encephalopathy, and stroke. In addition, recent data implicate activation of intracellular inflammasome pathways and KYN system activation in perpetuating short- and long-term SARS-CoV-2 brain pathologies.

Anosmia/Ageusia (Loss of Taste). SARS-CoV-2 infection does not directly infect olfactory neurons in the nasal mucosa but instead causes significant infection of the olfactory neural supporting cells known as sustentacular cells. Specific vulnerability of sustentacular cells can result from the expression of angiotensin-converting enzyme (ACE) -2 receptors and surface expression of transmembrane serine protease two that facilitates viral entry. SARS-CoV-2 has not yet been demonstrated to infect the brain directly; few viral proteins were detected in the brain parenchyma. However, the hypothesis that anosmia may result from impairment of olfactory bulb function has been effectively replicated in animal models. Neuroimaging studies have indicated increased hyperintensity and swelling of the olfactory bulb consistent with acute inflammation, which resolved during subsequent follow-up. Anosmia and loss of taste are common following mild infections but persist for longer durations.

Delirium and Altered Mental Status. Encephalopathic changes underlie the development of delirium among hospitalized SARS-CoV-2 infections. Elevated plasma and CSF levels of cytokine and neurofilament light chain proteins (generated from the breakdown of fibrils in large-caliber nerve fibers) correlate with pathologic and behavioral changes among acutely confused patients. In addition, overactive astroglia was seen in widely distributed cortical regions among the very ill. Region-specific increases in microglial and cytotoxic T-cell activity have also been related to SARS-

CoV-2 infections. Inflammasome and KYN pathway activation may underlie some, if not all, of the SARS-CoV-2.

Stroke. Profound inflammatory response involving the endothelium of cerebral blood vessels resulting in strokes, hemorrhages, and disseminated encephalopathies are frequent during acute phases of the infections. This is attributed to the enrichment of ACE receptors on cerebral endothelial cells, which are the primary portals of entry for SARS-CoV-2. Stroke remains the most damaging and life-threatening of neurologic COVID-19 pathologies. Large vessel cryptogenic strokes complicated by hemorrhagic transformation have been reported. In addition, progressive microvascular changes associated with chronic white matter pathologies associated with cognitive and psychiatric symptoms have also been noted.

Behavioral Syndromes. The data on psychiatric manifestations of SARS-CoV-2 infections are emerging. Hence, only a preliminary overview of the encountered syndromes will be presented below. Current information on the neuropsychiatric sequelae of SARS-CoV-19 infection is based on cohorts of seriously ill hospitalized patients. However, the reader must remember that many infected individuals experienced mild to moderate infections that did not lead to hospitalization.

Cognitive Difficulties. Subjective cognitive difficulties described as “mental fog” are among the commonest self-reported symptoms following SARS-CoV-2 infections, especially among nonhospitalized subjects. The symptoms are characterized by decreased attention, concentration, and possibly impaired memory symptoms. Complaints of subjective cognitive symptoms are more frequent during the acute phase of the illness, and it is not yet clear if these symptoms will persist over a longer follow-up period.

Fatigue. Fatigue is common after several viral infections such as Epstein–Barr virus infections and SARS-CoV-2 infections resemble many of them. Pathologic overlaps between myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS) are an area of active investigation.

NEUROPSYCHIATRIC SYMPTOMS. Neuropsychiatric symptoms have been examined in recent meta-analytic reviews. During the acute phase included depressed mood (33%), anxiety (36%), impaired memory (34%), impaired attention concentration (38%), insomnia (42%), and confusion (28%). The cognitive symptoms appeared to be independent of the age of the samples. Upon follow-up, the point prevalence of anxiety disorder diagnoses was 14.8% (mean follow up of 11.6 months), depression was 14.9% (mean follow-up of 22.6 months), PTSD was 32.2% (mean follow-up of 33.6 months). Unfortunately, reports of period prevalence have not yet been published. However, symptom severity scores indicated mild to moderate anxiety and depression scores during follow-up. In addition, some papers noted greater severity of PTSD symptoms, especially in terms of intrusion, avoidance, and hyperarousal symptoms. Several subjects also reported poor subjective quality of life, including mental well-being. On the contrary, several subjects also reported positive emotions, including gratitude to support and appreciation for the value of life and relationships.

SARS-COV-2 INFECTION AMONG MENTALLY ILL. The likelihood of a positive test was 22.3% for the schizophrenia spectrum group, 25.4% for the mood disorder group, 24.1% for the anxiety disorder group, and 28.2% for the reference group. However, 22% to 25% of subjects diagnosed with schizophrenia, mood, and anxiety disorders were positive for SARS-CoV-2 using a medical record–based study. In addition, a premorbid diagnosis of a schizophrenia spectrum disorder was significantly associated with 2.67 times increased mortality following SARS-CoV-2.

PSYCHOTROPICS AND ANTI-COVID TREATMENTS. Given the high risk of SARS-CoV-2 exposure among the mentally ill, it would be helpful to review some risks of combining psychotropics with outpatient anti-COVID medications. The most notable development in the treatment is the temporary approval of antiviral combination medications (Paxlovid, Pfizer Inc.) for acute SARS-CoV-19. The drug is composed of two agents, nirmatrelvir and ritonavir, the latter being a powerful inhibitor of the P450 (CYP) 3A4 system. Medications such as carbamazepine and herbals such as St. John’s wort can decrease the efficacy of Paxlovid. Risk of serious toxicity are likely with clonazepam, diazepam, clobazam, estazolam, flurazepam, clozapine, lumateprone, lurasidone, quetiapine, and pimozide. It is recommended that these medicines be discontinued before initiation and not resumed till 3 days after the conclusion of Paxlovid therapy. Drugs with potential interaction include trazodone, aripiprazole, haloperidol, iloperidone, risperidone, alprazolam, buspirone, and flunitrazepam. It has been recommended that Paxlovid should not be initiated unless these agents can be safely discontinued if necessary. Finally, agents with possible risks include ziprasidone and zolpidem. The recommendations include fully counseling patients to discontinue these agents if they feel unwell.

FACTORS ASSOCIATED WITH IMMUNE ACTIVATION IN PSYCHIATRY

Multiple individual variables impact immune–brain communication in a variety of psychopathologic states. Several of these factors, such as social adversity, stress, and health status, have been discussed under appropriate headings. However, some factors transcend disease categories and are reviewed below.

Aging

Aging is paradoxically associated with a deteriorated immune defense (immunosenescence) and increased basal levels of tissue inflammation (inflammaging). Inflammaging is associated with the exaggerated inflammatory response of innate cells. This change results in an increased or exaggerated inflammatory activity at baseline and in responding to immune stimulation. Paradoxically, this exaggerated immune response is less efficient in fighting pathogens or mounting immune responses to immunizations. This exaggeration in inflammation often results from phenotypic changes in immune cells such as macrophages and monocytes, resulting in increased secretion of cytokines such as TNF, IL-6, and IL-1, and chemokines such as MCP-1, leading to increased synthesis of CRP. Notably, microglial cells in the brain also develop a similar exaggeration in the immune-response profile. In addition, recent studies indicate that astroglial cells also transform into a hypersecretory phenotype that can amplify and exaggerate brain immunity. The precise meaning of these increases in age-associated inflammatory cell changes is far from clear.

One possible explanation is that immune cells undergo “priming” by the age-associated accumulation of spontaneously mutating neoplastic cells or misfolded proteins such as beta-amyloid or alpha-synuclein. In addition, other brain insults incurred during the long human lifespan may also play a contributory role. Some of these include chronic cerebrovascular disease, diabetes, obesity, and intermittent episodes of traumatic brain injury. The exaggerated immune response of primed cells may help partially neutralize threats but may lead to other unintended consequences via “collateral” tissue damage. For example, it is well known that chronic immune activation in healthy and chronically depressed individuals may be associated with a wide array of age-associated chronic medical disorders.

There are two divergent views on understanding innate immune activation in age-associated brain disorders. One perspective emphasizes that priming and inflammatory bias of glial cells is conducive to more efficient removal of cellular debris and misfolded proteins and may serve a valuable purpose. The contrarian view holds that exaggerated immune cell activity in the brain may lead to greater neuronal loss and neurodegeneration. While there may be truth in both views, much more research will be necessary to understand the biologic meaning of these changes. Of note, most if not all inflammatory changes in major depression are exaggerated among older depressed patients.

The adaptive immune response is decreased with aging. The precise nature of adaptive immune changes with aging is even less well understood. However, recent studies indicate that the decline in adaptive immune responses may result from increased “checkpoint” regulation, thus suppressing adaptive immune activity, beneficial to clearance of amyloid and other debris. Thus, the recent development and discovery of checkpoint inhibitors may one day improve brain health and prevent disorders such as AD.

Nutrition, Obesity, and Activity

Obesity, defined as BMI greater than 30 kg/m^2, represents the commonly encountered threat to neuroimmune homeostasis. A two-way association between the immune system and glucose/lipid management systems has been consistently reported. Obesity/high BMI is reliably linked with chronic low-grade increases in inflammatory activity measured using proinflammatory markers such as CRP and IL-6. This universal association is common to all population categories, especially the mentally ill. It is well known that adipocytes in abdominal fat pads recruit inflammatory proteins and cells that generate chronic inflammation.

On the other hand, immune molecules also may cause weight gain. Recent data have indicated that inflammatory molecules reprogram cellular glucose metabolism and promote insulin resistance, hyperglycemia, and hyperlipidemia, thus promoting metabolic syndrome. Reinstatement of TLRs in genetically null mice (TLR-null mice) leads to rapid weight gain following a high-fat diet. In addition, chronic sympathetic activation resulting from stress leads to gene expression changes among tissue macrophages in brown adipose tissue, leading to aberrant thermogenesis and weight loss.

Lifestyle modifications geared toward weight reduction generally result in a reduction of chronic inflammatory activity. For instance, reduction in CRP and related cytokines are associated with "healthy" Mediterranean style diets and increases in CRP and sTNFR2 have been noted following intake of high transfat/high-caloric diet. Along similar lines, fitness-promoting activities and physical exercise are well documented to lower the proinflammatory molecules and their activity. Conversely, a sedentary lifestyle has been linked with significant increases in proinflammatory activity in several population groups, including the mentally ill. Furthermore, obesity tends to combine with other inflammation-promoting factors such as advancing age, stress, smoking/alcohol use, and chronic medical disorders to accentuate chronic inflammatory activity.

As stated earlier, increased inflammation may characterize a distinct subgroup of depressed subjects. Most recent formulations have concluded that the presence of obesity and early-life adversity may phenotypically identify a subgroup of depressed subjects with high inflammation. Improved response to L-methyl folate augmentation of antidepressant therapy was seen among subjects with high BMI and high inflammation. Similarly, several authors, including the previous edition of this textbook, had noted that the link between early life adversity and BMI is likely to be strong in and of itself. Thus, it may be very difficult to dissociate the effects of stress and BMI upon chronic inflammation among psychiatrically ill populations. Most studies of bipolar disorder indicate that high BMI, high-calorie diet, sedentary lifestyle, and lack of exercise are high-risk factors for poor treatment outcomes. It is most likely that inflammation is an underlying common link among these factors. Intriguingly, obesity and high inflammation are also common among first-episode psychotic patients. Though the relationship between psychosis, obesity, and inflammation is unclear, inflammation may be related to the disease process itself rather than obesity. In addition, links between PTSD and inflammation have been reported even after controlling for obesity.

These data indicate that obesity plays a substantial role in the etiology of chronic inflammation among mentally ill subjects. It may play a direct role in driving up the inflammatory status among patients. In addition, it may exacerbate the inflammatory potential of other disease mechanisms in disorders such as schizophrenia and PTSD and add to the proinflammatory potential of lifestyle factors such as inactivity, tobacco/alcohol use, and stress.

Microbiome

A detailed description of microbiota is beyond the scope of this chapter, and the readers are referred to reviews on this area. The collection of microorganisms associated within a certain location is called microbiota, and its collective genetic material is called the microbiome. The human body has a large amount of microbiota, mostly located in the gastrointestinal system. It has been stated that most of the genetic material found in the human body is made up of microbial genes. While some microbial invaders lead to profound immune stimulation, human microbiota is predominantly symbiotic and often does not stimulate host inflammatory responses. It is likely that the human gut hosts microbes from more than 60 genera. Recent advances in the analysis of microbial DNA have led to a better understanding of the influence of microbiota on various aspects of the host's brain health. Multiple modes of interaction between the brain, including synthesis of metabolites and neurotransmitters, activation of the vagus nerve, and activation of the anti-inflammatory arc of the immune system, have all been reported.

Colonization of the human gut microbiome begins at birth mostly by exposure to the maternal birth canal in natural delivery and the maternal skin in C-section. Other factors such as prematurity, breastfeeding, presence of pets, caloric intake, and obesity may all impact the developing microbiome. Dietary intake is believed to be an important factor in the regulation of the gut microbiome. For instance, a fiber-rich Mediterranean diet is associated with Prevotella species, while a high-calorie Western diet is associated with Bacteroides. There is a complex two-way relationship between the gut and brain. Significant preclinical data appear to support the notion that gut microbiota influence brain development and function. Intriguingly, there is emerging evidence that brain functions may also disrupt the microbiome. Stress alters the microbiota composition in various species, and probiotics have been shown to reverse the effects of stress in animal models.

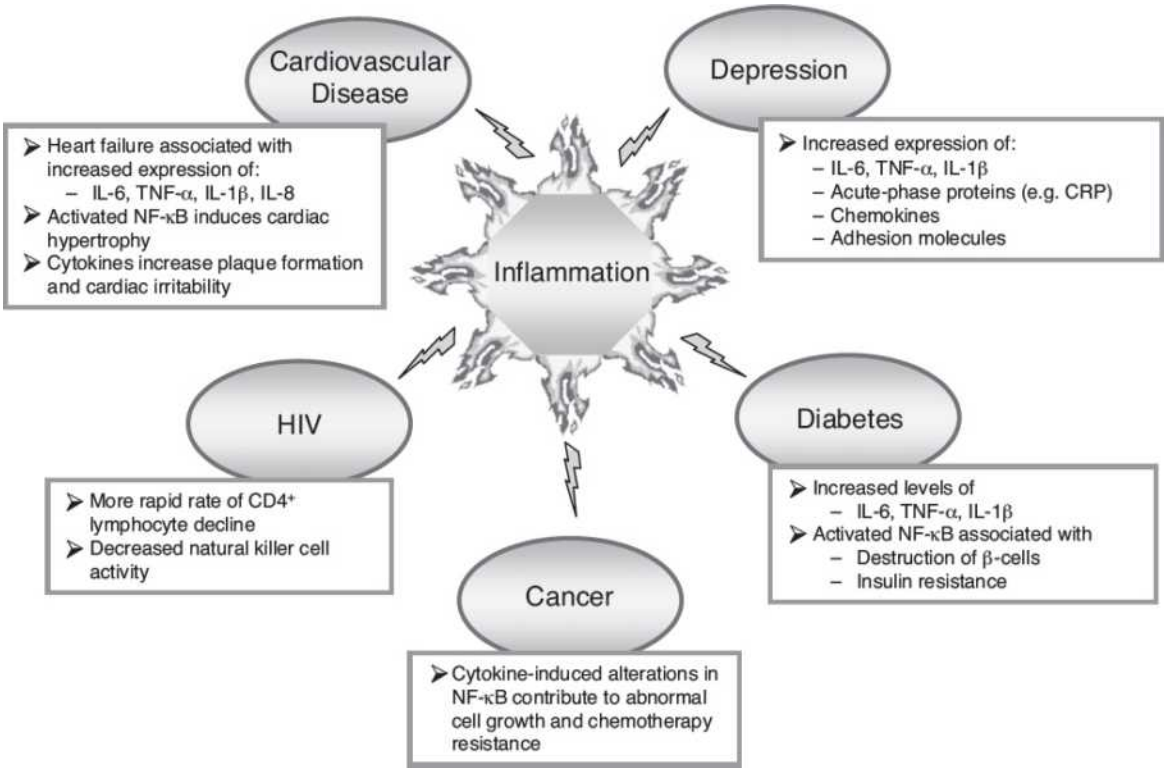
Reduced prevalence of Lactobacillus and Bifidobacterium species were noted among subjects with the first-episode psychosis. Importantly, differences in microbiota predicted severity of negative symptoms and quality of remission during follow-up. Differences in the oropharyngeal microbiome were also reported from schizophrenic subjects. Probiotic treatment yielded no perceptible clinical benefits, but it improves severe bowel problems in a group of subjects with schizophrenia. Differences in two separate genera of Firmicutes and a positive response to probiotic supplementation were noted in bipolar disorder.

The most compelling evidence implicating microbiome in psychiatric disorders comes from the study of depression. Preclinical data also indicate that probiotic and prebiotic therapies may reduce depressive behavior in rodent models. Multiple systematic reviews indicate that probiotics may improve mood in depressed humans. Notably, transplantation of the gut microbiome from depressed humans induced greater depressive and anxiety-like behavior in rodents. Several studies have noted altered microbial composition in depressed subjects with a reduction in the relative abundance of *Feacalbacterium* species that has been negatively correlated with the severity of depression.

In summary, the development of mental illnesses may be related at least in part due to the loss of immunomodulatory effects of microbiota. The precise mechanisms by which microbiota trigger or alter inflammatory pathologies are still unclear. However, it has been proposed that the balance between microbiota with pro- and anti-inflammatory biases may be disrupted during times of stress leading to an exaggeration of inflammation-promoting organisms. This change may result in possible activation of gastrointestinal mucosa leading to the release of inflammatory cells and microbial products directly into the systemic circulation. This “leaky gut” hypothesis has attracted considerable attention in the etiology of chronic inflammation in stress-related disorders.

Human-Microbial Symbiosis—“Old Friends” Hypothesis. Figure 1.13–6 depicts how evolutionary pressures and adaptation to our current living conditions may have resulted in heightened inflammatory bias. Studies have argued that genes promoting depression may have evolved and persisted in the human genome, at least partly because many physiologic and behavioral aspects of depression in ancestral environments may have enhanced host defense against pathogens. In addition to microbiota, two more classes of commensal organisms (pseudocommensals and parasites) are collectively referred to as “old friends,” that is, organisms living within humans that promote healthy immune function while suppressing proinflammatory activity. Some recent authors have hypothesized that modern environmental practices have disrupted human relationships with “old friends,” leading to an increased prevalence of immune-based pathologies common in industrialized societies than in more primitive environments.

Significant in vitro and in vivo preclinical data indicate that all three classes of “old friend” organisms (microbiota, pseudocommensals, and parasites) have the potential to prevent or ameliorate pathology in animal models for autoimmune, allergic, and inflammatory bowel diseases, as well as neoplasms and certain infections, and do so via reductions in inflammatory activity. Human–microbial and human–parasitic interactions in disease pathogenesis lead to the possibility that organism-based interventions may show promise if delivered early to prevent the development of schizophrenia, autism, and mood disorders.



Cardiovascular Disease
Heart failure associated with increased expression of:
– IL-6, TNF-α, IL-1β, IL-8
Activated NF-κB induces cardiac hypertrophy
Cytokines increase plaque formation and cardiac irritability
Depression
Increased expression of:
– IL-6, TNF-α, IL-1β
– Acute-phase proteins (e.g. CRP)
– Chemokines
– Adhesion molecules
Inflammation
HIV
More rapid rate of CD4+ lymphocyte decline
Decreased natural killer cell activity
Diabetes
Increased levels of
– IL-6, TNF-α, IL-1β
Activated NF-κB associated with
– Destruction of β-cells
– Insulin resistance
Cancer
Cytokine-induced alterations in NF-κB contribute to abnormal cell growth and chemotherapy resistance

FIGURE 1.13–6. Early evolutionary pressures derived from human interactions with pathogens, predators, and human conspecifics (such as rivals) resulted in an inflammatory bias that included an integrated suite of immunologic and behavioral responses that conserved energy for fighting infection and healing wounds, while maintaining vigilance against attack. This inflammatory bias is believed to have been held in check during much of human evolution by exposure to minimally pathogenic, tolerogenic organisms in traditional (i.e., rural) environments that engendered immunologic responses characterized by the induction of regulatory T (TReg) cells, regulatory B (BReg) cells, and immunoregulatory M2 macrophages as well as the production of the anti-inflammatory cytokines interleukin-10 (IL-10) and transforming growth factor-beta (TGFβ). In modern times, sanitized urban environments of more developed societies are rife with psychological challenges but generally lacking in the types of infectious challenges that were primary sources of morbidity and mortality across most of human evolution. In the absence of traditional immunologic checks and balances, the psychological challenges of the modern world instigate ancestral immunologic and behavioral repertoires that represent a decided liability, such as high rates of various inflammation-related disorders including depression. (Reprinted from Miller A, Raison C. The role of inflammation in depression: from evolutionary imperative to modern treatment target. *Nat Rev Immunol* 2016;16:22–34. doi: 10.1038/nri.2015.5)

Sleep

Disturbances in sleep rhythm and cycle are ubiquitous in the field of psychiatry. Most recent authors consider sleep as a transdiagnostic marker that transcends conventional psychiatric diagnostic boundaries. Given the large volume of data linking sleep and inflammation, the readers are referred to source papers on this area. Naturally occurring sleep regulates the immune system by controlling the production of inflammatory cytokines and the distribution of inflammatory cells. It is well known that sleep regulates the functioning of stress response systems, including the HPA axis and SNS. Methodologically rigorous studies that repeatedly sampled immune markers during natural sleep and states of sleep deprivation have yielded intriguing results. Systemic levels of IL-6 tend to peak between 7PM and 5AM, and nocturnal sleep may be the single deciding factor in the nocturnal increases of IL-6 and decreases in TNF during the night. Experimental sleep deprivation leads to decreased nocturnal IL-6 levels, delays the nocturnal peak in IL-6 secretion, and possibly attenuates TNF production by monocytes during the night. Subjects with sleep disturbances, including decreased duration of slow-wave sleep and increased duration of rapid eye movement (REM) sleep, demonstrate increased daytime IL-6 coupled with its decreased nighttime production. Finally, nocturnal sleep appears to increase concentrations of the soluble IL-6 receptor (sIL6-R) during nighttime, increasing its ability to influence neuronal cells that are not normally responsive to the effects of IL-6. In a large-scale meta-analysis, sleep disruption was associated with higher CRP and IL-6 in the plasma.

More critically, psychosocial stressors and adversity may impact inflammation by disrupting sleep efficiency and quality. The characteristic changes in sleep architecture in depression are classic examples of such a shift. It has been hypothesized that this shift in the sleep cycle may induce an inflammatory transcriptional state in the immune cells such as monocytes leading to altered patterns of release of cytokines such as IL-6 and TNF.

In contrast, increases in peripheral inflammation can also disrupt sleep. For example, viral and bacterial infections are well known to alter the balance between non-REM and REM sleep—an effect mediated by inflammatory cytokines. Neural sensors of inflammation located in the vagus nerve are believed to convey immune signals to the sleep centers in the brain. Thus, resection of the vagus nerve appears to abolish the effect of immune molecules on sleep rhythm. A key area of research involves the relationship between sleep disturbance and inflammatory aging (inflammaging). Notably, one night of partial sleep deprivation–induced genomic and transcriptional changes suggestive of accelerated aging and increased cellular senescence in immune cells. The early or premanifest stage of AD is associated with increases in neuroinflammation and sleep disruptions. It has been proposed that both these processes combine to cause disease progression in AD. The neuroinflammation is believed to result from primed microglia (microglia stuck in a state of persistent activation) exposed to amyloid and tau proteins. Thus, neuroinflammation and sleep deprivation worsen each other in a manner that may contribute to illness progression.

Of note, sleep disturbance also has a role in the risk of medical illnesses (such as hypertension and diabetes) and lifestyle factors (sedentary lifestyle and social isolation), and sleep disorders (sleep apnea, REM-sleep disorder), all of which may increase the risk of dementia. Finally, the relationship between sleep disturbances in depression has been well studied in the literature. Persistent insomnia remains a strong predictor of depression recurrence. Notably, recent studies indicate that depressive response to inflammatory stimuli such as endotoxin challenge may be amplified by sleep deprivation. Alternatively, the onset of sleep disturbance in subjects with pre-existing inflammatory disorders can often precipitate the onset of depression. Thus, the use of behavioral sleep therapies that appears to improve natural sleep (as opposed to sleep induced by hypnotic drugs) may offer a promising avenue to reduce the impact of sleep disturbance on the onset of depression.

CONCLUSIONS TO THE CHAPTER

Disrupted immune–brain communication in psychiatric disorders may represent the cumulative effects of a complex causal chain. However, despite their complexity, a good grasp of immune–brain communication pathologies can help us better target a host of potentially modifiable risk factors that can improve the lives of our patients.

1.14 Chronobiology, Circadian Rhythm, and Psychiatry

CHESTER WU, M.D., AND JOSHUA J. RODGERS, M.D.

Chronobiology is the study of biologic rhythms. Of the various periodicities that fall within the realm of chronobiology, *circadian* (Latin: *circa,* about; *dies,* day) rhythms that have a period of about 1 day and serve to synchronize cellular processes and behavior with the environmental day–night cycle are among the most extensively studied and best understood biologic rhythms. Circadian rhythms are evolutionarily conserved across nearly all known living organisms, a fact that suggests these rhythms are fundamental to adaptive functioning on this planet.

The site of the primary circadian oscillator in mammals, including humans, is the suprachiasmatic nucleus (SCN), located in the anterior hypothalamus just dorsal to the optic chiasm from which the afferent retinohypothalamic tract (RHT) separates (Fig. 1.14–1). Via local genetic feedback loops of relatively fixed timing, the SCN generates a circadian period of approximately 24.18 hours. Therefore, the master circadian clock must constantly adjust to being effective at maintaining the proper phase relationships of behavioral and physiologic processes within the context of the 24-hour day. The characterization of persons as owls or larks ("night person" or "morning person") comes largely from variations in genetically determined longer or shorter circadian period lengths, respectively.

Organisms have evolved to use time cues or *zeitgeber* (German: *zeit,* time; *geber,* giver) to adjust or resynchronize the endogenous circadian clock. One of the most critical zeitgebers is the daily variation in light levels. Changes in illuminance are sensed by a photoreceptive apparatus that resides in the retina in humans and is communicated to the SCN via the RHT. Other nonphotic zeitgebers include food/feeding, social interactions, temperature, substances (such as amphetamines), and exercise. Signals from these stimuli are relayed to the SCN from the thalamus and midbrain raphe.

The circadian clock modulates almost all human physiology, from the molecular level with transcription and translation to larger order metabolic and cognitive functioning. It does this by driving rhythms, including behavior, core body temperature, sleep, feeding, drinking, and hormonal levels.

Taken together, the circadian axis of mammals can be divided into three distinct functional components: (1) a master pacemaker situated in the SCN, (2) a photoreceptive input to the SCN that originates in the eye, and (3) the myriad of rhythmic outputs that provide insight into the clockwork of the circadian pacemaker.

CIRCADIAN PACEMAKERS

Anatomy

The mammalian circadian system is organized as a hierarchy of pacemakers. The SCN is the master oscillator that orchestrates a multitude of oscillators outside of the SCN. These oscillators are found in a wide range of peripheral tissues, including the kidney, liver, lung, and other sites in the brain. The SCN consists of two paired nuclei in the hypothalamus situated immediately dorsal to the optic chiasm (see Fig. 1.14–1).

The neurons of the SCN are among the smallest neurons in the entire brain. They are densely packed and possess short dendrites that are not extensively branched. Subdivisions of the SCN have been defined according to immunohistochemical and neural tract tracing criteria. These subdivisions include the *core* of the SCN, defined by the presence of calbindin-positive neurons. The remainder of the SCN that surrounds the core is the *shell.* Afferent and efferent projections to and from these subdivisions are beginning to provide insights into their putative functions.

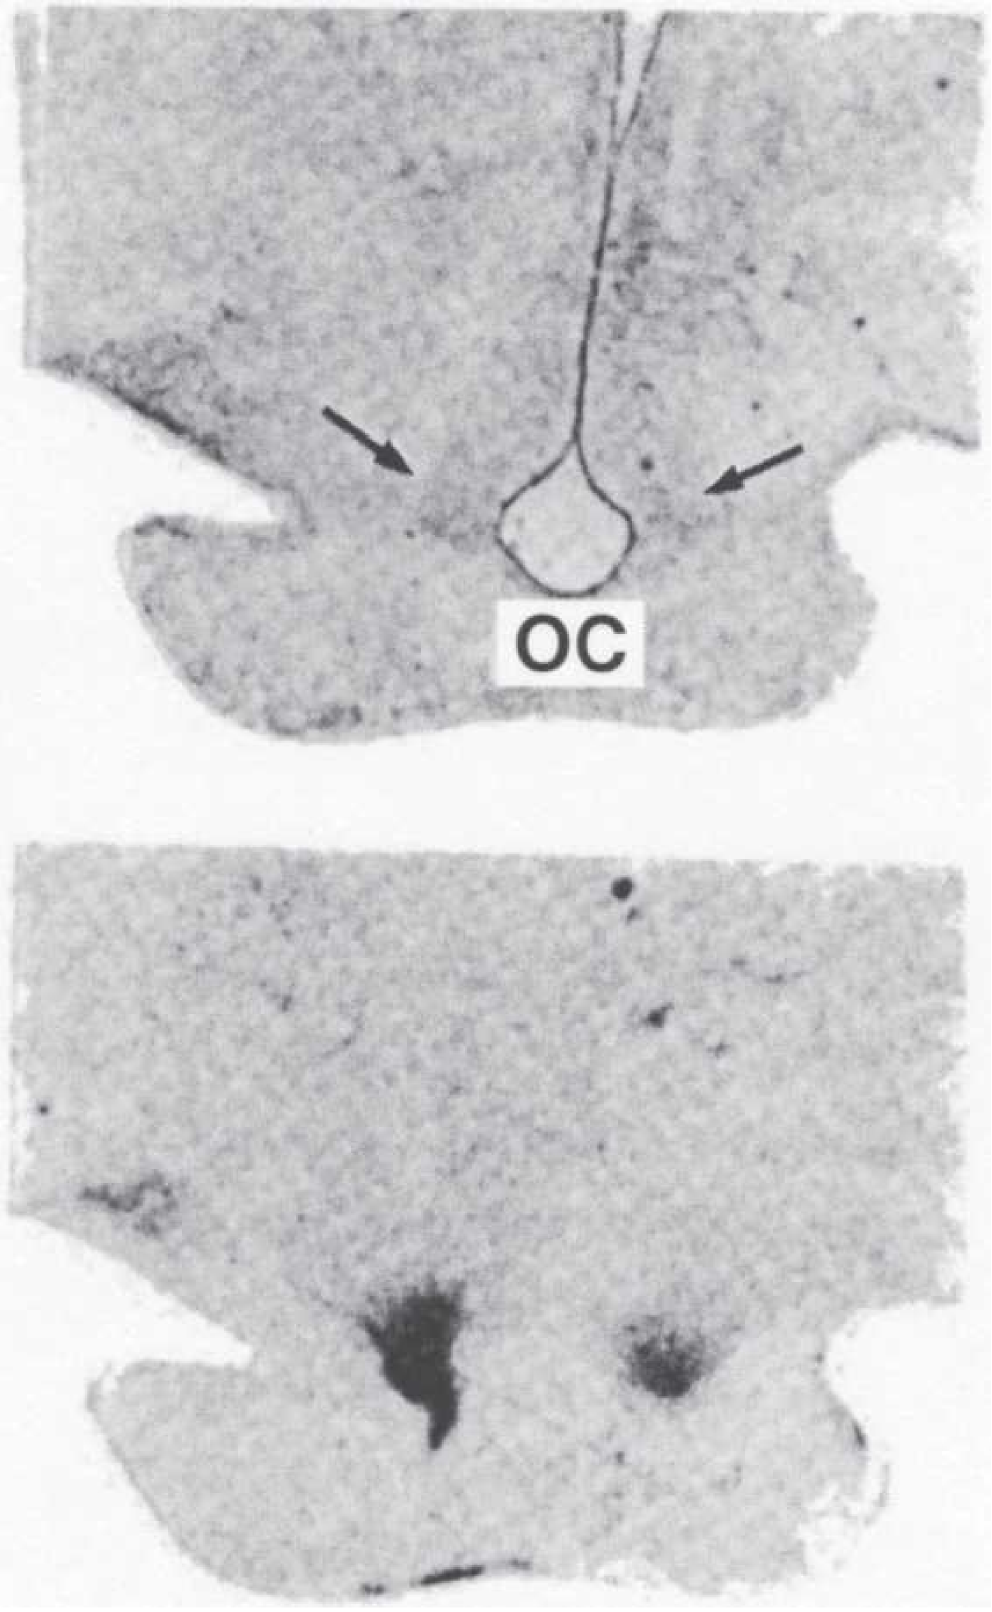

FIGURE 1.14–1. The human suprachiasmatic nucleus. **Top:** Nissl stain of section through the human hypothalamus. The suprachiasmatic nuclei are indicated by *arrows* and are located dorsal to the optic chiasm (OC). **Bottom:**

Reprinted with permission from AAAS. doi: 0.1126/science.2845576.)

Afferent Projections

The RHT is the primary afferent input to the SCN. It originates in the retina from a small subset of retinal ganglion cells, which are particularly sensitive to blue light wavelengths, and innervates the entire volume of the SCN. The excitatory neurotransmitter glutamate is the primary neurotransmitter of the RHT. Thus, glutamate receptor antagonists can block the effects of light on the circadian axis. Likewise, blue wavelength filters for computer screen output or blue wavelength blocking eyeglass lenses can also mute these signals.

Photic projections are also received from the geniculohypothalamic tract from the ipsilateral intergeniculate leaflet (IGL), providing a secondary pathway from the retina to the SCN. Neuropeptide Y (NPY) is the predominant transmitter of the IGL-to-SCN projection.

Additional afferent inputs include from median raphe nucleus and the pedunculopontine, parabigeminal, and laterodorsal tegmentum nuclei. Most prominent among these is a distinct serotonergic projection from the midbrain raphe. It is hypothesized serotonin modulates the effect of light on SCN function, potentiating glutamate input during the day and inhibiting it at night.

Efferent Projections

Most SCN efferent projections remain within the limits of the hypothalamus.

The best-studied projection originating in the SCN is the multisynaptic projection to the pineal gland, which is involved in the regulation of melatonin release. Axons of inhibitory GABAergic SCN neurons traverse the hypothalamus dorsally to the paraventricular nucleus (PVN). These signals are propagated to the superior cervical ganglion, which projects to the pineal gland. At the synapse to the pineal gland, norepinephrine release stimulates beta-1– and alpha-1–adrenergic receptors on pinealocytes to trigger the production of melatonin. The ultimate outcome of this negative-feedback efferent pathway is that melatonin synthesis increases when SCN activity decreases. Thus, melatonin is a hormone signal for “biologic night” (not just sleep) for the brain and body. In normal circumstances, natural melatonin plasma concentration begins to rise (the so-called dim light melatonin onset, DLMO) 2 to 4 hours before the onset of sleep.

FIGURE 1.14–2. Transcriptional–translational feedback loops that constitute the molecular clockworks of the mammalian circadian clock. (Adapted from Ko CH, Takahashi JS. Molecular components of the mammalian circadian clock. *Human Mol Genet* 2006;15(Rev 2):R271, by permission of Oxford University Press. doi:10.1093/hmg/ddl207.)

The SCN also coordinates peripheral circadian clocks contained in organs such as the lung, liver, kidney, and heart. A second, less understood efferent pathway from the SCN plays an important role in the control of cortisol which has a strong circadian component, being highest in the early morning in humans. Peak cortisol levels occur at approximately 6 AM to 8 AM, just as melatonin levels approach baseline.

The SCN projection to the hypothalamic PVN synapses on neurons that contain corticotrophin releasing hormone (CRH), eventually stimulating the release of adrenocorticotrophic hormone (ACTH), which in turn acts on the adrenal gland to release cortisol.

Molecular Regulation

Isolated SCN neurons can generate circadian rhythms. The mammalian circadian clockwork consists of interacting positive and negative transcriptional and translational feedback loops (Fig. 1.14–2). The expression of the period gene (*PER*) and cryptochrome genes (*CRY*) is positively regulated by the binding of Clock-Bmal1 (Bmal1) heterodimers to enhancers in the promoters of these genes. The products of the *Per* and *Cry* genes translocate back into the nucleus and repress their own transcription. This series of events constitutes the negative feedback limb of the core oscillation.

In addition to activating the transcription of the *PER* and *CRY* genes, the Clock-Bmal1 complex also activates the expression of the orphan nuclear receptor gene *Rev-Erba.* The gene product of *Rev-Erba,* in turn, translocates into the nucleus and represses transcription of the *Bmal1* gene through *Rev-Erb*/*Ror* response elements in the *Bmal1* gene promoter. Bmal1 subsequently heterodimerizes with Clock and again activates expression of the *PER, CRY,* and *Rev-Erba* genes. This derepression (or activation) of the *Bmal1* gene, subsequent heterodimerization with Clock, and activation of the *Per, Cry,* and *Rev-Erba* genes constitutes the positive feedback limb of the core oscillator.

The interactions of clock proteins and the translocations of these proteins between cellular compartments are tightly regulated by posttranslational modifications. For example, phosphorylation of some of the *Per* proteins by casein kinase Iε or δ is important for their translocation into the nucleus or their degradation in the cytoplasm.

SLEEP AND CIRCADIAN RHYTHMS

Sleep–Wake Regulation

Restful consolidated sleep is most appreciated when sleep disturbances are experienced. Sleep is the integrated product of two dynamic processes. The first process, frequently referred to as the *sleep* *homeostat,* or *process S* arises from the accumulation and dissipation of sleep debt. The biologic substrates encoding sleep debt are not fully known, although adenosine accumulation in the VLPO and other areas during wakefulness and its recycling during sleep is emerging as a primary candidate neuromodulator of the sleep homeostat. The adenosine receptor antagonist caffeine is thought to promote wakefulness by interfering with the homeostatic drive for sleep. The second oscillatory process, *process C*, is governed by the circadian clock and controls a daily rhythm in sleep propensity or, conversely, arousal.

The circadian promotion of arousal (wakefulness) steadily increases throughout the day, counteracting the homeostatic drive for sleep and reaching a maximum in the evening hours before beginning to wane, triggering the increase in plasma melatonin (Fig. 1.14–3). Arousal promotion subsequently decreases to coincide with the circadian trough in core body temperature. Experiments imposing forced sleep schedules throughout the circadian day have shown that an uninterrupted 8-hour bout of sleep is best obtained if sleep is initiated approximately 6 hours before the temperature nadir, which typically occurs around 5:00 AM to 6:00 AM. In healthy individuals, initiating sleep between 11:00 PM and 12:00 AM affords the highest probability of getting 8 solid hours of sleep.

Diurnal preference varies among individuals as a function of age, endogenous circadian periods, and other factors. Individuals who are labeled as morning types or *morning larks* tend to awaken earlier and experience the core body temperature minimum at an earlier clock time relative to those who are labeled as evening types or *night owls.* Sleep deprivation studies have shown that the homeostatic component of sleep is remarkably similar among individuals of similar age. Therefore, chronotype is dictated almost exclusively by the circadian process of sleep regulation. It should be noted that there is a well-established age-dependent decline in sleep need from infancy to adulthood. However, the more pronounced decline in total sleep time and sleep fragmentation experienced by many older adults is due to medical and psychosocial comorbidities, as well as, in some, degeneration of VLPO neurons and can result in consequential sleep deprivation.

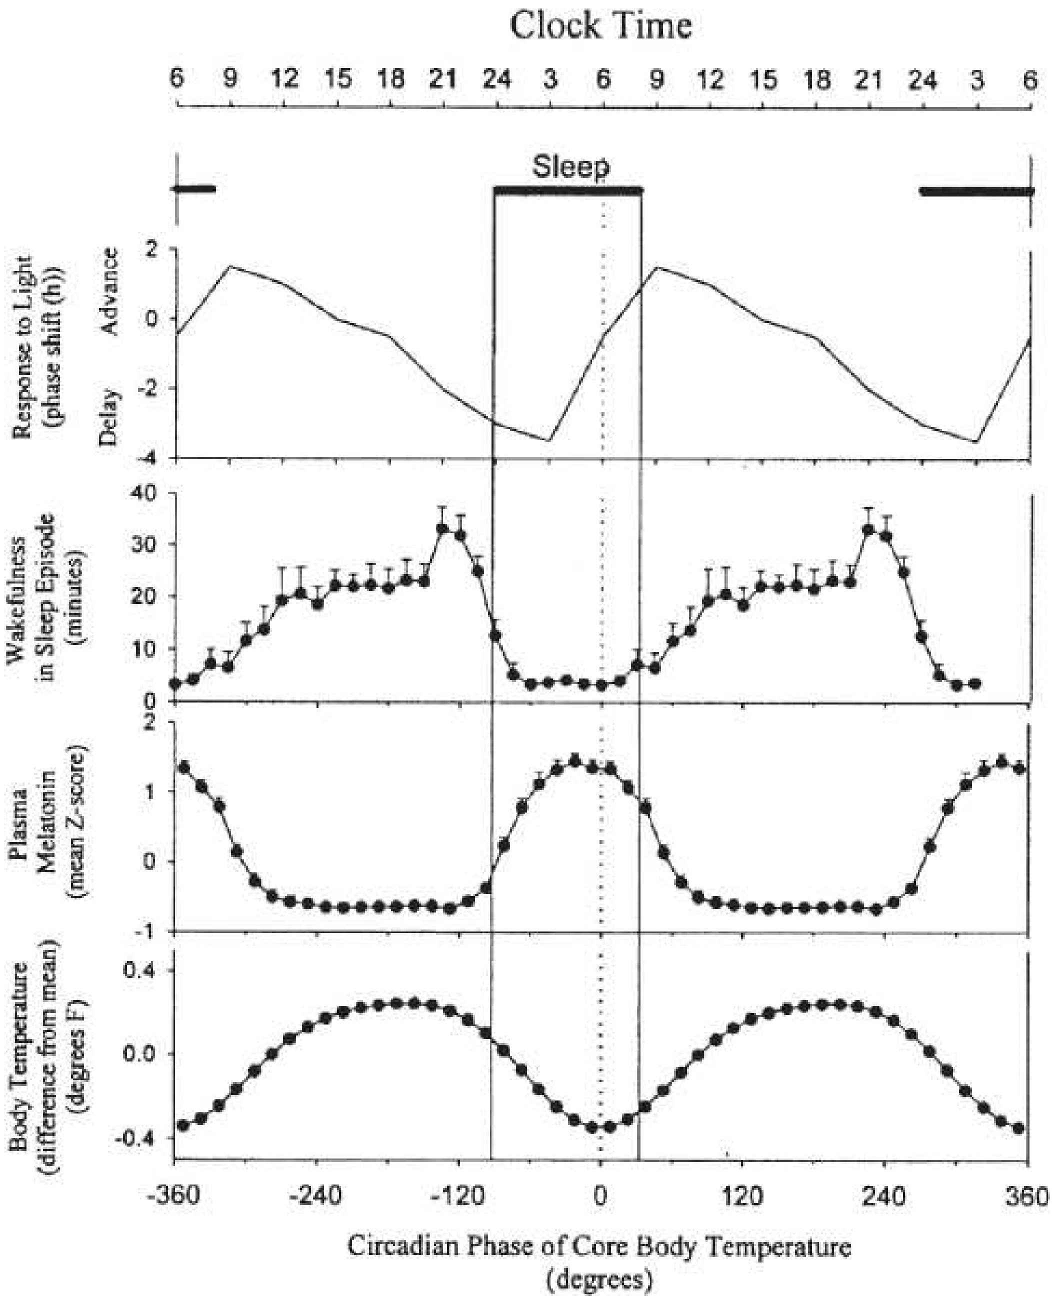

FIGURE 1.14–3. Relative phase relationship of sleep in young adults to other circadian phase markers. (From Dijk DJ, Lockley SW. Invited review: Integration of human sleep-wake regulation and circadian rhythmicity. *J Appl Physiol* 2002;92(2):852, with permission. doi:10.1152/japplphysiol.00924.2001.)

SEASONALITY

As described previously, melatonin levels are elevated during the night, not simply when sleeping. A long night, such as that experienced during the winter, results in an elevated melatonin profile of relatively long duration. A short summer night, by contrast, results in a short duration of elevated melatonin.

Seasonal variations in human behaviors include seasonal peaks in birth rate, sexual activity, conception, pain thresholds, suicide, and even criminal behavior. Seasonal variations are seen in biologic processes, including growth rate, cortisol, and testosterone levels. The general population experiences a winter worsening of mood, heightened appetite, lengthened sleep duration, lower energy, and less social behavior. These seasonal variations in mood and behavior are potentially maladaptive.

CIRCADIAN RHYTHMS IN PSYCHIATRIC DISORDERS

Seasonal Affective Disorder

Seasonal affective disorder (SAD) is the most overt manifestation of seasonality. It is characterized by recurrent major depressive episodes followed by periods of remission or change to mania or hypomania that recur on a seasonal basis. SAD is diagnosed as major depressive disorder (MDD), bipolar I, or bipolar II disorder, with the specifier "with seasonal pattern" in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). The seasonal pattern specifier criteria include:

A. Regular temporal relationship between the onset of major depressive episodes and a particular time of the year (unrelated to obvious season-related psychosocial stressors).
B. Full remissions (or a change to mania or hypomania) also occur at a characteristic time of the year.
C. Two major depressive episodes meeting criteria A and B have occurred in the last 2 years, and no nonseasonal episodes have occurred in the same period.
D. Seasonal major depressive episodes substantially outnumber the nonseasonal episodes over the individual's lifetime.

(Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. text rev. American Psychiatric Association; 2022:214.)

The most prevalent form of SAD has an onset in the late fall and early winter and remits in the late spring and early summer. This condition is frequently referred to as *winter SAD,* or *winter depression,* but is a clinically significant level of depression, unlike the “winter blues.” Surveys indicate the prevalence of winter SAD among the general population to be between 4% and 9%. Women are up to four times as likely as men to be affected, and as much as 20% of the population may have subsyndromal symptoms. Rates of SAD are higher among relatives of those with a confirmed diagnosis of SAD, and twin studies identified a heritability of 29% to 43% for seasonality and/or SAD.

The gold standard treatment for winter SAD is light therapy. About half of individuals with SAD experience remission in response to light therapy, representing one of the highest treatment response rates in the field. However, the mechanism behind light therapy is not yet clear. A typical prescription for light therapy involves 45 to 90 minutes of daily exposure to a broad spectrum, ultraviolet-filtered, white light source of relatively high irradiance (5,000 to 10,000 lux). Studies have suggested that cognitive behavioral therapy (CBT), which includes education on sleep hygiene, may be equally efficacious compared to light therapy for acute treatment and may offer prophylactic benefits against recurrences in subsequent years. Multiple antidepressant medications have also been used successfully to treat winter SAD.

The antidepressant effect of phototherapy in winter SAD patients has given rise to several hypotheses regarding the etiology of the disorder. One hypothesis proposes that SAD patients experience the consequences of a chronically phase delayed circadian clock, suggesting that the aberrant phase angle between the clock and the environment is causative of winter SAD. Although most individuals with SAD report being evening chronotypes, nearly half do not have significantly delayed rhythms. Some studies indicate that SAD patients have a longer duration of elevated melatonin that increases at the same clock time as that of controls but stays elevated longer, thus impinging on the morning hours. Although these data are not consistent with the phase delay hypothesis, they may explain the effectiveness of morning bright light therapy that would acutely suppress the extended melatonin profile of winter SAD patients. It should be noted that the sculpting of the melatonin profile by morning light exposure cannot entirely explain the proven success of phototherapy. In some winter SAD patients, bright light administered during the evening is also antidepressant. In fact, some phototherapy treatment paradigms prescribe morning and evening light exposures, although data suggest that morning light therapy is most effective for the average patient.

The success of light therapy administered at various clock times suggests that winter SAD may not have a circadian-based etiology. An alternate hypothesis proposes that patients experiencing winter SAD are generally less sensitive to light than their healthy counterparts. Such photic insensitivity would become apparent during the decreased light levels of late fall and early winter, depriving these individuals of the threshold of light required to stave off depression. Accordingly, daily supplementation of light through bright phototherapy would be expected to exceed this theoretical threshold.

In general, it cannot be denied that phototherapy has proven to be an effective treatment for winter SAD. The mechanisms by which bright light ameliorates the symptoms of this disease remain unknown.

NONSEASONAL UNIPOLAR DEPRESSION AND CIRCADIAN RHYTHMS

Abnormal circadian rhythms have been documented in those with unipolar, nonseasonal depression. For instance, individuals with depression are more likely to be evening chronotypes and often show delayed rhythms and reduced peak amplitude of melatonin and core body temperature relative to healthy controls. Daily patterns of worsening mood symptoms in the morning or afternoon are evident in nonseasonal depression and coincide with brain glucose metabolism in affect regulation areas of the brain. Several variants in clock genes have been found to be associated with a depression diagnosis, including *Clock* and *Cry,* although reports are inconsistent.

Sleep disturbances are characteristic of nonseasonal depression, particularly insomnia. Additionally, REM latency, or the time from sleep onset to the first REM episode, is shortened, and REM density is increased in depression. As improvement in sleep is an important marker of lower recurrence rates, circadian control of sleep is a potential avenue to improve long-term outcomes in depression. A curious phenomenon related to depression and sleep is that total sleep deprivation can provide a transient antidepressant effect in a majority (approximately 60%) of depressed patients. This “wake therapy” involves sleep restriction for one night or for the latter half of one night but cannot be used as monotherapy because depressive symptoms will return after a full night of sleep, and the treatment effect must be maintained with another type of treatment. Other chronotherapies beyond this type of sleep deprivation include advancing sleep phase, bright light therapy, and melatonin administration. Some studies indicate that bright light therapy can lead to improvement for nonseasonal depression, suggesting that light therapy can be an option for adjunctive treatment in addition to antidepressant medication.

Given that wake therapy can result in fast antidepressant effects, the practice of combining wake therapy with antidepressant medications and/or light therapy shows some promise for achieving a rapid response followed by sufficient maintenance of the antidepressant response. In addition, it appears that nearly all effective antidepressant medications have therapeutic effects on sleep processes, such as inhibiting excessive REM sleep or lengthening REM latency, possibly reflecting underlying circadian resynchronization.

When negative life events occur in depression, this may lead to a disruption of social rhythms (e.g., timing of first daily social encounter after the death of a spouse). Limited evidence suggests that such disruption or irregularity of social rhythms leads to similar disruptions in biologic rhythms and that treatments to restore the regularity of social rhythms may be effective (see the next section for a discussion of Interpersonal and Social Rhythm Therapy). Circadian regulation of hormonal, temperature, and mood rhythms differ, may be differentially influenced by social zeitgebers as well as genetic factors, and are likely to interact, underlining the complexity of circadian influences on mood disorders.

Bipolar Disorder

As in nonseasonal depression, circadian abnormalities have been suggested as a potential important etiologic mechanism in the development of Bipolar disorder. Bipolar disorder has been linked to variants in the core clock genes in humans and in animal models. For example, mice with a mutation in the *Clock* gene (*Clock*Δ19) show manic-like behaviors, including hyperactivity and decreased sleep. These *Clock*Δ19 mice have offered a helpful model to better understand the contribution of circadian disruption in bipolar disorder. *Clock*Δ19 mice have increased dopamine synthesis in the VTA, suggesting the importance of the *Clock* gene in dopaminergic activity in the ventral tegmental area (VTA). Further, expression of CLOCK protein in the VTA rescues most of the *Clock* mutant mice's manic-like behavior, including hyperactivity and anxiety. Together, *Clock*Δ19 mice models suggest the importance of the circadian modulation of dopaminergic activity within the VTA in bipolar disorder.

Human studies in bipolar disorder also point to abnormal circadian regulation as a potential etiologic mechanism. Circadian abnormalities seem to vary based on which state an individual is experiencing. For example, depression is associated with a phase delay, whereas mania is associated with a phase advance. Therefore, stabilization of these rhythms may help prevent or reduce the occurrence of manic or depressive episodes in bipolar individuals. Indeed, interpersonal social rhythm therapy (IPSRT), in which zeitgebers are routinized to effectively leverage circadian forces, was developed in response to the observation that irregular daily routines cause circadian dysregulation and precipitate mood episodes. IPSRT has been shown to be as effective as mood stabilizers for bipolar II disorder. Importantly, light therapy has been shown to unmask manic tendencies in those with a predisposition for developing bipolar disorder, perhaps due to the relatively abrupt circadian changes.

Circadian Sleep Disorders

In the DSM-5, circadian rhythm sleep–wake disorders include multiple disorders with circadian symptoms and presumed circadian etiology. Among these, advanced sleep phase syndrome (ASPS) is a pathologic extreme of the morning lark phenotype. An autosomal-dominant familial form of ASPS (FASPS) has been genetically characterized. Afflicted family members exhibit a striking 4-hour advance of the daily sleep–wake rhythm. They typically fall asleep at approximately 7:30 PM and spontaneously awaken at approximately 4:30 AM. Affected individuals have an SNP in the *PER2* gene leading to a mutant protein that is normally an integral component of the circadian molecular clockwork. Similarly, delayed sleep phase syndrome (DSPS) is likely influenced by genetics. A length polymorphism in a repeat region of the *PER3* gene appears to be associated with morning chronotype in DSPS patients, and the shorter allele is associated with evening chronotype.

Although sleep disorders are discussed in the next chapter such as DSPS, ASPS, hypersomnia, sleep maintenance insomnia in the older adults, jet lag and shift work disorders, and non–24-hour and irregular sleep–wake-type circadian rhythm disorders, all show improvement in response to bright light therapy. Light therapy is also helpful in normalizing sleep during withdrawal from alcohol and could therefore be considered as an adjunctive option for many disorders in which sleep and mood are impaired. Chronotherapeutics, treatments administered either according to biologic rhythms or to normalize biologic rhythms, include bright light therapy, melatonin, and its agonists, and wake and dark therapy. Such treatments are often the first line of treatment in circadian rhythm sleep–wake disorders. In chronotherapeutics, the appropriate timing of these interventions in relation to the environment or the desired schedule (e.g., for use in accommodating shift work) is critical. For example, as previously mentioned, dim light melatonin onset begins to rise 2 to 4 hours before sleep onset. Taking high-dose (5+ mg) exogenous melatonin at bedtime may be soporific (help induce sleep) but could also induce a phase delay in the circadian rhythm relative to the environment, an effect commonly referred to as “jet lag” as one is most likely to experience it when quickly changing time zones by flying.

Memory, Aging, and Neurocognitive Disorders

In general, as humans age and normative age-related memory problems begin, individuals experience a shortening of the circadian period, decreased amplitudes of most circadian rhythms, and phase advances resulting in earlier waking times and bedtimes. As mentioned previously, degeneration of VLPO neurons and other medical and psychosocial comorbidities may exacerbate these changes. Further, aging individuals may be less tolerant of dramatic phase shifts such as those caused by jet lag.

Age-related circadian changes, like decreases in amplitude or misalignment, are exacerbated in neurocognitive disorders, including neurodegenerative disorders (e.g., phase delay in Alzheimer disease [AD], phase advance in frontotemporal dementia [FTD], and sleep–wake reversal in Parkinson disease [PD] and progressive supranuclear palsy [PSP]). For example, those with moderate dementia exhibit fragmented rhythms and decreased amplitude in activity rhythms relative to mild dementia and healthy control counterparts. The amount of disruption in activity rhythms has also been associated with the severity of neuropathology found in postmortem brains, such that those with the most aberrant activity rhythms around their time of death also exhibited the most neuropathology, often with disruption of cholinergic functioning. Dysregulated circadian rhythms have been found to predate the occurrence of neurocognitive disorders (dementia) and/or clinical diagnosis of AD and significantly predict the occurrence of AD or mild neurocognitive disorder. Together, these pieces of evidence would suggest that circadian disruption may play a central role in the development of the neuropathology and neurocognitive deficits associated with AD. Light therapy aimed at normalizing an individual's circadian rhythms has been shown to improve AD patients' sleep and cognitive scores. Likewise, the disruption of cholinergic tone associated with circadian misalignment in these disorders is associated with the phenomena of "sundowning." These disturbances aggravate other symptoms, may be a major source of discouragement, increase the caretaker burden, and lead to earlier nursing home placement.

CIRCADIAN RHYTHMS AND PHARMACOTHERAPY

Circadian rhythmicity can be affected by drugs, and conversely, the circadian clock can modulate the efficacy of drugs throughout the course of the day. A better understanding of these interactions will lead to more effective pharmacotherapies. Some of the best-studied interactions between medications and the circadian clock have included the circadian effects of antidepressants. Elevated nocturnal body temperature is a common feature among depressed patients. This effect may be due to the reduced amplitude of the master circadian oscillator in the hypothalamus that drives body temperature. TCAs and SSRIs reduce elevated nocturnal body temperature while simultaneously enhancing circadian amplitude, and part of their antidepressant effect is thought to be in counteracting the dampened amplitude in daily activity rhythms depressed patients exhibit.

Short-acting benzodiazepines (e.g., triazolam [Halcion] and brotizolam [Lendormin]) also exert chronobiologic effects. In hamsters, triazolam or brotizolam administered during the middle of the subjective day induces circadian phase advances. Brotizolam has been shown to reduce the light-induced expression of clock genes *Per1* and *Per2* in the SCN.

Recreational drugs of abuse also impact the circadian system. 3,4-Methylenedioxymethamphetamine (MDMA) or "ecstasy" can act as a serotonin neurotoxin. Animal models have demonstrated that MDMA reduces medication-induced phase shifts, diminishes the ability to re-entrain rhythms, and reduces serotonergic axonal terminals in the SCN. Chronic administration of methamphetamine disorganizes rodent activity rhythms, although some studies indicate that it may help re-establish rhythmicity in rodents rendered arrhythmic through ablation of the SCN.

The efficacy and toxicity of many pharmacotherapeutics vary as a function of the circadian phase. Daily variations in fixed-dose lethal toxicity have been appreciated in rodents for years. Many anticancer drugs, ranging in mechanism from antimetabolites to DNA intercalators to mitotic inhibitors, have been shown to have 2- to 10-fold changes in tolerability in rodents over the course of the day. Much of this difference is attributed to circadian variations in the body’s ability to absorb, distribute, metabolize, and eliminate toxic compounds. These four processes are affected by underlying circadian rhythms in physiologic processes such as daily variations in gastric pH, gastrointestinal mobility, glomerular filtration rate, and membrane viscosity. The rhythmic intake of food during traditionally timed meals also influences how therapeutic drugs are handled by the body. It is becoming clear that to maximize efficacy and minimize the toxicity of drugs, the circadian phase of administration must be considered. The emergence of the field of chronotherapy is a reflection of the increased understanding of the impact of the circadian system on the effectiveness of pharmacologic treatments.

FUTURE CONSIDERATIONS

A growing body of research indicates that the influence of the circadian system is broad and foundational to normal functioning. Desynchrony between the SCN and peripheral oscillators is likely to be involved in the pathogenesis of multiple maladies, including psychiatric disorders. As our appreciation of the relationship between circadian disturbances and the pathophysiology of psychiatric illness improves, hopefully, treatments designed to manipulate the light input, central clock, or clock output mechanisms will show increasing promise in treating psychiatric disorders.

1.15 Basic Science of Sleep

Ruth M. Benca, M.D., Ph.D., Chiara Cirelli, M.D., Ph.D., and Giulio Tononi, M.D., Ph.D.

Sleep is a fundamental behavior of all animal species, although its specific functions are not yet fully understood. Sleep occupies approximately one-third of the human lifespan, and loss of sleep can lead to cognitive, emotional, and physical impairment. Systems involved in the regulation of sleep and wakefulness appear to overlap or interact with systems involved in the regulation of emotion and other behaviors. Therefore, it is not surprising that sleep abnormalities are commonly found in patients with psychiatric disorders, part of the diagnostic criteria for several disorders, and have predictive value for the future development of psychiatric disorders. Furthermore, a majority of commonly used psychiatric medications have effects on sleep.

NORMAL HUMAN SLEEP

Definition of Sleep

From a behavioral standpoint, sleep is a state of decreased awareness of environmental stimuli that is distinguished from states such as coma or hibernation by its relatively rapid reversibility. Sleeping individuals move little and tend to adopt stereotypical postures. Although sleep is characterized by a partial disconnection from the external world and a general lack of memory of the state, unlike in comatose states, people generally recognize when they feel sleepy and are aware that they have been asleep at the termination of an episode.

For clinical and research purposes, sleep is generally characterized by combining behavioral observation with electrophysiologic recording. Like most other mammals, humans express two types of sleep: rapid eye movement (REM) and nonrapid eye movement (NREM) sleep. These states have distinctive neurophysiologic and psychophysiological characteristics. REM sleep derives its name from the frequent bursts of eye movement activity that occur. It is also referred to as *paradoxical sleep* because the electroencephalogram (EEG) during REM sleep is similar to that of waking. In infants, the equivalent of REM sleep is called *active sleep* because of prominent phasic muscle twitches. NREM sleep, or *orthodox sleep,* is characterized by decreased activation of the EEG; in infants, it is called *quiet sleep* because of the relative lack of motor activity.

Stages of Sleep

Within REM and NREM sleep, there are further classifications called *stages* (Table 1.15–1 and Fig. 1.15–1). For clinical and research applications, sleep is typically scored in epochs of 30 seconds, with stages of sleep defined by the visual scoring of three parameters: EEG, electrooculogram (EOG), and electromyogram (EMG) recorded beneath the chin. Most of the criteria defined by Rechtschaffen and Kales in 1968 are still accepted in clinical practice and for research around the world, although new rules that modify the older criteria were adopted in 2007 by the American Academy of Sleep Medicine (AASM) in *The AASM Manual for the Scoring of Sleep and Associated Events*, which was most recently updated in 2020. During wakefulness, the EEG shows a low-voltage fast activity or activated pattern. The EMG has a high tonic activity with additional transient muscle activity related to voluntary movements. Voluntary eye movements and eye blinks can also be observed during wakefulness. When the eyes are closed in preparation for sleep, alpha activity (8 to 13 Hz) becomes prominent, particularly in the occipital regions.

Table 1.15–1.
Stages of Sleep—Electrophysiologic Criteria

	EEG	EOG	EMG
Wakefulness			
Stage W	Low-voltage, mixed frequency Alpha (8–13 Hz) with eyes closed, vertex sharp waves	Eye movements and eye blinks	High tonic activity and voluntary movements
Nonrapid Eye Movement			
Stage N1	Low-voltage, mixed frequency Theta (4–7 Hz) and vertex sharp waves may be present	Slow eye movements	Tonic activity slightly decreased from wakefulness
Stage N2	Low-voltage, mixed-frequency background with sleep spindles (12–14-Hz bursts) and K-complexes (negative sharp wave followed by positive slow wave)	None	Low tonic activity
Stage N3	High-amplitude (≥75 μV) slow waves (≤2 Hz) occupying at least 20% of epoch	None	Low tonic activity
Rapid eye movement	Low-voltage, mixed frequency Saw-tooth waves, theta activity, slow alpha activity may be present	Rapid eye movements	Tonic atonia with phasic twitches

Criteria from Iber C, Ancoli-Israel S, Chesson AL, Quan SF. *The AASM Scoring Manual for the Scoring of Sleep and Associated Events*. American Academy of Sleep; 2007.

NREM sleep, which usually precedes REM sleep, is subdivided into three (N1 to N3) stages (Table 1.15–1 and Fig. 1.15–1). Sleep usually begins with a transitional state, stage N1 (formerly stage 1 sleep), characterized by the loss of alpha activity and the appearance of a low-voltage, mixed-frequency EEG pattern with prominent theta activity (4 to 7 Hz) and occasional vertex sharp waves (V waves) over the central regions. Eye movements become slow and rolling, and skeletal muscle tone relaxes. Subjectively, stage N1 may not be perceived as sleep, although there is a decreased awareness of sensory stimuli, particularly visual, and mental activity becomes more dreamlike. Motor activity may persist for a number of seconds during stage N1. Occasionally individuals experience sudden muscle contractions, sometimes accompanied by a sense of falling and/or dreamlike imagery; these hypnic jerks (or sleep starts) are generally benign and may be exacerbated by sleep deprivation. Typically, sleep-deprived individuals will enter periods of “microsleep” consisting of brief (5 to 10 seconds) bouts of stage N1 sleep; these episodes are unavoidable in sleepy individuals and can have serious consequences in situations that demand constant attention, such as driving a motor vehicle.

After a few minutes of stage N1, sleep usually progresses to stage N2 (formerly stage 2), which is heralded by the appearance of sleep spindles (11 to 16 Hz, lasting ≥0.5 seconds) and K-complexes (high-amplitude, negative sharp waves followed by positive slow waves, lasting ≥0.5 seconds) in the EEG. Stage N2 and subsequent stages of NREM and REM sleep are all subjectively perceived as sleep. Particularly at the beginning of the night, stage N2 is generally followed by N3 (formerly stages 3 and 4), a period when 20% or more of each sleep epoch consists of slow waves, that is, waves of 0.5- to 2-Hz frequencies with peak-to-peak amplitudes of >75 μV over frontal regions. N3 is also defined as *slow-wave sleep (SWS)*, *delta sleep,* or *deep sleep* because the arousal threshold increases incrementally from stages N1 to N3. Previously, SWS was subdivided according to the proportion of slow waves in the epoch (stage 3, 20% to 50%; stage 4, >50%), and older studies used this nomenclature, but the validity and biologic significance of this subdivision was called into question. Eye movements typically cease during stages N2 and N3, and EMG activity decreases further.

REM sleep, or stage R, is not subdivided into stages but is rather described in terms of tonic (persistent) and phasic (episodic) components.

Tonic aspects of REM sleep include the activated EEG similar to that of stage N1, which may exhibit increased activity in the theta band and a generalized decrease of the tone of skeletal muscles except for the extraocular muscles and the diaphragm. Sawtooth waves, trains of triangular, serrated 2- to 6-Hz waves may also be present. Phasic features of REM include irregular bursts of REMs and muscle twitches. An example of stage R showing tonic and phasic components is shown in Figure 1.15–2.

Organization of Sleep

The amount of sleep obtained during the night varies among individuals and with age; the National Sleep Foundation convened an expert panel to review the scientific literature to make recommendations for sleep duration across the lifespan. They concluded that most adults need about 7 to 9 hours of sleep per night to function optimally, although those over

65 might only require 7 to 8 hours. Although these are population-based recommendations, there also exist short sleepers who appear to function adequately with less than 6 hours per night and long sleepers who may need 12 or more hours per night. In addition to age and genetic factors that influence daily sleep needs, medical or psychiatric disorders also strongly influence sleep patterns. Regardless of the number of hours needed, the proportion of time spent in each stage and the pattern of stages across the night is fairly consistent in normal adults (Fig. 1.15–3). A healthy young adult will typically spend about 5% of the sleep period in stage N1 sleep, about 50% in stage N2, and 20% to 25% in each of stages N3 and R. Sleep occurs in cycles of NREM–REM sleep, each lasting approximately 90 to 110 minutes. SWS (stage N3) is most prominent early in the night, especially during the first NREM period, and diminishes as the night progresses. As SWS wanes, periods of REM sleep lengthen while showing greater phasic activity and generally more intense dreaming later in the night. Older adults have decreased amounts of SWS.

The ascending arousal system sends projections from the brainstem and posterior hypothalamus throughout the forebrain. Neurons of the laterodorsal tegmental (LDT) nuclei and pedunculopontine tegmental (PPT) nuclei send cholinergic fibers (Ach) to many forebrain targets, including the thalamus, which then regulate cortical activity. Aminergic nuclei diffusely project throughout much of the forebrain, regulating the activity of cortical and hypothalamic targets directly. Neurons of the tuberomammillary nucleus (TMN) contain histamine (HIST), neurons of the raphe nuclei contain serotonin (5-HT), and neurons of the locus coeruleus (LC) contain noradrenaline (NA). Sleep-promoting neurons of the ventrolateral preoptic (VLPO) nucleus and other regions of the anterior hypothalamus and basal forebrain contain GABA and galanin (Gal).

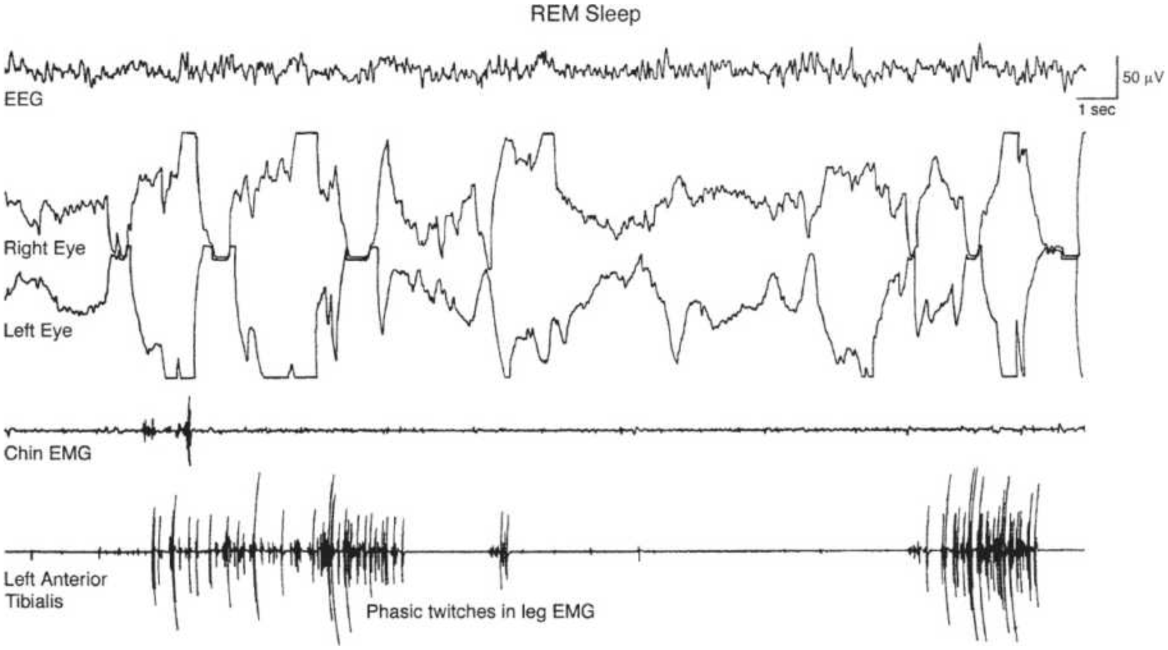

FIGURE 1.15–2. Example of human rapid eye movement (REM) sleep. EEG, electroencephalogram; EMG, electromyogram. (From Butkov N. *Atlas of Clinical Polysomnography*. Synapse Media; 2010, with permission.)

EFFECTS OF AGE ON SLEEP

Sleep patterns change markedly across the lifespan, with the most rapid changes occurring during the first years of life. Development of EEG patterns of sleep and wakefulness begins at about 24 weeks of gestational age, and differentiation into active (REM) and quiet (NREM) sleep occurs during the last trimester. Newborn infants spend about 14 to 17 hours per day sleeping, and premature infants may sleep even more. Infants do not show evidence of strong diurnal sleep patterns for the first several months of life; they exhibit short sleep–wake cycles of about 3 to 4 hours and a reduced length of active–quiet sleep cycles (about 50 minutes). At birth, active sleep occupies about half of their sleep time, and they tend to enter sleep through active rather than quiet sleep. At approximately 3 to 4 months of age, several important developmental changes occur: Babies shift to the adultlike pattern of initiating sleep with NREM, sleep starts to become consolidated during the night, and the sleep EEG shows more mature waveforms characteristic of NREM and REM sleep. Sleep duration also drops slightly, to 12 to 15 hours per day.

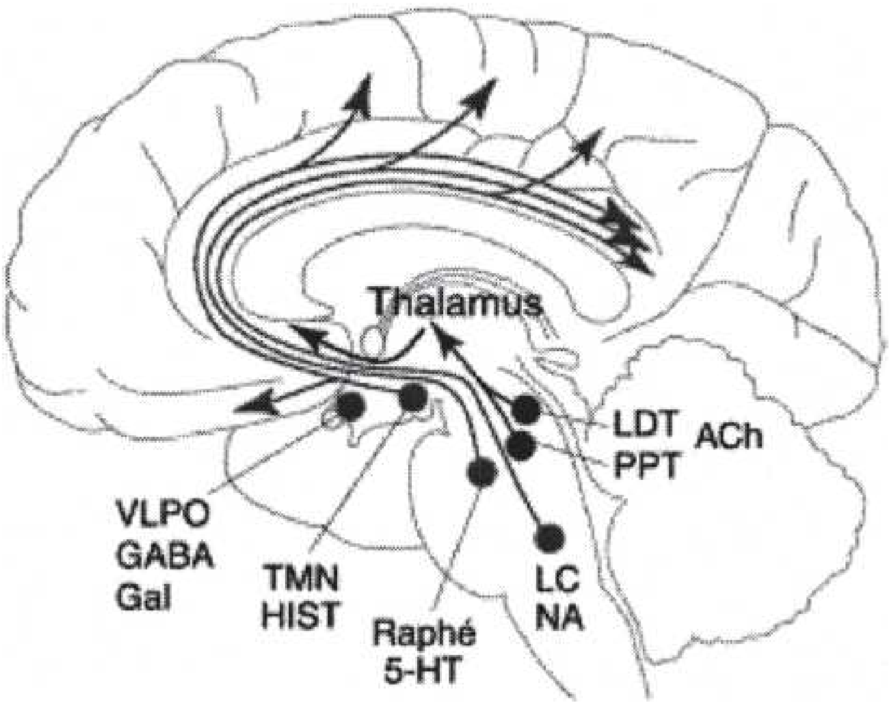

FIGURE 1.15–3. The ascending arousal system sends projections from the brainstem and posterior hypothalamus throughout the forebrain. Neurons of the laterodorsal tegmental (LDT) nuclei and pedunculopontine tegmental (PPT) nuclei send cholinergic fibers (Ach) to many forebrain targets, including the thalamus, which then regulate cortical activity. Aminergic nuclei diffusely project throughout much of the forebrain, regulating the activity of cortical hypothalamic targets directly. Neurons of the tuberomammillary nucleus (TMN) contain histamine (HIST), neurons of the raphe nuclei contain serotonin (5-HT), and neurons of the locus coeruleus (LC) contain noradrenaline (NA). Sleep-promoting neurons of the ventrolateral preoptic (VLPO) nucleus contain γ-aminobutyric acid (GABA) and galanin (Gal). (Reprinted from Saper CB, Chou TC, Scammell TE. The sleep switch: hypothalamic control sleep and wakefulness. *Trends Neurosci.* 2001;24(12):726–731. Copyright © 2001, with permission from Elsevier.)

During early childhood, total sleep time continues to decrease, such that recommended sleep amounts for preadolescent school-aged children range from 9 to 11 hours per night, and REM sleep proportion drops to adult levels (20% to 25%). Napping normally continues during the preschool years but is often abandoned once children begin school full-time. Young children show the highest percentages of SWS, with particularly high arousal thresholds; this accounts for both the difficulty in arousing them at the beginning of the sleep period as well as the high incidence of bedwetting and SWS-related parasomnias such as sleepwalking and night terrors.

SWS duration and the amplitude of slow waves diminish significantly during adolescence, possibly related to cortical synaptic pruning. Irwin Feinberg has suggested that abnormalities in synaptic elimination may account for the seemingly coincidental timing of the maturation of sleep patterns and the increasing incidence of schizophrenia in late adolescence and early adulthood. In addition to showing decreases in SWS duration, adolescents often decrease their total sleep time significantly, although this is probably due to behavioral changes rather than representing a true decrease in sleep need; their recommended sleep amount is estimated at 8 to 10 hours per night. They also show a tendency to become “night owls,” preferring to stay up late rather than wake up early. This shift to “eveningness” may be related to an increase in the intrinsic period of the circadian clock.

In addition to the changes in amounts of SWS, there are dramatic changes in the topography of scalp slow-wave activity (SWA) that mirror the pattern of cortical brain maturation. Occipital regions that develop first show the most SWA in very young children. As the cortex matures in a posteroanterior direction during development, maximal SWA also shifts forward, showing the adult pattern of dominance over the frontal cortex by late adolescence/early adulthood.

Older adults show an increased incidence of primary sleep disorders (e.g., sleep apnea and periodic limb movements [PLMs]), medical illnesses, and psychiatric disorders that may interfere with sleep; it is, therefore, difficult to determine which sleep changes represent normal versus pathologic aging. SWS declines across adulthood and may disappear entirely by age 60; SWA declines globally over the scalp. Sleep also becomes more fragmented, with prolonged latency to sleep onset, increased numbers of arousals, more time spent awake during the sleep period, and increased daytime napping. Older adults thus may spend more time in bed but obtain less sleep; 5 to 6 hours may be a sufficient amount of sleep for some individuals. The older adults also show a trend to wake up earlier and feel more alert in the morning than in the evening. The percentage of REM sleep only shows a small decline with age in normal individuals. Patients with Alzheimer disease and other degenerative disorders of the CNS, however, show a loss of REM sleep and deterioration in diurnal patterns of sleep–wakefulness; this deterioration may become so severe that nursing home patients may not spend a single hour of the day where they are consistently either asleep or awake.

MONITORING HUMAN SLEEP

Sleep–wakefulness-related alterations in the human EEG were first reported by Hans Berger in 1929. Since this discovery, the EEG and other electrophysiologic parameters have been used to investigate normal human sleep. Starting in the 1970s, researchers and clinicians began to use similar monitoring techniques to characterize and diagnose sleep disorders. In addition to the EEG, the EOG and EMG are recorded to measure eye movements and muscle activity, respectively, both requisites to distinguish wakefulness and the stages of sleep. The EEG is recorded from electrodes affixed to the scalp overlying specific regions of the brain according to the International 10–20 system of electrode placement. Because the EEG features that define wakefulness and the stages of sleep are most readily recorded bilaterally from different regions of the brain, a minimum of three strategically chosen regions (frontal, central, and occipital) are required. K-complexes and slow waves are optimally recorded with the frontal pair of electrodes. Sleep spindles (Fig. 1.15–1) are instead best recorded from electrodes placed over the central region. The third pair of electrodes is placed over the occipital lobe to optimize the detection of alpha activity, correlated to a relaxed waking state with closed eyes. Additional electrodes are applied to obtain a higher spatial resolution of EEG activity under certain research or clinical circumstances (e.g., diagnosis of sleep-related seizure disorders). The EOG recording is used to detect REMs associated with wakefulness and REM sleep, as well as the slow rolling eye movements that occur during stage N1 sleep. Because the retina is electrically negative compared to the cornea, eye movements generate small electrical fields that can be detected from electrodes attached to the skin near the eyes. The EMG recording is used to detect tonic and phasic changes in muscle activity that correlate with changes in behavioral state. In particular, skeletal muscle tone reaches the lowest tonic levels during REM sleep, reflecting the general paralysis associated with this stage of sleep. Typically, the EMG is recorded from electrodes attached to the chin. In clinical settings, additional EMG electrodes are placed over the anterior tibialis and intercostal muscles to detect leg movements and respiratory effort, respectively. Depending on the presenting symptoms, clinical monitoring may also include additional monitoring such as respiratory effort and flow sensors, ECG, oxyhemoglobin saturation, end-tidal and/or transcutaneous CO_2 levels, and limb EMG recording.

Standard Sleep Stage Scoring

Standardized visual scoring rules were first instituted by Rechtschaffen and Kales in 1968 and are still used, with more recent modifications, to quantify time spent in wakefulness and each sleep stage as well as the temporal distribution, or architecture, of sleep across the recording period. In addition, mathematical techniques, such as power spectral analysis based on the *Fast Fourier Transform*, are frequently employed to quantify the relative contributions of various brain wave frequencies to the overall EEG recording. For example, power spectral analysis has shown that SWA is greatest early in the sleep period and progressively declines across successive periods of SWS, a finding that provided the basis for the two-process model of sleep regulation.

Sleep stage scoring yields several measures of sleep quantity and quality, including clinically relevant markers of sleep and psychiatric disorders. Specific clinical or research circumstances may call for slightly different definitions for each sleep measure. *Sleep latency* is the time elapsed from the start of the recording to the onset of any stage of sleep. *REM sleep latency* is defined as the time elapsed from sleep onset to the first epoch of stage R sleep. *Total sleep time* is the cumulative time spent in all sleep stages, and *sleep efficiency* is how much of the total recording time was spent in any stage of sleep. Other measures of interest include the proportion of sleep spent in each sleep stage.

Other clinical events scored in clinical sleep studies include respiratory events and limb movements. Respiratory events include apneas (drops in respiratory sensor signal of at least 90% for at least 10 seconds) and hypopneas (drops in respiratory sensor signal of at least 30% for at least 10 seconds and with an oxygen saturation drop of at least 3%). Respiratory events are classified as obstructive if respiratory effort continues and central when there is no inspiratory effort. Sleep apnea is considered mild with an average of 5 or more respiratory events per hour of sleep, and moderate to severe with 15 or more events per hour. Limb movements are recorded from electrodes placed over the anterior tibialis muscles, and a leg movement is scored when there is an increase of at least 8 µv that lasts for at least 0.5 seconds. When leg movements occur repetitively during sleep (i.e., at least four leg movements separated by 5 to 90 seconds), they are considered PLMs; 15 or more per hour is considered abnormal.

Measuring Daytime Sleepiness

In addition to characterizing sleep patterns across the major sleep period, researchers and clinicians are sometimes interested in quantifying daytime sleepiness. Daytime sleepiness manifests as an increased propensity to fall asleep and/or a decreased ability to maintain wakefulness. Sleepiness can be measured using subjective questionnaires or objective electrophysiologic monitoring. Sleep questionnaires such as the Stanford Sleepiness Scale (SSS) or Epworth Sleepiness Scale (ESS) are easy to use in the laboratory or physician's office. The SSS asks the individual to rate their current level of sleepiness, whereas the ESS asks the individual to rate their probability of falling asleep under various circumstances. Both questionnaires may be influenced by the individual's ability to assess their level of alertness or propensity to fall asleep, as well as their motivation to obtain treatment.

Objective measures of sleepiness generally require time-consuming, laboratory-based testing but yield a more reliable estimate of sleepiness. Two standardized objective tests are typically employed to measure daytime sleepiness; the multiple sleep latency test (MSLT) measures the propensity to fall asleep, whereas the maintenance of wakefulness test (MWT) measures the ability to maintain wakefulness. Both tests employ the electrophysiologic sleep-monitoring techniques described above. The MSLT consists of four or five sleep latency tests spaced 2 hours apart. At the start of each test, individuals are asked to lie quietly in a darkened room and allow themselves to fall asleep. The latency to sleep onset is recorded, and if sleep does not occur within 20 minutes, the test is terminated. In the clinical setting, patients who fall asleep are usually allowed to sleep for 15 minutes to determine whether they tend to enter REM sleep in an abnormally short period of time. The mean sleep latency is calculated as well as the number of tests in which REM sleep was detected. A mean sleep latency of <8 minutes reflects excessive sleepiness and may indicate a CNS hypersomnia such as narcolepsy or idiopathic hypersomnia, whereas a mean sleep latency ≥15 minutes is considered normal. Idiopathic hypersomnia may also be diagnosed in individuals who sleep >660 minutes on a 24-hour polysomnographic recording in the absence of chronic sleep deprivation. In conjunction with other symptoms, two or more tests with REM sleep are suggestive of narcolepsy. During the MWT, individuals are placed under similar conditions to that described for the MSLT, but rather than being asked to fall asleep, they are asked to stay awake. Although 20- to 40-minute tests can be used, the 40-minute protocol has the advantage of minimizing ceiling effects. A mean sleep latency >35 minutes on the 40-minute MWT is considered normal. Although both the MSLT and the MWT are objective tests of sleepiness, the results can be influenced by various factors, such as an individual's prior sleep history. In the clinical setting, the goal is to assess whether a patient exhibits a pathologic degree of sleepiness despite obtaining normal amounts of sleep at night; short sleep latencies on the MSLT are of limited clinical utility if the patient is clearly sleep deprived. Consequently, it is critical that the patient's prior sleep history be evaluated by monitoring in the sleep laboratory during the preceding night and questionnaires logging sleep habits for the previous week. Under certain circumstances, patients may wear small devices on their wrist that detect and log motion, a correlate of wakefulness, for several days or weeks before undergoing laboratory testing. Such activity monitoring (or actigraphy) is also used to obtain objective measures of probable sleep at home in patients complaining of insomnia. Other objective measures of sleepiness based on power spectral analysis of the EEG, pupillary activity, and performance on cognitive tests are currently under development.

PHYSIOLOGY IN SLEEP

An appreciation of the physiologic changes that occur during sleep helps understand the effects of normal and disturbed sleep on medical disorders. Various neuroendocrine and autonomic nervous system (ANS) physiology parameters show changes related to circadian rhythms and/or sleep itself (Table 1.15–1).

Autonomic Nervous System

During NREM sleep and tonic REM sleep, there is a relative increase in parasympathetic activity relative to sympathetic activity. The ANS reaches its most stable state during SWS in comparison to wakefulness; for example, blood pressure, heart rate, and respiratory rate are at their lowest mean values and least variable during SWS. However, during phasic REM sleep, there are brief surges in both sympathetic and parasympathetic activity, resulting in a high degree of autonomic instability.

Cardiovascular System

Blood pressure, heart rate, and cardiac output decrease during NREM sleep, reaching their lowest average values and least variability in SWS. Although on average, these parameters remain somewhat reduced during REM sleep in comparison to waking, they attain their peak values during REM sleep. Arrhythmias are also more prevalent during REM sleep, which may contribute to the increased rate of cardiovascular mortality in the early morning, the time of greatest REM sleep propensity. It is also possible that increased mortality rates related to cardiovascular causes seen in major depression might be related to the tendency of depressed patients to have increased amounts of REM sleep with greater phasic activity.

Pulmonary System

Temporary breathing instability and/or periodic breathing may occur at the onset of sleep and are related to the loss of waking-related respiratory drive as well as a decreased sensitivity of central chemoreceptors to pCO_2; sensitivity to pCO_2 declines further during REM sleep, along with a decrease in the ventilatory response to reduced pO_2. Respiratory rate and minute ventilation decrease during sleep and upper airway resistance increases as a result of muscle relaxation, most significantly during REM sleep. These changes contribute to exacerbations of underlying pulmonary disease as well as sleep-related breathing disorders such as sleep apnea.

Thermoregulation. In addition to the circadian-related nocturnal decrease in body temperature, sleep directly affects thermoregulation. Brain and body temperature are downregulated during NREM sleep, particularly SWS, due to both a decreased hypothalamic temperature set point and active heat loss. People commonly experience this phenomenon when they go to sleep feeling somewhat cold and wake up several hours later to throw off their extra covers because they feel too warm and may have been sweating. There is a decreased ability to regulate body temperature during REM sleep through sweating and shivering.

Neuroendocrine Changes. Most hormones regulated by the circadian system also show significant interactions with sleep–wakefulness patterns. Growth hormone (GH) is released primarily during the early part of the night, and SWS enhances its secretion. Sleep also stimulates prolactin secretion, although prolactin peaks after GH, usually during the middle portion of the night. However, pulses of GH and prolactin can occur after sleep onset, regardless of the timing. Both GH and prolactin may have feedback effects on sleep as well; GH seems to enhance SWS, whereas prolactin may increase REM sleep. In contrast, *TSH* reaches its peak level in the evening just before sleep onset; its secretion is inhibited by sleep and stimulated by sleep deprivation. The *HPA axis* is usually at its most inactive state at nocturnal sleep onset. Sleep onset inhibits cortisol release, whereas *ACTH* and *cortisol* levels rise at the end of the sleep period, shortly before awakening, and likely contribute to morning arousal. Severe sleep disruption or sleep deprivation may have significant clinical effects on the endocrine system; for example, patients with obstructive sleep apnea show decreased levels of GH and prolactin, and sleep deprivation produces evidence of HPA axis activation in the evening of the day following deprivation.

Melatonin secretion is mediated by a combination of circadian control and the effects of the light–dark cycle. It can only be released at night if it is dark; darkness does not stimulate melatonin secretion during the day. Thus melatonin can transduce the duration of the photoperiod; it has a significant role in timing reproductive function in some mammals, although its function in humans is less clear. Melatonin can feedback on the circadian clock and may serve to maintain entrainment, which is why it is sometimes recommended for the treatment of jet lag or sleep schedule disorders. It may also have a modest hypnotic effect in humans but can produce arousal in nocturnal animals, suggesting that it acts as a modulator of nocturnal behaviors.

Sexual Function

One of the characteristics of REM sleep in men is the occurrence of penile erections, beginning in infancy and persisting into old age. Nocturnal penile tumescence studies are therefore helpful in determining whether cases of impotence are related to organic or psychogenic etiologies. In women, REM sleep produces increased vaginal blood flow and clitoral erection. These changes are not necessarily linked to sexual content in associated dreams.

NEUROBIOLOGY OF SLEEP AND WAKEFULNESS

Sleep and wakefulness are governed by separate yet interacting systems. Although the specific mechanisms are not fully understood, it is clear that multiple structures and systems in the medulla, brainstem, hypothalamus, and basal forebrain are involved in the orchestration of wakefulness, NREM sleep, and REM sleep. No single brain lesion has been able to produce persistent insomnia or sleep. Given the importance of these behaviors to survival, it is not surprising that there is a certain amount of apparent redundancy in their mechanisms.

Wakefulness

As mentioned above, the waking EEG is characterized by an activated pattern with low-voltage fast activity. Correspondingly, PET studies show that blood flow and metabolic activity are higher during resting wakefulness than in NREM sleep. As indicated by increased regional cerebral blood flow (rCBF), the most active brain areas include the prefrontal cortex, anterior cingulate, parietal cortex, and precuneus, which are areas known to be involved in attention, cognition, and memory.

Maintenance of wakefulness is dependent on the *ascending reticular activating system* (ARAS), which is comprised of inputs from the oral pontine and midbrain tegmentum as well as posterior hypothalamus (Fig. 1.15–4). In animals, electrical stimulation of these regions produces an activated EEG pattern and behavioral arousal. Lesions may produce a comalike state, although recovery of cortical activity can sometimes occur given sufficient time, suggesting that structures outside the brainstem reticular formation are also involved in maintaining wakefulness. Clinically, lesions in the midbrain, diencephalon, or posterior hypothalamus can produce somnolence, stupor, or coma.

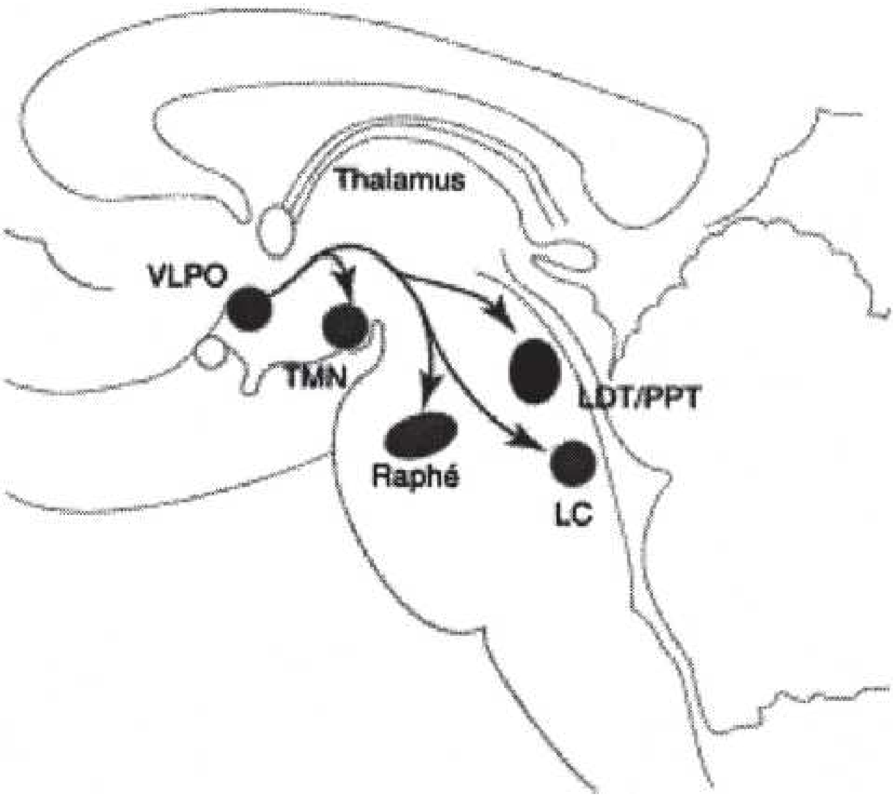

FIGURE 1.15–4. The projections from the ventrolateral preoptic (VLPO) nucleus to the main components of the ascending arousal system. LC, locus coeruleus; LDT, laterodorsal tegmental nuclei; PPT, pedunculopontine tegmental nuclei; TMN, tuberomammillary nucleus. (Reprinted from Saper CB, Chou TC, Scammell TE. The sleep switch: hypothalamic control sleep and wakefulness. *Trends Neurosci.* 2001;24(12):726–731. Copyright © 2001, with permission from Elsevier.)

It is now known that several distinct structures and neurochemical systems with diffuse projections are involved in wakefulness, including noradrenergic cells in the LC, cholinergic cells in the *PPT* and *LDT* nuclei, histaminergic cells in the *TMN* of the posterior hypothalamus, orexin/hypocretin cells in the lateral hypothalamus, and glutamatergic and GABAergic neurons in various structures in the CNS. The ARAS produces cortical activation via input to the thalamus as well as through an extrathalamic pathway with projections to the hypothalamus and basal forebrain.

Noradrenergic cells from the LC project directly throughout the forebrain and cerebral cortex and show their highest discharge rates during wakefulness. These cells decrease their firing during NREM sleep and cease firing altogether during REM sleep. Converging evidence suggests that wakefulness and sleep differ not only in terms of behavior, metabolism, and neuronal activity but also in terms of gene expression. LC cells are responsible for at least some of the changes in gene expression that occur in the brain between wakefulness and sleep, and specifically for the upregulation of plasticity-related genes involved in synaptic potentiation during wakefulness. The LC has long been considered a homogeneous cell group with broad and uniform action on the cortex, but recent experiments found little overlap among the LC projections to three subregions of the rat prefrontal cortex, including the medial prefrontal cortex (mPFC), or between the LC afferents to each of these prefrontal areas and the primary motor cortex, M1. Moreover, relative to the neurons targeting M1, LC cells projecting to mPFC have a spontaneous firing rate three times as high, and are more excitable, suggesting that decision-making prefrontal areas are under a stronger modulatory influence by the LC than movement-generating cortical areas.

Cholinergic cells from the oral pontine region fire at high rates when the EEG is activated (i.e., during wakefulness and REM sleep) but reduce firing during NREM sleep. They promote cortical activation through inputs to the thalamus, hypothalamus, and basal forebrain. In addition, cholinergic cell bodies in the basal forebrain, including the nucleus basalis, substantia innominata, diagonal band of Broca, and septum, receive input from the ARAS and in turn provide excitatory input to the entire cortex. Stimulation of the basal forebrain results in cortical release of acetylcholine, EEG activation, and depolarization of cortical neurons. Moreover, the cholinergic cells of the basal forebrain also fire maximally during wakefulness and REM sleep and minimally during NREM sleep. Optogenetic experiments in mice suggest that cholinergic cells in the pons promote REM sleep more than wake, while cholinergic cells in the basal forebrain may mainly promote EEG activation. Loss of cholinergic cells in Alzheimer patients is associated with slowing of the cortical EEG. Drugs with anticholinergic activity, including tricyclic antidepressants and atropine, can cause sedation, suppress REM sleep, and increase SWA. However, cholinergic agonists (e.g., nicotine) or anticholinesterase inhibitors (e.g., neostigmine) enhance arousal.

Histaminergic neurons in the TMN of the posterior hypothalamus also appear to have an important wakefulness-promoting function, in part inferred from the fact that antihistaminergic drugs typically produce sedation. The significance of this region for waking was first identified by

Constantin von Economo in the early part of the 20th century following an outbreak of viral encephalitis; encephalitis lethargica, as it was called, produced lesions of the posterior hypothalamus and profound somnolence. Histaminergic TMN neurons project throughout the cortex and, like noradrenergic cells, fire at the highest rates during wakefulness and are inhibited during sleep. However, cholinergic and noradrenergic cells in the pons increase firing hundreds of milliseconds or even a few seconds before the EEG switches from the synchronized NREM sleep pattern to the activated wake pattern suggesting a causal role in arousal, while histaminergic neurons increase firing only at wake onset. Histamine infusion into the CNS causes arousal, whereas experimental lesions of the TMN decrease waking and increase SWS and REM sleep. The wakefulness-promoting effect of histamine is mediated by H_1 receptors. Histamine promotes wakefulness in the thalamus, cortex, basal forebrain, and pontine tegmentum by enhancing glutamatergic and cholinergic transmission.

The dopaminergic system also appears to modulate arousal. Dopamine-containing neurons in the substantia nigra and VTA innervate the frontal cortex, basal forebrain, and limbic structures. The mean firing rate of these cells does not change across behavioral states. However, their bursting activity, which is known to induce synaptic dopamine release, increases during the consumption of palatable food and during REM sleep relative to NREM sleep. Lesions of areas containing dopaminergic cell bodies in the ventral midbrain or their ascending pathways can lead to the loss of behavioral arousal while maintaining cortical activation. Psychostimulants such as amphetamines and cocaine that block the reuptake of monoamines, including norepinephrine, dopamine, and serotonin, promote prolonged wakefulness and increase both cortical activation and behavioral arousal.

The importance of the peptide hypocretin (orexin) in the maintenance of wakefulness was defined through discovering its role in the disorder narcolepsy. Hypocretin is produced by cells in the lateral hypothalamus that provide excitatory input to all components of the ARAS, including the LC, PPT and LDT, VTA, basal forebrain, and TMN. These cells, too, are most active during waking, especially in relation to motor activity and exploratory behavior, almost completely stop firing during both NREM and REM sleep, and start firing again before the EEG activates upon arousal. Optogenetic stimulation of hypocretin cells promotes arousal from sleep, although not as quickly as the stimulation of noradrenergic cells. Narcolepsy in animal models is related to deficits in the hypocretin system; canine narcolepsy is caused by a mutation in the hypocretin type 2 receptor gene, whereas narcoleptic symptoms (sleep attacks and sleep-onset REM periods) occur in hypocretin knock-out mice. Mouse experiments also show that the slow and progressive elimination of hypocretin cells mimics many aspects of human narcolepsy: sleep fragmentation is the first symptom, and cataplexy develops only after ~95% of all hypocretin cells are lost. Human narcoleptics show the loss of hypocretin cells and/or protein in the CSF. Hypocretin cell loss is also present in Parkinson disease, which is often associated with sleep disturbances similar to narcolepsy.

Serotonergic cells from the *dorsal raphe* nucleus also project widely throughout the cortex. Serotonergic neurons, like noradrenergic neurons, fire at higher levels during waking, lower levels in NREM sleep, and fall silent during REM sleep. However, in sharp contrast to noradrenergic neurons, serotoninergic neurons are inactivated during orientation to salient stimuli and are activated instead during repetitive motor activity such as locomotion, grooming, or feeding. Selective Serotonin Reuptake Inhibitors (SSRIs) tend to decrease sleep time and increase arousal during sleep. However, the role of serotonin in sleep is not straightforward since there is also evidence that serotonin may be involved in sleep induction (see below).

Several other neurotransmitters and neuromodulators appear to have wakefulness-promoting effects. These include substance P, neurotensin, epinephrine, and hypothalamic peptides such as corticotrophin-releasing factor, VIP, and thyrotropin-releasing factor, all of which can increase arousal levels. Cortisol also promotes wakefulness. It is thus possible that sleep disturbance in depression, including early morning awakening, could be related in part to the associated hyperactivity of the HPA axis.

NREM Sleep

The EEG of NREM sleep is dramatically different from that of waking and is characterized by oscillatory waveforms such as sleep spindles, K-complexes, slow waves (0.5 to 2 Hz), and slow oscillations (mainly 0.7 to 1 Hz). Brain activation generally decreases in NREM sleep, particularly SWS, which is characterized by an overall decrease in CBF. PET imaging studies show the deactivation of many structures, including the brainstem, thalamus, anterior hypothalamus, basal forebrain, basal ganglia, cerebellum, and frontal, parietal, and mesiotemporal cortical areas.

The control of NREM sleep, like wakefulness, involves multiple structures ranging from the lower brainstem through the thalamus, hypothalamus, and forebrain. Electrophysiologic studies in animals have clarified the production of various thalamocortical oscillations that produce the characteristic waveforms in NREM sleep. The generation of sleep oscillations requires the interplay between intrinsic cellular properties and synaptic activity mediated by corticocortical, corticothalamocortical, and thalamoreticular loops. Work in animals has shown that, shortly before the transition from waking to sleep, changes in the activity of cholinergic, noradrenergic, histaminergic, hypocretinergic, and glutamatergic neuromodulatory systems with diffuse projections belonging to the ARAS bring about a change in the firing mode of thalamic and cortical neurons. Thalamocortical cells are hyperpolarized, whereas reticulothalamic cells are facilitated and further inhibit thalamocortical cells, with the consequence that sensory stimuli are gated at the thalamic level and often fail to reach the cortex. Rebound firing due to the activation of intrinsic currents in thalamocortical cells leads to the emergence of oscillations in the spindle frequency range within local thalamoreticular circuits. Local thalamic spindle sequences are globally synchronized and grouped with other rhythmic activities by the slow oscillations that originate in the cortex. Intracellular recordings have shown that the slow oscillation is the result of a brief hyperpolarization of cortical neurons (lasting a few hundred milliseconds), which is seen in the surface EEG as a high-amplitude negative wave. The hyperpolarization phase, also known as the down state, is followed by a slightly longer depolarization phase, known as the up state, during which the firing of cortical neurons entrains and synchronizes spindle sequences in thalamic neurons, resulting in EEG-detectable spindles. K-complexes are made up of the cortical depolarization phase followed by its triggered spindle. The slow oscillation also organizes the slow (also called) delta waves (0.5 to 4.5 Hz), which can be generated both within the thalamus and in the cortex. The hyperpolarization phase of the slow oscillation is associated with the virtual absence of synaptic activity within cortical networks. By contrast, during the depolarized phase, cortical cells fire at rates that can be higher than those seen in waking. Moreover, during the depolarized phase, thalamocortical neurons often fire rhythmically in the gamma range (around 40 Hz), which was previously thought to be exclusively associated with activated states such as wakefulness and REM sleep. The slow oscillation is found in virtually every cortical neuron and is synchronized across the cortical mantle by corticocortical connections. Intrinsic currents are also involved in initiating and terminating the oscillation.

The importance of hypothalamic structures for sleep induction was recognized in early studies in which electrical stimulation of the anterior hypothalamus resulted in increased SWA in the cortex. Conversely, some cases of encephalitis lethargica, in which lesions occurred in the anterior rather than posterior hypothalamus, were characterized by severe insomnia. A few years ago, attention became focused on a small portion of the anterior hypothalamus, the VLPO area, as a possible sleep switch. However, it is now clear that many other neurons scattered through the anterior hypothalamus (for instance, in the median preoptic nucleus, MnPO) and the basal forebrain also play a major role in initiating and maintaining sleep. These neurons tend to fire during sleep and stop firing during wakefulness. MnPO neurons can also track sleep pressure, because their firing is higher during the first sleep cycle when sleep pressure is high and declines in later cycles. When they are active, many release GABA and the peptide galanin and inhibit most wakefulness-promoting areas, including cholinergic, noradrenergic, histaminergic, hypocretinergic, and serotonergic cells. In turn, the latter groups of cells inhibit several sleep-promoting neuronal groups. This reciprocal inhibition provides state stability in that each state reinforces itself as well as inhibits the opposing state. A subset of cortical GABAergic cells is also active during sleep and may track sleep pressure. Finally, sleep-promoting GABAergic cells were recently identified in the medulla, in the parafacial zone. Stimulation of this cell group promotes NREM sleep by inhibiting the wake-promoting neurons of the parabrachial nucleus, located at the junction between the midbrain and pons, which send glutamatergic projections to the basal forebrain.

In terms of NREM sleep neurochemistry, many substances modulate sleep, but no unique sleep factor has been identified. GABA, the major inhibitory neurotransmitter in the CNS, appears to be involved in thalamocortical oscillations and inhibition of waking centers by sleep-active cells. Most hypnotics, including barbiturates, benzodiazepines, and several of the newer nonbenzodiazepine hypnotics, act by enhancing

GABA transmission. However, many GABAergic neurons in the brainstem and basal forebrain are active during waking.

Adenosine has been increasingly recognized as having a role in sleep. Caffeine probably exerts its stimulant effects by blocking adenosine receptors. Adenosine, a degradation product of adenosine triphosphate (ATP), is a byproduct of brain metabolism whose levels increase as a result of increased glutamatergic activity. It accumulates in the basal forebrain and cerebral cortex during prolonged wakefulness and decreases during sleep, suggesting that it may serve to transmit the homeostatic signal for sleep. Adenosine inhibits cholinergic neurons in the pons and basal forebrain, as well as hypocretin neurons and cortical glutamatergic neurons. By contrast, adenosine excites VLPO neurons, and its infusion promotes NREM sleep.

Early studies raised the possibility that serotonin might also be involved in SWS because lesions of serotonergic nerve cells in the dorsal raphe led to insomnia. However, more recent evidence suggests that some of the early results may have been confounded by lesion-induced loss of thermoregulation, which caused increased locomotion (and thus decreased sleep) as a compensatory response to maintain body heat. Serotonergic neurons decrease firing rates in NREM sleep and are completely inhibited during REM. However, they inhibit cholinergic neurons and produce behavioral inhibition, raising the possibility that they help facilitate sleep onset, although they may not be directly involved in inducing or maintaining sleep. It remains controversial as to how much serotonin contributes to sleep versus arousal.

Many other substances, including peptides and neuromodulators, have been attributed with having sleep-promoting properties. These include a variety of hormones, such as melatonin, αMSH, GH-releasing factor, insulin, CCK, and bombesin; cytokines such as interleukin-1, interleukin-6, and TNF; muramyl peptides produced from gut bacteria; and dozens of other substances. Most of these factors have mild hypnotic and/or circadian effects consistent with the usual timing of their release (e.g., melatonin or GH-releasing factor, which is normally released at night) or the physiologic state of the organism (e.g., cytokines produced during infectious illness promote sleep).

REM Sleep

REM sleep is characterized by an activated EEG and increased neuronal activity and CBF. Recent studies using functional imaging techniques have shown that, during REM sleep, there are some brain regions showing increased activation as well as others with decreased activation in comparison to wakefulness. Areas involved in REM sleep generation in the mesopontine tegmentum, thalamus, posterior cortical areas, and limbic areas, particularly the amygdala, are highly activated during REM sleep. In contrast, frontal and parietal cortices are relatively deactivated.

REM sleep is somewhat unique among the three states because a specific brain region—the *pons* and *caudal midbrain*—is both necessary and sufficient to generate the main features of REM sleep and represent the final common pathway for the induction of REM sleep. A series of transection studies have demonstrated that REM sleep is preserved only in the portion of the CNS containing these structures. Bilateral lesions within the pons and caudal midbrain can completely eliminate REM sleep. Although these findings have created a tendency to focus on brainstem mechanisms of REM sleep, more rostral brain regions, including the preoptic area, are also important in the homeostatic regulation of REM sleep and in organizing REM episodes through the night.

As in wakefulness, cholinergic neurons produce EEG activation and a hippocampal theta rhythm during REM sleep. LDT/PPT neurons provide input to the thalamus and cholinergic basal forebrain neurons that in turn activate the limbic system and cortex. Hobson and McCarley proposed the reciprocal interaction hypothesis to explain NREM–REM cycles based on interactions between cholinergic and aminergic neurons in the mesopontine junction. Cholinoceptive and/or cholinergic REM-on cells in the PPT and LDT regions become activated during REM sleep, whereas noradrenergic or serotonergic REM-off cells are inhibitory of the REM-on cells. The aminergic cell groups are most active during waking; they decrease activity somewhat during NREM sleep, and meanwhile, cholinergic activity increases to turn on REM sleep. REM sleep episodes are terminated because REM-on cells are self-inhibitory and provide excitatory input to the REM-off cells. Recent experiments show that GABAergic and glutamatergic neurons in the mesopontine tegmentum are also very important in controlling REM sleep.

The role of cholinergic–monoaminergic interactions in regulating REM sleep is supported by a variety of experimental data. Local infusion of cholinergic agonists such as carbachol in the region of the LDT/PPT of cats or systemic administration of physostigmine, arecoline, pilocarpine, or other cholinergic agonists in humans produces prolonged REM sleep episodes and reduced latency to REM sleep. Cholinergic induction of REM sleep appears to be related primarily to the activation of M_2 muscarinic receptors in the pontine reticular formation. Facilitation of REM sleep also results from the depletion of brainstem monoaminergic activity, for example, in human subjects with an acute depletion of serotonin after being fed a tryptophan-deficient diet. Most antidepressants cause significant reductions in REM sleep, particularly those that increase synaptic availability of norepinephrine and/or serotonin; anticholinergic effects seen in TCAs and MAOIs may also contribute to REM sleep suppression.

Muscle atonia in REM sleep can be eliminated by small lesions in the pontine reticular formation lateral to the LC or in the medial medulla that eliminate inhibitory input from this area to the spinal motoneurons. Spinal motoneurons are inhibited by both GABA and glycine and excited by NA, serotonin, and glutamate. The brainstem circuit responsible for REM sleep atonia includes two major pathways: (1) a glutamatergic projection from the subcoeruleus area to the medullary reticular formation, which then sends GABAergic and glycinergic inputs to motoneurons; (2) a glutamatergic projection from the subcoeruleus area to GABAergic interneurons, which then inhibit motoneurons. Disfacilitation of spinal motoneurons resulting from decreased noradrenergic and serotonergic activity also contributes to the suppression of muscle tone during REM sleep. Several clinical conditions illustrate how atonia may be separated from the state of REM sleep. In narcolepsy, muscle atonia can occur during wakefulness, either as cataplexy, a sudden loss of muscle tone usually brought on by emotional stimuli, or sleep paralysis, in which atonia persists briefly after waking out of REM sleep. In contrast, patients with REM sleep behavior disorder do not develop atonia during REM sleep and act out their dreams, sometimes with such violence that they may injure themselves or their bed partners. REM-sleep–suppressing antidepressants such as TCAs, MAOIs, and SSRIs may induce REM sleep behavior disorder in some individuals.

In animals, ponto-geniculo-occipital (PGO) waves that occur sequentially in the pons, lateral geniculate nucleus of the thalamus, and occipital cortex appear just prior to the initiation of REM periods and in conjunction with phasic activity in REM sleep, including eye movements and muscle twitches. They originate from cholinergic burst cells in the peribrachial region and are suppressed by serotonergic cells in the raphe nuclei. Eye movements during REM sleep are tightly linked to PGO waves and are mediated by inputs to vestibular neurons that in turn activate oculomotor cells. PGO waves are thought to be the internal representation of orienting responses because they can also be observed during a startle response during waking. In humans, PGO-like potentials have been recorded in the pons before and during REM sleep and in the subthalamic nucleus.

In addition to imaging data showing dramatically increased activity in forebrain structures during REM sleep, previous anatomical work has also suggested forebrain involvement in REM sleep regulation. Transection studies that separate the forebrain from pons disrupt NREM–REM cycling caudal to the transection. The amygdala has reciprocal connections with REM-generating brainstem regions, and electrical stimulation or infusion of carbachol into the amygdala can increase REM sleep. Abnormal activation of limbic structures occurs in depression and may contribute to associated changes in REM sleep.

CIRCADIAN AND HOMEOSTATIC REGULATION OF SLEEP

The regulation of sleep—both NREM and REM—involves at least two key components—a circadian and a homeostatic component. The circadian component is responsible for the change in sleep propensity tied to the time of day, with obvious adaptive advantages. The homeostatic component refers to the fact that the longer one stays awake, the greater the propensity to sleep, and it represents the essential aspect of sleep whose function remains mysterious.

The Two-Process Model

Several models of sleep regulation positing a circadian and a homeostatic process have been proposed and validated on the basis of a large amount of data. One of the most influential is the *two-process model* developed by Alexander A. Borbély and colleagues, which predicts sleep propensity based on the interaction between the homeostatic *process S* and the circadian *process C.* Process S builds up across the day in response to the increase in sleep pressure caused by wakefulness and decreases during sleep. The circadian process C for sleep propensity, however, reaches its peak during the latter half of the night. Thus nocturnal sleep onset is primarily driven by process S, whereas process C maintains sleep through the latter part of the night. It is common for humans to have a brief period of arousal in the middle of the night, possibly related to a reduction in overall sleep drive from the fall in process S before process C has reached its maximal values. Similarly, the tendency for afternoon napping may be caused by the increase in process S across the day before process C has reached its lowest values in the late afternoon/early evening. Although napping during the day has become relatively uncommon in industrialized societies, most people experience a period of increased sleepiness in the afternoon. This afternoon “dip” can produce significant daytime sleepiness in individuals who are already somewhat sleep-deprived, are taking sedating medications, and/or have sleep disorders causing excessive daytime sleepiness such as sleep apnea.

Circadian Rhythms

In humans and other mammals, the primary pacemaker for generating circadian rhythms lies in the *SCN* of the hypothalamus. The SCN regulates several neuroendocrine and behavioral parameters, including sleep propensity as measured by process C, to coordinate the state of the organism with the 24-hour light–dark cycle. Circadian sleep regulation is strongly linked to the endogenous temperature rhythm; subjective sleepiness, sleep propensity, and REM sleep propensity are all maximal at the minimum (nadir) of core body temperature, usually in the very early morning, several hours prior to waking up. Sleep tendency is greater during the falling phase of the temperature curve during the night. When core body temperature begins its rising phase in the morning hours, people tend to wake up; arousal levels, performance, and cognitive function are maximal in association with the rise of body temperature across the day.

In animals with lesions of the SCN, sleep is no longer concentrated in one main episode but is dispersed across the entire 24-hour cycle. Still, sleep propensity increases in these animals as a function of previous waking. Thus, although process C and process S normally work together and interact significantly, they can, to a large extent, be separated. Several approaches have been used to investigate specifically the circadian regulation of sleep in humans. The *constant routine* protocol was designed to minimize the influences of factors other than the circadian clock on behavioral state. In this protocol, subjects are kept awake, usually for more than 24 hours, while sitting in bed in a dimly lit room. This technique has been used successfully to demonstrate the persistence of various circadian outputs in the absence of external cues, but the need to enforce sleep deprivation limits the duration of the experiment. With *temporal isolation,* subjects are placed in an environment without time cues for periods of weeks to months. Although circadian rhythms of sleep persist, the "day length" as defined by the period between successive bedtimes is close to 25 hours. These results led to the conclusion that the endogenous period of the human circadian clock is about 25 hours and that the light–dark cycle serves to entrain it to the 24-hour day.

To accurately determine the endogenous period of the circadian pacemaker, it is necessary to disentangle the circadian output from the effects of sleep or prolonged sleeplessness; however, neither of the two protocols discussed above can satisfactorily achieve this. The *forced desynchrony* protocol, originally developed by Nathaniel Kleitman in 1938, consists of having subjects live on a 28-hour "day" while living in temporal isolation. Since it is not possible to entrain the human circadian clock to a period of 28 hours, after a sufficient period of time, sleep periods will have occurred at all phases of the circadian cycle. Thus, circadian and homeostatic influences on human sleep organization can be teased apart. Data from forced desynchrony studies suggest that the endogenous human circadian period is, in fact, close to 24 hours (24.1 to 24.2 hours). Moreover, they show that SWS is primarily regulated by the homeostatic sleep drive, whereas REM sleep is primarily regulated by the circadian clock. However, REM sleep is also homeostatically regulated, as indicated by increased attempts to initiate REM sleep if that stage of sleep is prevented.

More recent studies have demonstrated that circadian timekeeping is more complex; in addition to the central pacemaker in the SCN, there are peripheral clocks in many cells and organs. These peripheral clocks, with their local circadian oscillations, are likely important in the regulation of secretion of multiple hormones, and both misalignment of the central SCN oscillator with the light–dark cycle as well as internal desynchronization between the SCN and peripheral oscillators may be contributory to metabolic and endocrine disorders, as well as to a number of psychiatric disorders.

HOMEOSTATIC REGULATION OF SLEEP AND THE EFFECTS OF SLEEP DEPRIVATION

In humans, as well as in virtually all animal species in which sleep has been carefully studied, sleep deprivation produces sleepiness and increased sleep pressure that soon becomes overwhelming. Sleep deprivation is followed by a “sleep rebound,” that is, a compensatory increase in the duration and/or the intensity of sleep. After sleep deprivation, sleep latency is decreased, and sleep efficiency is increased; that is, sleep is less fragmented. The amount of NREM sleep (especially stage N3 in humans) increases, together with markers of NREM sleep intensity such as SWA, which measures the predominance of slow waves in the cortical EEG. REM sleep amount also increases, but it is unclear whether this is also true for REM sleep “intensity.” Such exquisite homeostatic regulation is one of the most important indications that there must be a distinct physiologic, biochemical, or molecular process that builds up beyond its usual level in the brain if sleep initiation is postponed.

The most prominent effect of total sleep deprivation in humans is cognitive impairment, with striking practical consequences. It is estimated that 35% to 40% of Americans suffer from chronic sleep disorders resulting in difficulty falling asleep or daytime sleepiness. Each year, the costs attributed to sleep problems, including the direct costs of treatment as well as the indirect costs of absenteeism, decreased productivity, accidents, and increased morbidity and mortality, range into the hundreds of billions of dollars in the United States alone. Moreover, the National Highway Traffic Safety Administration reported that in 2017 drowsy driving was responsible for at least 91,000 automobile crashes, resulting in 50,000 injuries and 800 fatalities, according to police reports, but that the true number of yearly fatalities due to drowsy driving is likely about 6,000 according to analyses reported by the Centers for Disease Control. A sleep-deprived person tends to take longer to respond to stimuli, particularly when tasks are monotonous and low in cognitive demands. However, sleep deprivation produces more than just decreased alertness. Tasks requiring higher cognitive functions, such as logical reasoning, encoding, decoding, and parsing complex sentences; complex subtraction tasks; and tasks requiring divergent thinking, such as those involving the ability to focus on a large number of goals simultaneously; are all significantly affected even after one single night of sleep deprivation. Tasks requiring sustained attention, such as those including goal-directed activities, can also be impaired by even a few hours of sleep loss. Thus, sleep loss causes attention deficits, decreases in short-term memory, speech impairments, perseveration, and inflexible thinking. These deficits can explain why sleep-deprived subjects underestimate the severity of their cognitive impairment, often with tragic consequences. Another reason people may underestimate their impairment due to sleep loss because the lack of sleep does not completely eliminate the capacity to perform but rather makes the performance inconsistent and unreliable. Thus, a sleepy driver will either normally respond to an emergency or not at all due to rapid changes in vigilance state and the sudden intrusion of microsleeps during waking. Similarly, subjects may still be able to transiently perform at baseline levels in short tests even after 3 to 4 days of sleep deprivation. However, the same subjects will perform very poorly when engaged in tasks requiring sustained attention. New evidence suggests that not just a few hours of sleep but several days of normal sleep–wake patterns are required to normalize cognitive performance after sleep deprivation.

Cognitive impairment is not only the consequence of total sleep deprivation. Cognitive performance is also affected by sleep restriction (6 hours per night or less) if it continues for several days and by chronic sleep discontinuity such as that occurring in patients with chronic pain, sleep apnea, or other sleep disorders. According to the 2020 “Sleep in America” poll conducted by the National Sleep Foundation in United States residents of at least 18 years of age, 44% reported feeling sleepy 2 to 4 days per week, and 28% felt sleepy 5 to 7 days per week. Women reported feeling sleepy an average of 3.4 days per week, whereas men felt sleepy 2.7 days per week on average. Respondents attributed their sleepiness either to not sleeping well enough (55%) or having insufficient time to sleep (44%). Those who reported feeling sleepy were far more likely to report an impact on their mood, attention, and work performance. A recent analysis of sleep duration obtained from the National Health Interview Survey found that sleep duration decreased from 2013 to 2017, more noticeably among Hispanics and non-Hispanic blacks; overall, 32.9% of adults reported <6 hours of sleep per night. Whether chronic sleep restriction, due to inadequate opportunity or poor quality of sleep, is sufficient to affect objective measures of cognitive performance is not known, but it is certainly concerning given the data from sleep restriction studies that point to impairment and decreased performance. It is becoming apparent that almost all sleep measures, such as the duration of total sleep or SWS and the amount of SWA in the cortical EEG during NREM sleep, show great variability across different subjects but high consistency within the same individual from one night to another. The extent of the cognitive impairment after sleep deprivation also varies significantly across subjects. Converging evidence shows that individual differences in the cognitive impairment caused by sleep deprivation are stable over time and traitlike, suggesting a genetic basis.

Brain and peripheral tissues respond differently to sleep loss. Like in sleep-deprived animals, the peripheral metabolic rate is increased in sleep-deprived human subjects and in normal sleepers on nights of poor sleep relative to baseline nights; this increased rate is also present generally in people with insomnia relative to normal sleepers. In both animals and humans, glucose metabolism is higher in many brain regions in waking than that in NREM sleep. After one day of sleep deprivation, selective brain areas can still be activated metabolically when the subject is engaged in specific tasks. However, the global cerebral metabolic rate does not increase and actually decreases relative to normal waking values in areas such as the thalamus and the midbrain. Thus, while peripheral metabolic rate is persistently increased during sleep deprivation, brain metabolic rate is not. This may be an indication that the brain cannot sustain high-energy metabolism for too long.

In addition to causing cognitive impairment, sleep deprivation in humans may also affect various physiologic systems with impacts on overall health. It has been suggested that sleep loss can affect host defense systems; for example, sleep-deprived rats show increased rates of bacteremia. Sleep deprivation has also been shown to lead to decreased glucose tolerance, increased sympathetic nervous system (SNS) activation, and elevated cortisol levels, suggesting that it may contribute to disorders such as diabetes, hypertension, and obesity. Patients with insomnia have increased rates of health problems, including cardiac disease, further suggesting a possible causal relationship between reduced sleep amounts and health outcomes. Some studies in both humans and animals have linked long-term disturbances in sleep with reduced longevity. Others have suggested that, in fact, short sleep and insomnia are associated with little risk distinct from comorbidities. Whether there is a U-shaped association between sleep duration and mortality risk (i.e., both short sleep and long sleep are associated with increased mortality) remains unclear, and meta-analyses have come to conflicting conclusions. Recent meta-analyses, published in 2019 and 2020, concluded that long sleep duration was associated with increased risk for all-cause mortality in men and women, but short duration of sleep was significantly associated with all-cause mortality only in men and in only one of the analyses. However, it is important to note that insomnia is not equivalent to sleep deprivation and does not necessarily indicate reduced sleep amount.

The most extreme case of prolonged sleep loss in humans is observed in patients affected by fatal familial insomnia (FFI), a prion disorder characterized by near-complete loss of sleep and associated with various neurologic symptoms and spongiform degeneration in selected brain regions. The disease is invariably fatal after a few months to 2 to 3 years. In FFI with a short clinical course (death in <1 year), insomnia is almost complete from the onset, and spongiform degeneration is mainly restricted to the thalamus and inferior olive but does not extend to the cerebral cortex. In FFI cases with a longer clinical course (death in 2 to 3 years), insomnia develops more gradually, and spongiform degeneration is found in most cortical regions. While several clinical aspects of FFI can be attributed to diffuse spongiform degeneration, sleep loss per se likely plays an important role in determining the evolution of the disease, especially in short-course FFI. Indeed, the severity of the clinical course correlates with the severity of insomnia rather than with the accumulation of prion protein.

In humans, sleep deprivation is never enforced for more than 3 to 4 days (the record is 11 days but in only one subject), making it impossible to determine whether there are other more severe effects of very prolonged sleep loss. Prolonged sleep deprivation is possible in animals, where several techniques have been used, from forced locomotion to pharmacologic stimulation with amphetamines. Irrespective of the method used, an important and consistent finding is that even drastic manipulations such as brain electrical stimulation are unable to enforce complete and uninterrupted wakefulness after the first 24 hours. Even prolonged sleep deprivation attempts cannot enforce complete and uninterrupted wakefulness for more than one day. Evidently, sleep pressure overcomes whatever method is used to maintain wakefulness in animals as well as in humans. This pressure can manifest itself in different ways. The most obvious way is “microsleeps,” short lapses lasting a few seconds during which the waking EEG clearly switches to a sleep pattern. Microsleeps can cause obvious impairment in performance, for instance, losing control of the car while driving. Less obvious changes consist in an overall “slowing of the EEG,” with an increase in low range frequencies (delta/theta activity). This change is detectable by quantitative analysis of the EEG but not by simple visual observation, although it may still affect performance in cognitive tasks. Finally, an even more subtle change is the recently identified phenomenon of “local sleep” during wake. This phenomenon, first described in rodents using intracortical recordings, refers to the fact that during prolonged wakefulness, rats can move around and show a normal wake activated EEG, while some cortical neurons may go “offline” and stop firing, showing down states of membrane hyperpolarization and neuronal silence similar to those normally present only during NREM sleep. Because these down states are local and short-lasting, they can only be detected using invasive intracortical recordings. However, in humans, a useful EEG correlate of this phenomenon is the occurrence of local delta/theta waves (2 to 6 Hz), which can be identified using high-density EEG (hd-EEG, 256 channels). When human subjects stay awake for 24 hours and engage in intensive learning of cognitive tasks, hd-EEG can detect a local increase in delta/theta waves mainly in the cortical areas mostly involved in these tasks. During recovery sleep after sleep deprivation, the same areas will show a local increase in SWA.

The most comprehensive series of sleep deprivation studies in animals have been performed using the *disk-over-water apparatus* (DOW), which can prevent sleep for days and even weeks. This method uses minimal stimulation to enforce chronic sleep deprivation in the sleep-deprived rat, while it simultaneously applies the same stimulation to the control rat but without severely limiting its sleep. Sleep deprivation in rats with the DOW produces dramatic physiologic changes that invariably culminate in death after 2 to 3 weeks of sleep loss. Within the first 1 to 2 days, rats develop a syndrome characterized by increased food intake, energy expenditure, and heart rate, followed by a decrease in body weight and a decline in body and brain temperature. The sleep deprivation syndrome and its lethal consequences have also been observed after selective REM sleep deprivation, although the pathology associated with the loss of sleep takes longer to appear, the survival time is longer (4 to 5 weeks rather than 2 to 3 weeks), and body and brain temperature are not significantly decreased. Despite a long series of studies, the DOW sleep deprivation syndrome has not been fully explained, nor is it clear why the animals die of sleep deprivation. It is evident, however, that the syndrome produced by the DOW is not unique, and other methods of chronic sleep deprivation used in different animal species have produced similar effects. Also, in dogs, rabbits, and to a lesser extent, cats, sleep deprivation for several days causes an increase in food intake and heart rate, weight loss, and eventually death. Even fruit flies, if prevented from sleeping for several days, die of sleep deprivation. Again, these findings suggest that there must be at least one potentially vital function for sleep and that this function is conserved across different animal species.

DREAMING

For a long time, sleep has been regarded as the annihilation of consciousness, save for the occasional dream that is remembered when one wakes up. Just as the old notion that the brain is silent during sleep has been disproved, so has the myth of cognitive death during sleep. Most subjects, if awakened and asked to report whatever may be going through their minds, report some kind of mental activity most of the time. Often such mental activity constitutes a dream, which can be defined as a complex, temporally unfolding, hallucinatory episode that occurs during sleep.

The Relationship between Dreaming and Normal Waking Consciousness

Dream hallucinations are typically more vivid than waking images. Images are predominantly visual, although all modalities can be represented, and impossible motor activities, such as flying, may occur. Hearing speech or conversation is extremely frequent. Dreaming is generally delusional—events and characters in the dream are taken for real—and confabulatory—a dream involves making up a story. There is often disorientation, that is, uncertainty about space (where one is in the dream), time (when the dream is taking place in personal history), and confusion about the gender, age, and identity of dream characters. However, dreams appear to run in real time, as there are good correlations between the subjective duration of a dream, the length of the dream report, and the time it would take to reenact a dream. Emotions are prominent in many dreams, especially fear and anxiety. While the self is almost always at the center of the dream, there is some reduction of reflective consciousness. Dreams have been described as single-minded, that is, missing the alternation of primary and reflective consciousness that characterize wakefulness. Self-monitoring, directed thinking, and volition are reduced, leading to an inability to analyze situations, to question assumptions, and to make appropriate decisions. The ability to form new memories is drastically impaired (dream amnesia), in part due to low noradrenergic activity. Not surprisingly, psychiatrists have pointed out similarities between some aspects of dreaming cognition and certain psychotic symptoms, as well as delirium.

Despite these psychopathologic traits, perhaps the most important fact about dreaming consciousness is how remarkably similar it can be to waking consciousness. The sleeping brain, disconnected from the “real” world, is capable of generating an imagined world, a “virtual reality,” which is fairly similar to the real one and is indeed experienced as equally real. Considering dreams from the perspective of the waking state, people are often intrigued by the bizarre quality of some dreams, especially morning dreams. Bizarre dreams may be more memorable; however, if collected systematically throughout the night, dreams are much more mundane—they are a faithful replica of waking life. As a rule, one can only dream what one can imagine, although dreams can be much more vivid, probably because of the reduced competition from external signals.

Conditions that affect people’s brains during wakefulness extend to their dreams. For instance, if blind people can still construct visual images, then they have visual dreams; otherwise not. If a stroke abolishes the ability to perceive color during waking, then visual images, as well as dreams, become achromatopsic. Like the ability to form mental images, dreaming seems to depend most strongly on the integrity of cortical areas higher than the primary visual cortex. Similarly, somatosensory/motor and audioverbal/motor imagery are normal in the dreams of hemiplegic and aphasic patients. Another example of the close connection between waking and dreaming cognitive competence comes from the study of children’s dreams. Dream reports are rare and extremely short until 4 to 5 years of age—in agreement with the limited ability of children below that age to imagine and narrate complex stories with high emotional content. Finally, there is a good correlation between waking and dreaming mood, imaginativeness, and personality. Studies of dream content in psychiatric populations, especially in depression and PTSD, have generally been unremarkable. However, some intriguing findings have been reported, for example, that changes in dream content may anticipate changes in the course of the disorder.

Dreaming and Sleep Stages

It was initially suggested that full-fledged dreams could be elicited almost exclusively during REM sleep. However, later studies have shown conclusively that dreamlike mental activity can also be elicited from NREM sleep, especially at sleep onset and during the last part of the night—the times when NREM sleep is less deep. Up to 15% of subjects, however, never recall any mental content when awakened from NREM sleep. Moreover, typical REM dream reports can easily be distinguished from NREM ones by being, on average, much longer (up to seven times). When dream reports are longer, this suggests a longer duration of the actual dream, but they may also be due to an increased density or bizarreness of the experienced scenes. Whether REM dreams are not only longer but also qualitatively different—more bizarre, hallucinatory, delusional, narrative, and emotional than NREM dreaming—remains controversial. So is the suggestion that NREM dreams may be “covert” REM dreams due to an intrusion of REM characteristics in NREM sleep. There is no doubt, however, that typical dreams, as well as nightmares, can be experienced in certain phases of NREM sleep. Dreamlike mental activity having a hallucinatory–delusional character can also occur during quiet wakefulness, especially under conditions of reduced sensory input (daydreaming). Conversely, some waking-like mental activity—nonhallucinatory and nondelusional—is occasionally reported at sleep onset. A good example of a mixed state is lucid dreaming, where dreamers are aware that they are dreaming and, to some extent, can control the course of their dreams.

The initial equating of the cognitive state of dreaming with the physiologic state of REM sleep was encouraged by the remarkable similarity between the EEG of REM sleep with that of conscious waking and by their equivalent differences from the NREM sleep EEG. It seemed natural to infer that the activated (low-voltage, high-frequency) EEG of waking and REM sleep would support vivid conscious experience, while the deactivated (high-voltage, low-frequency) EEG of NREM sleep would not. While frequent dream reports at sleep onset could still be reconciled with the mixed EEG of stage N1 sleep, the presence of dreamlike experiences, although shorter, during NREM stages characterized by EEG slow waves seemed paradoxical. This paradox may be resolved by considering the time course of neural excitability during the slow oscillation of NREM sleep. It is now known that, during the depolarized phase of the slow oscillation, neural activity is as intense as in waking or REM sleep, and neurons are highly excitable. However, during sleep, the depolarized phase is interrupted by a hyperpolarized phase during which neural activity ceases throughout the cerebral cortex, and neurons are much less excitable. The inevitable occurrence of hyperpolarization (down state) after a period of depolarization (up state) occurs exclusively during NREM sleep and reflects a peculiar bistability of cortical circuits. This bistability is especially strong during SWS early in the night—the depolarized phase may not last longer than a second or so before it is followed by the hyperpolarized phase—and becomes less marked during stage N2 sleep late in the night when longer periods of depolarization are possible. Thus, if dreamlike experiences occur during the depolarized phase, then they will be short and poor during SWS early in the night and become progressively longer and richer later in the night. Altogether, it would seem that the likelihood of conscious experience during sleep is related to moment-to-moment cortical activation, where activation should be understood as the readiness of cortical neurons to respond in a rich and differentiated manner to incoming signals.

Neural Correlates of Dreaming Consciousness

Recently, lesion and imaging studies have provided new insights into brain correlates of the characteristic differences between dreaming and waking consciousness. The most obvious difference is that dreaming consciousness is only marginally influenced by external stimuli, very few of which are incorporated into the dream narrative. During NREM sleep, partial functional disconnection is mediated by thalamic inhibition. During REM sleep, external stimuli more easily pass the thalamic gate and reach primary cortical areas, but they do not seem to influence higher cortical areas, as if the brain were not paying attention to them. The hallucinatory character of dreams is obviously facilitated by such sensory disconnection. Visual hallucinosis of dreams is indeed associated with increased activity in higher visual areas, while the primary visual cortex is less active, as indicated by PET studies. Whether the intense visual experience and scene changes characteristic of dreams are triggered primarily by phasic signals from the brainstem, areas involved in visual imagery, or both is an unresolved issue.

Another relevant difference between dreaming and waking consciousness concerns the ability to reflect on oneself and one's experience, especially the ability to judge the verisimilitude of dreaming experience. Imaging studies indicate that the dorsolateral prefrontal cortex (DLPFC), a brain region implicated in volitional control and self-monitoring, is less active in sleep compared to waking. Reduced activation of the DLPFC may also contribute to the disorientation and reduction of directed thinking and working memory observed in dreams and contribute to dreaming amnesia. Recent episodic memories are conspicuously absent in dreams, and memory for dreams is strikingly labile unless one wakes up and rehearses the dream.

Dreams are also characterized by a high degree of emotional involvement, especially fear and anxiety. Correspondingly, imaging studies have revealed a marked activation of limbic and paralimbic structures such as the amygdala and anterior cingulate, insular, and medial orbitofrontal cortices during REM sleep. Altogether, cognitive activity during sleep provides a powerful indication of the extent to which fluctuating levels of several neuromodulators, whose dysfunction is implicated in several psychiatric disorders, can affect mental function in healthy subjects. Indeed, Hobson has suggested that most aspects of dreaming cognition can be explained by considering the level of three processes—brain activation, input source (external or internal), and neuromodulation—across the sleep–wakefulness continuum.

Recently, hd-EEG has also been used to characterize the neural correlates of conscious experience during sleep. These experiments have used a no-task, within-state paradigm in which sleeping subjects recorded with hd-EEG reported retrospectively whether they had been conscious or not. It was found that the neural correlates of consciousness in both NREM and REM sleep map to two localized hotspots: (1) a parieto-occipital hotspot characterized by reduced low-frequency EEG activity and (2) a frontal hotspot characterized by increased high-frequency EEG activity. It was also found that the frontal hotspot is involved in highly thought-like experiences, while the parieto-occipital hotspot is implicated in highly perceptual experiences, suggesting that the neural correlate of consciousness during sleep may be restricted to a single hotspot and change in location depending on the nature of the subject's dream. These studies have also shown that specific contents of a subject's dreams—such as faces and spatial setting—are associated with increased high-frequency EEG activity in specific cortical areas that closely match those engaged during waking perception of the same contents. These results provide strong evidence that dream reports reflect conscious experience that occurs during sleep and are not simply confabulations that are produced upon awakening.

Theories of Dreaming

In what he considered his most important work—*The Interpretation of Dreams*—Freud suggested that dreams provide disguised wish fulfillment and, if properly interpreted, would provide essential clues to the most profound determinants of psychic life, "the royal road to the unconscious." The systematic investigation of dreams has not provided much support for this notion.

A radically different suggestion was made by Hobson and McCarley based on their neurophysiologic studies of REM–sleep-generating mechanisms in the brainstem. According to their activation–synthesis hypothesis, dreams were the forebrain's attempt to make sense of the random activation of thalamocortical networks by the upper brainstem, like the music produced by unmusical fingers wandering over the keys of a piano. Another suggestion, based on a comprehensive evaluation of dream reports, was made by Foulkes and others. According to this view, dreams reveal not so much the psychodynamic unconscious but instead the cognitive development, competence, and style of the dreamer, just as in waking cognition. This view carefully eschews the one-to-one conflation of dreams with REM sleep.

Along these lines, Solms has recently reviewed neuropsychologic evidence and shown that the ability to dream depends not on the upper brainstem but on forebrain regions. In more than 100 cases of cessation of dreaming, the responsible lesion was either the parieto-temporo-occipital junction (uni- or bilaterally) or white matter near the orbitomesial prefrontal cortex (bilaterally). Despite the cessation of dreaming, REM sleep was almost always preserved. The parieto-temporo-occipital junction is important for mental imagery, spatial cognition (on the right side), and symbolic cognition (on the left side), all central features of dreaming. The white matter underlying the ventromedial prefrontal cortex that is necessary for dreaming is the same brain area that is targeted by modified prefrontal leucotomy. Its lesion reduces the positive symptoms of schizophrenia but produces adynamia. Chemical activation of these circuits by stimulants such as amphetamines, as well as by 3,4-dihydroxy-L-phenylalanine (L-DOPA), can produce hallucinations and delusions, suggesting that dreams may be facilitated by the activation of the mesolimbic and mesocortical dopaminergic systems.

THE FUNCTIONS OF SLEEP

The function of sleep is still a mystery. Sleep may have evolved from the circadian rest–activity cycle and may thus represent a default state. However, it is likely that sleep serves some more fundamental function. Otherwise, why should animals engage in prolonged periods of quiescence with increased arousal thresholds during which they cannot monitor potential dangers in the environment? Sleep seems to be universal. All animal species studied so far sleep, from invertebrates such as fruit flies and bees to birds and mammals, although mammals and birds generally display more elaborate sleep cycles that include an alternation of NREM and REM sleep. Ridding or even reducing the body’s need for sleep does not seem to be easy. Some marine mammals who may need continuous vigilance while flying or swimming, such as certain dolphins and porpoises, have developed alternating unihemispheric sleep rather than eliminating sleep altogether. Sleep deprivation in all species studied leads to an increase in sleep pressure, manifested as sleepiness, which rapidly becomes irresistible. Sleep pressure may lead to microsleeps or piecemeal sleep that result in cognitive impairment. Sleep deprivation is followed by longer and more intense sleep, suggesting a regulated need for sleep. If sleep is prevented for several weeks, then the consequences are fatal. Rats deprived of sleep for more than 2 to 3 weeks invariably die. Humans affected by a rare prion disorder called FFI also die, although it is not certain whether death is due to sleep deprivation per se.

Many hypotheses have been formulated about the functions of sleep. A good hypothesis should account for the following facts: (1) Sleep involves partial disconnection from the environment, which is potentially dangerous; sleep must therefore provide something not provided by quiet waking. (2) Sleep is accompanied by intense neural activity in most brain regions; an explanation is needed for the brain's activity in the absence of overt behavior. (3) Sleep seems to constitute a universal requirement, but its amount varies greatly across different species; conservation of sleep across species must be accounted for while accommodating key differences in sleep patterns. (4) In most species, sleep is prevalent early in life; sleep should perform important functions both during development and in the adult. (5) Sleep is often made up of both NREM and REM stages; it must be explained whether the sequence of the two stages is important and whether both stages serve a similar function. These various functions and characteristics of sleep have proved difficult to accommodate within one hypothesis; no single hypothesis has been proposed that can account for all these facts.

Sleep and Brain Restitution

Most hypotheses currently under investigation are concerned with a role of sleep in restoring some metabolic function or in serving neural plasticity. It is likely that sleep may preserve energy by enforcing body rest in animals with high metabolic rates. Indeed, animals and humans eat more during sleep deprivation. However, in humans, the metabolic efficiency of sleep is only marginally better than that of quiet waking. Most bodily organs can obtain rest through quiet wakefulness, except for the brain; thus, sleep may be especially important for the brain. Some molecular pathway or chemical in the brain may be depleted during waking and restored during sleep. For example, it has been suggested that sleep may favor the replenishment of glycogen in glial stores, although recent evidence shows that this may only be true in a few brain regions. Alternatively, sleep could counteract synaptic fatigue by favoring the replenishment of calcium in presynaptic stores, the replenishment of glutamate vesicles, the resting of mitochondria, recycling of membranes, or transfer of proteins along axons and dendrites. While recent studies have revealed that molecular changes do occur between sleep and waking and after sleep deprivation, the significance of such changes is still unknown. If sleep restores something lost during waking, it is not known what it is.

Sleep, Learning, and Memory

A connection between sleep and memory was noted a long time ago. For example, after struggling to learn a new piece of music for much of the day, one will often play it better after a night of sleep. Recently, the importance of sleep and even naps occurring after certain types of declarative and nondeclarative learning has been documented in well-controlled experiments. Moreover, recent evidence suggests that sleep deprivation impairs not only the ability to consolidate previously learned tasks but also the capacity to acquire new information. Sleep could indeed offer a favorable context for certain aspects of learning and memory. The sensory disconnection associated with sleep reduces interference between ongoing activities and the consolidation of previously acquired memories. Moreover, sleep has been suggested to permit the repeated reactivation, in an off-line mode, of the neural circuits originally activated during a memorable experience. Studies using multielectrode recordings in animals and PET in humans have shown that brain areas or cells activated during waking are preferentially reactivated during subsequent sleep, although this reactivation also occurs during periods of quiet wakefulness following the learning experience. A further advantage of sleep could be that the relevant neural circuits can be reactivated in a spaced and interleaved fashion. This would favor the integration of new with old memories and would avoid catastrophic interference. The intense, high-frequency bursts of spontaneous neural activity that occur during sleep may be particularly important for both triggering molecular mechanisms of synaptic consolidation and enlarging the network of associations.

Many unknowns remain, however, as to whether sleep may favor the consolidation of newly established memories or the maintenance of older ones. The molecular correlates of such processes are still not known. Molecular markers of memory acquisition are turned off during sleep, which may be advantageous given that the intense neural activity of sleep occurs while the animal is disconnected from the environment. Much of the early literature connecting sleep and memory was concerned with REM sleep. However, prolonged inhibition of REM sleep in humans through MAOIs does not seem to disrupt memory, nor does the complete disappearance of REM sleep after certain brainstem lesions. Perhaps the most convincing evidence concerns the role of sleep in developmental plasticity. Recent experiments have shown that REM sleep deprivation in newborn rats and NREM sleep deprivation in kittens influence the activity-dependent development of visual system circuits. If sleep affects synaptic maturation and plasticity, then one can expect that sleep disturbances in early life may affect psychopathologic development.

SLEEP AND PSYCHIATRY

Historically, psychiatrists have been interested in sleep and dreaming and their relationship with mental illness. From Sigmund Freud and Carl Jung in the latter part of the 19th century, the interpretation of dreams became an important tool in psychoanalytical psychotherapy. After the discovery of REM sleep in 1953, psychiatrists began to explore whether specific sleep abnormalities could be correlated with psychiatric disorders. One of the first questions addressed was whether schizophrenia might represent a disorder of REM sleep, given the similarities between dreaming and psychosis. Although psychosis could not be explained as a REM sleep disorder, both REM sleep and schizophrenia were later found to be associated with decreased activity in the DLPFC. Narcolepsy, however, turned out to be caused by the abnormal intrusion of REM sleep phenomena into wakefulness.

Research has focused more on sleep in depression than any other psychiatric aspects of sleep by far. Even before the discovery of REM sleep, people with depression were known to have disrupted sleep. Sleep EEG recordings in the 1950s and 1960s also showed that they had a relative loss of SWS in comparison to age-matched control subjects as well as specific changes in REM sleep, including reduced latency to REM sleep, greater proportion of REM sleep during the first third of the night, increased frequency of REMs during REM sleep (i.e., increased REM density), and increased percentage of sleep time spent in REM sleep. Although not every patient with depression shows changes in REM sleep and not every patient with short REM latency has depression, REM sleep abnormalities are one of the more robust biologic markers for depression. Both reduced REM sleep latency and loss of SWS appear to be trait markers for depression in that they persist even during clinical remission and are found at higher rates in first-degree family members of people with depression. Although the mechanisms for sleep changes in depression are not fully understood, there is a convergence of data suggesting that sleep and mood are regulated by common systems. For example, the cholinergic–monoaminergic imbalance hypothesis of depression is consistent with the observed increase in REM sleep and reduction in SWS that would be caused by increased cholinergic activity. Individuals with depression show a heightened sensitivity to REM sleep induction by cholinergic drugs in comparison to nondepressed control subjects as well.

Sleep deprivation studies are even more suggestive of a functional relationship between sleep and mood. Total deprivation of a single night of sleep or even partial deprivation of sleep in the latter half of the night can have an immediate antidepressant response in many moderately to severely depressed individuals. Sleep loss can induce or perpetuate mania in bipolar patients, who may go for periods of several days with little or no sleep. In contrast, even a short bout of sleep can reverse the antidepressant effect of sleep deprivation, and prolonged sleep can induce depression in some individuals. Functional imaging studies have shown that sleep deprivation, like antidepressant drug therapy, normalizes the increased metabolic activity seen in the anterior cingulate gyrus in individuals with depression. Selective REM sleep deprivation has also been shown to have antidepressant effects, and it has been suggested that REM-sleep–suppressing antidepressants may act in part through their effects on sleep. REM sleep suppression, however, is not a requirement for antidepressant efficacy because some agents such as bupropion and nefazodone appear to cause no significant reduction of REM sleep. More recent evidence suggests that both sleep deprivation and antidepressant medications may act by similar mechanisms, namely, by selectively upregulating genes involved in neural plasticity and synaptic potentiation.

Although therapeutic sleep deprivation may be beneficial for some cases of depression, the preponderance of evidence suggests that disturbed sleep is a risk factor for the development of psychiatric illness. People with insomnia as well as hypersomnia have higher rates of psychiatric disorders, particularly mood and anxiety disorders; in primary care settings, insomnia is more strongly associated with depression than with any other medical disorder. Individuals who have insomnia or even difficulty sleeping during times of stress are significantly more likely to develop depression in the future. A causal link between sleep and depression has not yet been established, but the fact that both sleep deprivation and depression are becoming more prevalent in society suggests that the relationship between the two must be clarified. In patients with psychiatric disorders as well as in those without known psychiatric illness, insomnia is an independent risk factor for suicidal behaviors.

From an epidemiologic perspective, although sleep disturbance is most strongly associated with psychiatric disorders, there are a number of other significant health-related correlates. People with insomnia have higher rates of other medical illnesses, use more health care services, have higher rates of absenteeism, accidents, and disability, and have poorer outcomes with some medical disorders, including cardiac disease. Whether treatment of sleep problems can prevent the development of any of these comorbidities remains to be seen.

Sleep abnormalities are also seen in virtually all other psychiatric disorders, particularly disturbances in sleep continuity, including prolonged latency to sleep onset, diminished efficiency of sleep, and decreased amounts of total sleep. During NREM sleep, individuals with insomnia show increased fast beta activity (16 to 32 Hz) globally, as well as increased alpha activity (8 to 12 Hz) more centrally, suggestive of hyperarousal during sleep. REM sleep abnormalities similar to depression have been described in some studies of patients with schizophrenia, alcoholism, eating disorders, and borderline personality disorder. Patients with panic disorder may have panic attacks arising from sleep, usually at the transition into SWS, which further emphasizes the biologic etiology of this disorder. Recent studies using hd-EEG have demonstrated a loss of spindle activity and decrements in SWA in schizophrenic subjects, which may be related to a dysfunction in the thalamocortical network and associated with clinical features of sleep disruption and cognitive impairments. Furthermore, spindle deficits have been reported both in schizophrenic patients early in the course of illness as well as in unaffected first-degree relatives, suggesting that they may represent biomarkers and/or risk factors for schizophrenia.

An appreciation of sleep neurobiology is essential for clinicians, because psychiatric patients often have sleep problems associated with their illnesses and most psychiatric drugs have significant effects on sleep; these range from sedation caused by many antipsychotics, benzodiazepines, TCAs, and antiparkinsonian agents to sleep disturbance caused by MAOIs, SSRIs, and psychostimulants. Antidepressants may precipitate some sleep disorders, such as periodic movements in sleep and REM sleep behavior disorder, and abrupt withdrawal of REM-suppressing antidepressants including tricyclics, MAOIs, and SSRIs can lead to REM sleep rebound, characterized by increased duration and intensity of REM sleep and sleep disruption. Sleep apnea may be exacerbated by drugs that produce muscle relaxation (e.g., benzodiazepines or barbiturates) or weight gain (e.g., antipsychotics, antidepressants, and mood stabilizers).

Sleep is a revealing, though not yet transparent, window into the functional state of the human brain. The study of sleep has shed light on many aspects of consciousness and the workings of the human brain. Clarifying the functions and mechanisms of sleep will undoubtedly provide us with a greater understanding of psychiatric disorders and their treatments.

1.16 Pain Systems: Interface with Affective and Motivational Mechanisms

John Lotfi, M.D., J.D., and Jon-Kar Zubieta, M.D., Ph.D.

Pain is a cardinal symptom of many somatic diseases. Acutely, it serves to warn of danger and shapes behavior to avoid the environment eliciting the stimulus. It is also a subjective experience that incorporates sensory (e.g., intensity, location, quality), affective, and cognitive dimensions. Its chronification is associated with adaptive and maladaptive neurobiologic changes serving to perpetuate the experience, leading to an increase in its aversive and motivational significance. In individuals for whom acute pain transitions into a persistent condition, its experience no longer serves a protective role and is frequently associated with the development of depression and anxiety comorbid conditions in approximately 50% of cases, with bidirectional exacerbation.

While the modulation of acute pain can be achieved pharmacologically by the introduction of agents that reduce nociceptive input (e.g., opioid compounds, pharmacologic conduction blockade and modulation, monoamine reuptake inhibitors), the relief of persistent pain is not adequately achieved in many conditions, particularly those without obvious or identifiable pathophysiology (e.g., fibromyalgia, irritable bowel syndrome, nonneuropathic back pain). The negative effects of chronic opioid use have received much attention because of the development of tolerance to these compounds, withdrawal symptoms, and their potential for misuse. In this context, opioid use disorders have grown into a public health crisis in the United States. Currently, annual drug-related deaths exceed the number of casualties linked to either automobile or handgun deaths. In 2015, according to the Centers for Disease Control and Prevention (CDC), more than 33,000 people died accidentally from an opioid overdose. Three years later, in 2018, the death toll from an opioid overdose had risen even higher, to 48,802, and the combination of the opioid epidemic with the COVID-19 pandemic has further strained fragile health care infrastructure, particularly for more complex, comorbid conditions.

The main nonopioid strategies to reduce pain severity and comorbidity include potentiation of monoaminergic neurotransmission through reuptake inhibition or similar mechanisms. However, agents that reduce inflammatory responses and neuronal excitability are increasingly studied to reverse neuroplastic changes that take place during the transition from acute to chronic pain.

PAIN SYSTEMS

Pain perception is typically initiated by the activation of peripheral nociceptors, sensory end organs in the skin, muscle, joints, and viscera that selectively respond to noxious or potentially damaging stimuli. An important property of nociceptors is their sensitization as a consequence of tissue injury and inflammation, reducing their threshold of response and increasing the magnitude of their responses to noxious stimulation, this being a potential new target for pharmacologic interventions. Nociceptor endings in tissue are unencapsulated ("free") and are commonly associated with either (1) medium diameter myelinated Aδ axons, which transmit acute, well-localized "first pain" signals, or (2) small-diameter, unmyelinated slowly conducting C fibers that convey poorly localized, "second pain," "burning," or slow pain. Aδ and C nociceptors are further subdivided into multimodal or more specialized types, responding to mechanical, chemical, or heat stimuli with varying degrees of sensitivity. Larger, rapidly conducting myelinated Aβ fibers respond to innocuous mechanical stimulation such as touch.

The cell bodies of nociceptors for the body are located in the dorsal root ganglia (DRG) of the spinal cord, whereas the trigeminal ganglion houses the cell bodies of nociceptors for the face, which transmit information through the trigeminal nucleus caudalis. Axonal projections from the DRG neurons transmit information through excitatory glutamatergic and peptidergic neurotransmission to second-order neurons of the dorsal horn of the spinal cord. Second-order neuron axons then cross contralaterally and form ascending pathways that synapse in the brainstem (spinoreticulothalamic tract) and thalamic nuclei (spinothalamic tract), thought to respectively subserve less localized and more sensory-discriminative (e.g., intensity and localization) elements of pain.

Spinoreticulothalamic projections to the rostroventral medulla (RVM) and periaqueductal gray (PAG) engage descending pain inhibitory pathways in feedback loops that regulate dorsal horn neuronal excitability while thalamic nuclei project to cortical structures. Other spinoreticulothalamic projections reach the parabrachial nucleus of the pons, which is directly connected to the amygdala. The amygdala is a region implicated in the representation and modulation of aversive, affectively negative elements of the pain experience and which provides further input to the insular cortex.

The regulatory functions of the PAG and RVM have received much attention since they are engaged as a modulatory mechanism of the nociceptive signal, which is heavily influenced by neurotransmitters such as the enkephalinergic endogenous opioid, serotonin, and norepinephrine systems. These are the targets of commonly used pain control agents, such as monoamine reuptake inhibitor antidepressants and opioid medications. Pain signals to the PAG activate excitatory and peptidergic transmission, which projects to the RVM. In the RVM, “on” cells become activated in response to noxious painful stimuli and are involved in the formation of protective “nocifensive” behaviors, such as withdrawal reflexes. “Off” cells, on the other hand, respond acutely to endogenous opioids, GABA, and serotonin, to induce analgesic responses through descending connections to the dorsal horn of the spinal cord. Norepinephrine, through alpha 1 and alpha 2 receptors, respectively, can have both pro- and antinociceptive effects by modulation of “on” and “off” cells of the RVM (Fig. 1.16–1).

Thalamic input reaching the somatosensory cortex is implicated in sensory-discriminatory functions, while projections to regions such as the anterior cingulate and insular cortex are thought to integrate sensory and emotional aspects of the experience. Often referred to as “lateral” (sensory-discriminatory) and “medial” (affective-cognitive) projections, they form a large, distributed brain network “pain matrix” that reflects and processes the complex, multifaceted experience of pain. During acute pain, the primary and secondary somatosensory cortices, insular cortex, anterior cingulate, and prefrontal cortices become consistently activated. The basal ganglia, amygdala, and hippocampus are also involved in these processes.

It should be noted that many of these “medial projection” integrative areas overlap with those implicated in the representation of other nonpainful, salient, or stressful stimuli and are thought to be dysregulated when pain becomes chronic, reflecting alterations in reward and motivational mechanisms observed in persistent pain conditions. Notably among these, the anterior insular, anterior cingulate, and prefrontal cortices, as well as the nucleus accumbens and amygdala, are thought to be implicated in the representation and regulation of emotional, motivational, and evaluative aspects of the pain experience as discussed in further detail below. Conversely, the ventrolateral thalamus, somatosensory cortex, dorsal posterior insula, and some cellular groups of the anterior cingulate and anterior insular cortex are thought to be more pain-specific, responding to variations in pain intensity and being differentially activated by pain stimuli as opposed to nonpain-specific sensory stimuli or other components of the experience of pain. In addition to the modulatory role of the PAG and RVM on nociceptive suppression, telencephalic regions that include the dorsolateral prefrontal cortex, anterior cingulate and insular cortices, thalamus, nucleus accumbens, and amygdala are implicated in regulating the pain experience across sensory and affective (e.g., unpleasantness) components through the local activation of endogenous opioid and other neurotransmitter systems such as the noradrenergic, GABA, endocannabinoid, and glycinergic, as well as through descending projections to the PAG and RVM (Fig. 1.16–2).

PAIN AND MOTIVATIONAL MECHANISMS

From an evolutionary perspective, pain is a strong motivational signal with negative affective connotations, while pain relief can be conceptualized as a form of relief and reward. Therefore, pain represents a potent factor directing behavior. The basal ganglia and associated limbic cortex are thought to integrate internal and external signals to encode the value of the sensory signals received. They are engaged during anticipation of pain or expectations of pain relief and, together with prefrontal cortical structures, are implicated in the integration of sensory information but also the modulation of pain through endogenous opioid modulatory systems.

During acute pain, brain functional activity of the saliency/reward/motivation network, which includes the orbitofrontal cortex, nucleus accumbens, and ventral tegmental area, is increased and associated with the capacity to express endogenous opioid analgesia in humans. Interindividual variations in the capacity of the nucleus accumbens to respond to reward value have been further linked to the capacity to develop placebo-induced analgesic responses, suggesting that reward and saliency evaluation mechanisms are also engaged to induce appropriate analgesic responses when required to maintain homeostasis.

The nucleus accumbens receives pain information through regions involved in pain and emotional processing, such as the prefrontal cortex, anterior cingulate, and the amygdala, and direct projections from spinal cord neurons to the nucleus accumbens have been described. During experimental pain in humans, dopamine neurotransmission is activated in the basal ganglia. In dorsal regions receiving input from the somatosensory cortex, dopamine is released in a manner proportional to the intensity and sensory elements of the pain signal, while in the nucleus accumbens, it was related to negative affective responses in humans. This effect appears to be localized in the nucleus accumbens core based on animal model data, while in the shell area of this region, it is released after pain stimulus termination. This is consistent with the concept that pain relief represents a form of positive reinforcement upon its termination as shown using neuroimaging data in humans diagnosed with persistent pain. The transition from injury and acute pain to persistent low back pain in humans has been further associated with alterations in the functional connectivity of the basal ganglia to prefrontal cortical structures, suggesting that persistent pain-induced alterations in motivational systems form a critical part in the perpetuation of the pain experience in humans.

In patients diagnosed with persistent pain conditions, such as fibromyalgia and chronic back pain, dopamine receptors and dopaminergic neurotransmission in the nucleus accumbens are downregulated compared to those of healthy individuals. These reductions appear adaptive in nature, hampering the salience of the chronic noxious stimulus but also enhancing the functional capacity of downstream antinociceptive endogenous opioid mechanisms. However, dysregulation of nucleus accumbens function in the context of chronic pain has also been linked to reductions in motivation, such as the capacity to perform effortful tasks to gain rewards in animal models. Therefore, nucleus accumbens function and dopaminergic neurotransmission in this area are involved in the signaling of the negative value and salience of noxious input and have been implicated in the transition from acute to persistent pain. Dopaminergic mechanisms also seem to become adaptively downregulated in the context of persistent pain, however, with potentially negative behavioral consequences such as the diminished capacity to engage motivational mechanisms and the effortful pursuit of rewards, core features of anhedonia and depression.

PAIN AND AFFECTIVE REGULATION AND DYSREGULATION

Persistent pain becomes a form of physical and emotional stressor that induces negative mood states, part of maladaptive responses to chronic noxious stimuli. Clinically significant symptoms of depression and anxiety appear in approximately half of the patients diagnosed with persistent pain conditions and form part of the comorbid pathology associated with chronic pain. Psychopharmacologic therapies for comorbid depression and anxiety that may also modulate descending neuropathic pain pathways are discussed below.

Brain regions such as the anterior cingulate, which receive nociceptive signals through the spinothalamic pathway, are implicated in the encoding of pain unpleasantness. This unpleasantness can be modulated by cognitive processes such as hypnotic suggestions, whereby endogenous opioid mechanisms are engaged in the context of suggestions of analgesia during placebo administration. Opioid receptors mediating endogenous opioid analgesia are found downregulated in this and other regions, such as the thalamus, nucleus accumbens, and amygdala, in chronic pain states (such as inflammatory, central, and neuropathic pain as well as in fibromyalgia) with accompanying enhancements in negative affective and pain unpleasantness ratings. Similarly, in chronic back pain patients, deficits in endogenous opioid neurotransmission have been encountered in the amygdala, a region implicated in antinociception as well as responses and regulation of affectively valenced stimuli, and have been associated with both clinical pain ratings and greater negative affect. These findings parallel those encountered in patients diagnosed with major depression and are an example of alterations in biologic processes that overlap between pathologies.

The anterior insular cortex, one of the regions that mediate responses to emotional stimuli and is implicated in the pathophysiology of depression, has also been shown to have an important role in the encoding of interoceptive information in the context of pain. It has been linked to the formation of attentional biases towards physical physiologic cues, including pain and implicated in fear learning and anxiety responses to painful stimuli. Clinical interventions such as meditation-based therapies geared towards the reduction of interoceptive sensitivity and anxiety in patients diagnosed with persistent pain have been shown to regulate the anterior cingulate and anterior insular cortex in a manner proportional to clinical benefit.

Psychopharmacologic therapies for comorbid depression and anxiety that may also modulate descending neuropathic pain pathways in chronic neuropathic pain include serotonin and norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), gabapentinoids, and carbamazepine. SNRIs have antidepressant and anxiolytic effects stemming from their inhibition of serotonin and norepinephrine reuptake which increases the relative availability of these neurotransmitters. This increased availability of serotonin and norepinephrine may be the mechanism behind an SNRI's ability to inhibit descending pain pathways, although opioid mechanisms may also be indirectly implicated. TCAs similarly inhibit serotonin and norepinephrine reuptake for their antidepressant and anxiolytic effects; however, TCAs also act as antagonists at muscarinic acetylcholine, histamine, and adrenergic receptors, which result in a greater side-effect profile than SNRIs. Gabapentinoids bind with high affinity to the alpha-2-delta subunit of voltage-gated calcium channels which inhibits excitatory neurotransmitter release, although the exact mechanism of its anxiolytic and descending pain pathway modulation remains unclear. Carbamazepine acts as a use-dependent voltage-sensitive sodium channel blocker which inhibits the release of glutamate, acting to modulate pain pathways as well as manage acute treatment-refractory depression. Oxcarbazepine, which is structurally related to carbamazepine, may have similar effects but bears further study. Ketamine, an NMDA receptor agonist, also appears to be effective in reducing persistent pain in recent metanalysis, in a manner parallel to that described for major depression.

As noted above, substantial overlap exists among brain regions and neurobiologic mechanisms implicated in the processing of emotionally salient stimuli and those found to represent and regulate pain signaling. This is consistent with the concept of persistent pain as an allostatic process that promotes negative affective responses and enhances the individual propensity toward developing depression and anxiety symptomatology. Different psychopharmacologic therapies can target comorbid depression and anxiety while also modulating pain pathways.

COGNITIVE PROCESSING AND PAIN

The perception of pain is sensitive to mental processes such as attentional biases towards the noxious stimulus. Heightened attention and expectations of threat toward painful stimuli have been shown to induce catastrophic thinking and higher pain sensitivity. Conversely, a distraction from pain and reframing its meaning have been associated with reductions in pain-associated responses of the somatosensory cortex, thalamus, insula, and anterior cingulate cortex, with accompanying changes in sensory, cognitive, and affective appraisals of the painful stimulus. Therefore, both enhancements and reductions in pain reports can be achieved by the influence of higher-order cognitive processes effects that at least in part take place through the top-down engagement of the PAG and descending pain modulatory circuits impacting spinal nociceptive transmission. Executive cortical regions such as the dorsolateral and ventrolateral prefrontal cortex are thought to provide input to the anterior cingulate, insular, and thalamic circuitry, which in turn project to the PAG, a region that potently influences the intensity of ascending signals from the spinal cord.

Another example of how cognitive processes can affect pain processing is the so-called placebo analgesic effect. Besides the perspective that placebo effects confound controlled trials of potentially therapeutic agents, the information so far acquired points to neurobiologic systems that, when activated by positive expectations and maintained through reward learning, are capable of inducing physiologic changes that lead to the experience of analgesia and improvements in an emotional state. This line of research has described neural networks and neurotransmitter systems implicated in the formation of placebo analgesic responses. These include the dorsolateral prefrontal cortex, which is implicated in the processing of environmental cues and expectations, as well as the ventrolateral prefrontal cortex, anterior cingulate, insular cortex, nucleus accumbens, amygdala, and PAG. Salience assessments mediated by dopamine neurotransmission in the nucleus accumbens appear to engage pain regulatory networks across these regions, inducing the adaptive activation of pain and affect regulatory neurotransmitters and neural networks (or maladaptive in the case of nocebo responses, adverse effects in response to therapeutic cues). Endogenous opioids are centrally involved in these processes as well as the endocannabinoid and cholecystokinin systems. The formation of biologic placebo effects, therefore, appears to implicate the engagement of resiliency mechanisms with interindividual variations partially determined by genetic factors and uncovered by the cognitive-emotional integration of the expectations created by the therapeutic environment. Of note, similar mechanisms appear to take place in the formation of placebo antidepressant effects with partial regional overlap between those engaged during the development of placebo-induced analgesia.

FUTURE DIRECTIONS

The majority of the work carried out in the study of pain perception and regulation has been concerned with the transmission of nociceptive input and its regulation at the level of peripheral, spinal, and brainstem structures, providing exquisite detail on these processes. Increasing information is being acquired as to the contribution of inflammatory mechanisms in both glia and neurons as well as neuroplastic changes in excitatory pathways in the transition from acute to persistent pain and its further chronification. New insights have also been acquired as to telencephalic mechanisms that are engaged during acute, sustained, and persistent pain, particularly in humans, and which undoubtedly contribute to pain chronicity and comorbidity with depression, anxiety, and alterations in reward and motivation. Emerging literature demonstrates substantial overlaps between neural systems engaged during pain and those that respond to other stressors, the dysregulation of which would explain the complex presentation of patients diagnosed with persistent pain conditions. Future advancements in the area will require particular attention to those interfaces to exert actual change in pain chronicity and associated neuropsychiatric symptomatology, including the frequently comorbid substance use disorders, and to provide new insights into novel treatment targets for these conditions.

From a public health perspective, and given the complex relationships among pain, mental health, substance abuse, and disparities in economic and social status, the fragmentation of health care into silos of care is highly unproductive. Comorbidities are known to deeply impact health outcomes, with 80% of Medicare spending being directed toward patients with four or more chronic conditions. However, disease or organ-based practice continues to be the prevailing approach to care, reducing the capacity of health practitioners to personalize care for those with co-occurring conditions.

1.17 Basic Science of Appetite

NORI GEARY, PH.D., AND TIMOTHY H. MORAN, PH.D.

Appetite comprises the complexly determined and highly individuated behavioral and subjective phenomena related to eating. This chapter, (1) summarizes progress in understanding the core physiology of appetite, including eating behavior, the sensory signals that control it, the brain mechanisms that integrate these signals, and some important modulators of appetite, and (2) provides examples of basic research contributions to the understanding of disordered eating. Although much has been learned, both normal and disordered eating remains poorly understood. Thus, further research could facilitate the development of more effective treatment strategies than are presently available for disordered eating, whether presenting in psychiatric eating disorders or simple obesity.

Appetite Is a Network Function

Eating is controlled by a widely distributed neural network in the brain that integrates oral, nasal, and pharyngeal food stimuli, gastrointestinal (GI) signals, metabolic signals (including signals related to body adiposity), numerous other internal stimuli (e.g., circadian signals, stress responses, immune responses, reproductive-axis function), and external stimuli with learned meanings. Furthermore, the network displays structural and functional plasticity throughout the life span. This perspective emphasizes the multiple factors affecting eating, their varied effects on information processing in the brain, and their complex synergistic and antagonistic interactions. It contrasts with the traditional view that only one or a few signals, for example, blood-glucose levels, acting on a few circumscribed hypothalamic sites produce a unitary control of appetite.

The view that appetite is a property of a neural network rather than a single brain region has several important implications. (1) There may be no brain locus where all neural signals controlling appetite converge. (2) It is unlikely that a neural basis for a unitary motivational process for appetite will be found. (3) Controls of eating that are elaborated in different parts of the network may not always operate in a coordinated manner. For example, eating might simultaneously be inhibited by some controls (e.g., homeostatic signals related to metabolic fuel availability) and stimulated by others (e.g., flavor hedonics). For this reason, patterns of within meal-eating rates or patterns of spontaneous meal sizes and frequencies may change in the absence of changes in the total amount eaten. (4) The existence of such partially autonomous controls may contribute to the modest effects of pharmacologic therapies for disordered eating that are based on the manipulation of single signaling molecules.

The Meal as the Unit of Analysis

The meal is the most appropriate unit of analysis for both functional and physiologic analyses of appetite. The meal is the functional unit of eating. (1) The timing, size, and content of meals provide a complete description of the organism's response to all the influences affecting appetite described above. (2) Meal onset, the rate of eating during meals, meal termination, meal size, and intermeal intervals provide concrete metrics for the study of appetite. For example, accounts of hunger cannot succeed if they do not explain the timing of meal onset. (3) Disordered meals are the behavioral phenomenology of disordered eating. Abnormally large meals are the defining behavioral change in bulimia nervosa and in binge-eating disorder, and abnormally small meals are the defining behavioral change in anorexia nervosa.

The meal is also the biologic unit of eating. Humans and most other vertebrates organize eating into discrete bouts or meals, separated by intervals of noneating, with species-specific variations related to circadian, seasonal, and other influences. Meal-ending satiation is an active process: meals are followed by a period of sedation or sleep, which is clearest in animals and infants. These characteristics are undoubtedly products of both natural selection and cultural evolution, shaped by such influences as the digestive consequences of cooked rather than raw food and the logistics of food acquisition and preparation.

Behavioral Neuroscience of Eating

The behavioral neuroscience of eating follows three general approaches. (1) *Input approaches* are aimed at understanding the environmental and experiential contingencies and the exteroceptive stimuli and interoceptive sensory signals that influence eating. Exteroceptive stimuli include stimuli whose meaning is learned as well as a few innately meaningful stimuli such as the hedonic significance of sweet taste. Important interoceptive stimuli include circulating levels of hormones and metabolites as well as neural signaling from peripheral organs to the brain. (2) *Network approaches* focus on the central neural networks that integrate inputs and produce the motivational processes that drive eating. This is now done with increasingly sophisticated molecular-genetic approaches in animals, and functional brain imaging approaches in humans. An important advantage of imaging is the ability to associate subjective and brain responses. These approaches are most meaningful when meals are studied, rather than only summary measures such as calories ingested per day or only subjective measures. (3) *Motor approaches* include efforts to understand the neural control of the movements of eating, often called the microstructure of eating. Food is licked, sucked, bitten, or masticated prior to being moved by lingual and palatal movements to the oropharynx and swallowed. Analysis of these movements has the potential to track their neural control through the lower motor neurons of cranial nerves V, VII, IX, X, and XII into (i) the local circuits in the motor nuclei of these nerves, (ii) the central pattern generators in the hindbrain that project onto these nuclei, (iii) upstream integratory interneuronal networks, and (iv) ultimately to sensory and brain-autonomous inputs, such as memories, circadian rhythms, and so forth.

SIGNALS FOR MEAL INITIATION

Hunger Processes and Learning

The patterns of neural activity leading to food-seeking and meal initiation are conceptualized as hunger motivation. Three distinct motivational processes are thought to be involved: (1) a negative-reinforcement process, (2) a positive-reinforcement process related to flavor hedonics, and (3) a positive-reinforcement process related to postingestive consequences of eating (Fig. 1.17–1). Each of these suffices to stimulate eating, and eating leads to negative feedbacks that reduce hunger. However, only negative-reinforcement hunger involves an aversive state that one wishes to escape. In contrast, the expectation of satiation or of a positive hedonic state is usually pleasant. Most people rarely experience the aversive state of strong deprivation-induced hunger (among those who do are the poor, strict dieters, and people with anorexia nervosa). Although the upper GI tract is relatively empty after overnight fasts, people generally do not report intense hunger in the morning and breakfast is usually the smallest meal of the day. Thus, normal adult hunger probably represents a lifetime of positive-reinforcement learning with innate “homeostatic” mechanisms not usually playing important roles.

Studies in animals have suggested that partially independent brain processes mediate a motivational aspect of hedonics, known as incentive motivation or wanting, and a subjective aspect, known as liking. This distinction may be linked to the separable influences of flavor hedonics and flavor-nutrient learning on food selection discussed below.

Circadian Rhythms

Circadian rhythms importantly affect eating and may explain low morning hunger (Fig. 1.17–2). Such circadian rhythms presumably originate in the circadian pacemaker in the suprachiasmatic nucleus of the hypothalamus (SCN). This area has extensive neural connections with the arcuate nucleus of the hypothalamus (ARC), the dorsomedial nucleus of the hypothalamus (DMN), the lateral hypothalamic area (LHA), and other areas through which it could modulate the neural and endocrine signals controlling eating, as reviewed below.

Metabolic Signals

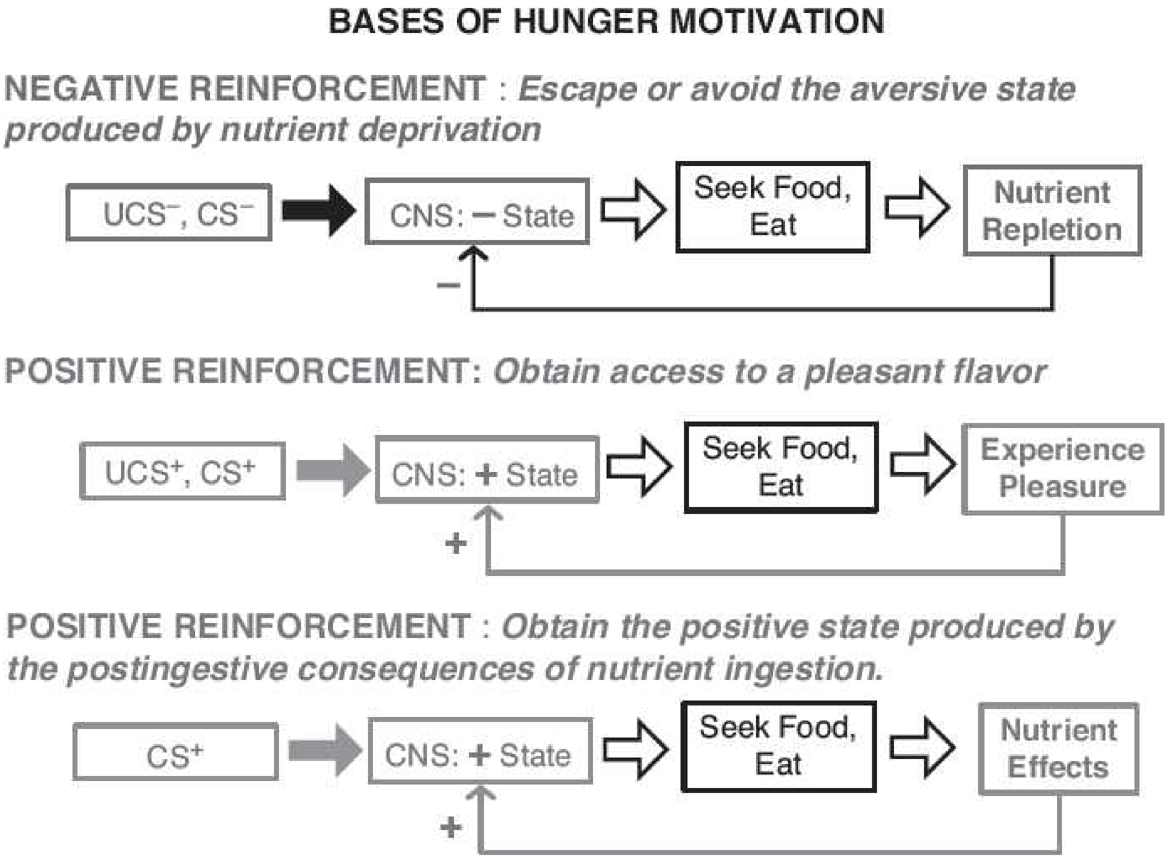
Stimuli resulting from decreased glucose or fatty-acid utilization can elicit hunger and meal initiation. These effects are clear in extreme conditions, such as during extended nutrient depletion, abrupt shifts in the macronutrient composition of the diet, and biochemical hypoglycemia. It seems unlikely that they operate under usual physiologic conditions.

Small transient declines in plasma glucose sometimes occur prior to spontaneous meals in rats and humans and may be a normally operating hunger stimulus. These are too small (∼10%) to influence cellular glucose availability. Rather, the temporal dynamics of the decline may signal hunger.

Endocrine Signals

Two GI hormones are candidate endocrine signals for hunger, ghrelin and motilin. Ghrelin has received more attention to date. Ghrelin is a peptide hormone synthesized and released primarily by enteroendocrine cells in the stomach and proximal small intestine. It is secreted in an inactive form and metabolized to the biologically active, acylated form, octanoyl- or acyl-ghrelin, by the enzyme ghrelin O-acyltransferase. Plasma levels are high in the morning, decrease after meals, and increase during intermeal intervals. The mechanism that stimulates ghrelin secretion is unknown. The gradual reduction in GI contents in the hours after meals apparently releases a tonic stimulatory control of ghrelin secretion from inhibition.

Inhibition is reinstated when nutrients reach the small intestine during and after meals. Carbohydrates and proteins inhibit ghrelin secretion more than isoenergetic lipid loads.



BASES OF HUNGER MOTIVATION
NEGATIVE REINFORCEMENT : Escape or avoid the aversive state produced by nutrient deprivation
UCS⁻, CS⁻
CNS: − State
Seek Food, Eat
Nutrient Repletion
−
POSITIVE REINFORCEMENT: Obtain access to a pleasant flavor
UCS⁺, CS⁺
CNS: + State
Seek Food, Eat
Experience Pleasure
+
POSITIVE REINFORCEMENT : Obtain the positive state produced by the postingestive consequences of nutrient ingestion.
CS⁺
CNS: + State
Seek Food, Eat
Nutrient Effects
+

FIGURE 1.17–1. Hunger-motivation constructs developed to explain food-seeking, meal initiation, and eating. **Top:** Negative-reinforcement hunger is the classical construct of hunger generated by nutrient depletion or homeostatic need. Depletion of metabolic energy supplies or of certain micronutrients such as sodium lead to aversive CNS states (UCS−) that are escaped by ingestion of the appropriate commodity. Such aversive states act as unconditioned negative reinforcers, such that with experience, initially arbitrary stimuli can elicit a similar state; these CS− permit avoidance as well as escape. **Middle:** Positive-reinforcement hunger generated by flavor hedonics. Some flavors such as sweet flavor, lead to positive CNS states (UCS$^+$) that elicit approach and ingestion. Other flavor stimuli (CS$^+$) come to elicit similar states via a variety of learning mechanisms, often not directly associated with UCS; even initially, aversive flavors such as chili pepper can become such CS$^+$. Such CS$^+$ are likely to be the most important hunger motivation mechanism in affluent humans. **Bottom:** Positive-reinforcement hunger generated by stimuli associated with postingestive GI or metabolic effects produced by ingested food. These effects generate positive CNS states that act as unconditioned positive reinforcers, which, with experience, can lead to the development of conditioned satiating stimuli (CS$^+$) that can elicit approach and ingestion. This process has been referred to as *appetition* because it is not clear that the GI and metabolic stimuli that generate it are identical to those that generate satiation. Note (i) that negative-reinforcement hunger is a negative feedback process (*solid black arrows*), whereas the

positive-reinforcement hungers are positive-feedback processes (*gray arrows*); and (ii) that the conditioned stimuli in all three types of hunger motivation can come to motivate eating without deprivation, which is presumably a cause of overeating.

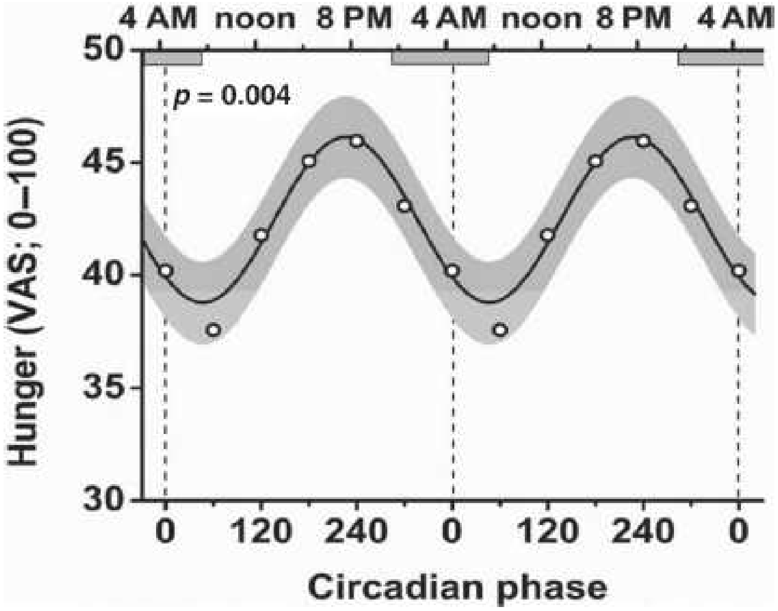


FIGURE 1.17–2. The circadian rhythm of hunger. Hunger was rated using visual analog scales (VAS; 0 = not at all hungry, 100 = extremely hungry) by healthy, normal-weight men who underwent a 13-day "forced desynchronization" protocol that balanced all behaviors, including meals and sleep periods, evenly across the endogenous circadian cycle under constant dim light. Data are double plotted; points are mean ratings in 4-hour bins; the black line is a cosine function ± 95% confidence interval (*gray area*) fit to the rating data, and horizontal gray rectangles indicate average habitual scheduled sleep episodes. Note that hunger minima occurred in the biologic morning and hunger maxima in the evening and that there was a 17% maximum–minimum difference. (From Shear FA, Morris CJ, Shea SA. The internal circadian clock increases hunger and appetite in the evening, independent of food intake and other behaviors. *Obesity (Silver Spring)*. 2013;21:421–423, with permission.)

Ghrelin became a candidate endocrine hunger signal when it was discovered that ghrelin infusion decreased the latency to eat and increased meal size in rats and mice; indeed, repeated ghrelin administration induced obesity. Animal experiments suggest that ghrelin may activate both negative- and positive-reinforcement hunger: (1) systemic ghrelin administration stimulated rats' ingestion of palatable foods more than normal chow and led to the formation of conditioned place preferences, suggesting that ghrelin stimulates positive-reinforcement hunger, and (2) ghrelin injected into the third cerebral ventricle failed to affect rats' initial rate of eating during the meal, which is an index of hedonic hunger, but did increase the rate of responding in a progressive-ratio test, an index of motivation, which together suggest that ghrelin elicited negative-reinforcement hunger. These results also suggest that ghrelin acts in multiple brain loci to stimulate eating. Among the sites of ghrelin, receptors suggested to mediate hunger are the ARC, the nucleus of the solitary tract (NTS), the ventral tegmental area (VTA), and the nucleus accumbens (NAc); these areas are discussed further below.

Evaluating Physiologic Endocrine Signaling. Endocrinology and neuroscience have evolved criteria for identifying normal physiologic functions of chemical signals. Table 1.17–1 presents a current set. Criteria 1 and 2 address the plausibility of the candidate hormonal signal to control a particular function; criteria 3 to 5 concern its sufficiency; and criterion 6, its necessity. For candidate endocrine signals such as ghrelin, plasma measurements and intravenous infusions suffice to test these criteria. As described below, however, some GI hormones also act locally. Modes of local action of GI hormones include paracrine effects and synaptic connections between processes of enteroendocrine cells called neuropods and vagal afferents. Assessing the physiologic relevance of such local actions requires measurements and administration in the local environment, that is, in the intestinal lamina propria or, like other neurotransmitters or neuromodulators, in the synaptic cleft.

Table 1.17–1.
Empirical Criteria to Assess Physiologic Status of Chemical Signals[a] in Meal-Related Functions

1. Concentrations of the molecule change at the site of action in a pattern consistent with the effect.[b]
2. Cognate receptors for the molecule are expressed at its site(s) of action.
3. Exogenous administration of the molecule in amounts duplicating the meal-related changes in endogenous patterns at the site of action produces the effect.
4. Administration of secretagogues for the molecule produces effects similar to the effect of the hormone.
5. The molecule's effect occurs in the absence of abnormal behavioral, physiologic, or subjective effects.
6. Administration of selective agonists and antagonists of the molecule's receptors produce effects that are consistent with their receptor pharmacologies.[c,d]

[a] Signaling molecules may be hormones, cytokines, neurotransmitters, and so forth.

[b] At a minimum, the change in concentrations of the proposed signal should precede the effect.

[c] For example, the administration of specific and potent receptor antagonists should delay or reduce eating in the case of a hunger signal or increase eating in the case of a satiation signal.

[d] We do not include phenotypic evaluation of global transgenic or spontaneous genetic loss-of-function models in this criterion. These are valuable research tools, but complications due to developmental compensatory effects, pleiotropic actions, and species differences preclude their use as a "necessity" criterion for physiologic function. Rapidly inducible, tissue-specific reductions in gene function, however, may complement the use of receptor antagonists in establishing necessity.

At present, ghrelin fulfills some but not all of these criteria. It is a plausible hunger signal (criteria 1 and 2) because plasma ghrelin levels increase before meals, increase during food deprivation, and decrease after meals in animals and humans (Fig. 1.17–3) and because the infusion of ghrelin to brain areas that contain ghrelin receptors simulates eating in animals. Such effects can be obtained without side effects (criterion 5). Two cardinal criteria, however, have not yet been met in humans: it is not known whether ghrelin infusions that mimic the changes in ghrelin produced by premeal increases in endogenous ghrelin are sufficient to stimulate eating (criterion 3) or whether antagonism of endogenous ghrelin signaling before meals is sufficient to delay meal onset (criterion 6), although this has been shown in animals. The recent discovery that liver-enriched antimicrobial peptide 2 (LEAP2), an endogenous GHS antagonist, changes levels in the opposite direction to changes in ghrelin levels with eating and body mass suggests that the critical stimulus for initiating eating could be the ghrelin/LEAP2 ratio.

MEAL MAINTENANCE

Flavor Hedonics

The maintenance of eating during the meal is attributed to the ongoing influence of the hunger processes reviewed above, together with the eating-stimulatory effect of positive flavor hedonics. Flavor stimuli elicited during eating arise from olfactory (cranial nerve I), gustatory (VII, IX, X), and somatosensory (V) receptors in the oronasopharynx. Flavor stimuli contribute to (1) detection and selection of foods; (2) stimulation or inhibition of eating, mainly through positive or negative hedonic processes, presumably via mechanisms overlapping with those producing hedonic hunger discussed above; and (3) associative learning processes, both as conditioned stimuli (CS) and, in the case of sweet and fat flavors, unconditioned or reinforcing stimuli. An important example is learned incentive salience. In this process, the perceptual salience and valence of stimuli associated with preferred flavors are increased with experience, leading to increased identification, selection, and intake of foods with those flavors.

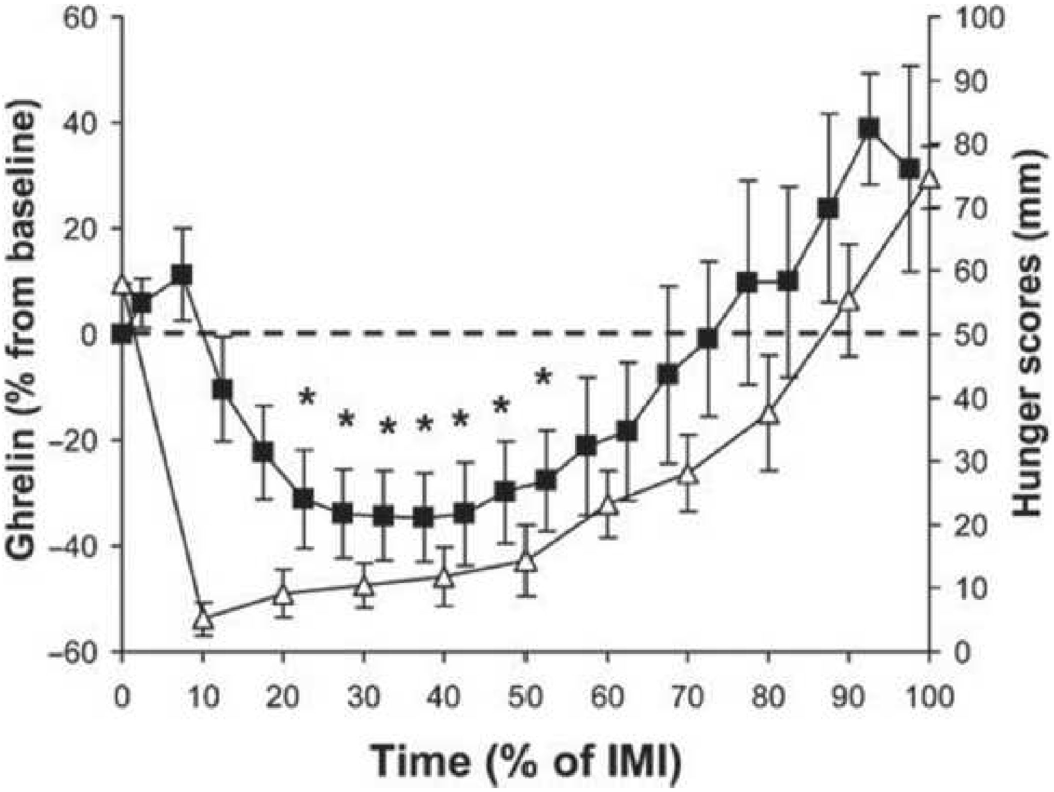

FIGURE 1.17–3. Close association of hunger scores (*open triangles,* rated on a 100-mm visual analog scale) and plasma ghrelin concentration (*filled squares,* total ghrelin-like immunoreactivity) during the interval between lunch (begun at time 0) and a freely requested dinner (time 100%). Subjects were six healthy, normal-weight males. The mean lunch size was 800 kcal, the mean lunch duration was 20 minutes and the mean intermeal interval was 359 minutes. Data are mean ± standard error of the mean. Baselines are values at lunch onset. *Significantly different from time 0. (Reprinted with permission from Cummings DE, Fayo RS, Marmonier C, Aubert R, Chapelot D. Plasma ghrelin levels and hunger scores in humans initiating meals voluntarily without time- and food-related cues. *Am J Physiol.* 2004;287(2):E297. doi:10.1152/ajpendo.00582.2003.)

Psychophysics. Subjective aspects of flavor hedonics are often measured with visual analog scales (VAS). One common scheme is to instruct subjects to indicate how pleasant a flavor is by marking a 100-mm line labeled at the ends as “not at all” and “extremely.” Most subjects produce reliable and coherent VAS ratings, but patients with anorexia nervosa often do not. In addition, it is now clear that VAS ratings are relatively insensitive to individual differences and not appropriate for comparisons between different classes of subjects who may use the scale differently, such as men versus women or individuals with and without obesity. This problem can be avoided with the use of generalized scales whose extreme values are labeled with the most intense imaginable affective experience of any kind.

Sham and Brief-Access Eating. Sham eating and brief-access eating tests are designed to isolate controls of eating by flavor stimuli in the absence of postingestive consequences. An elegant method for brief-access tests in rats involves measurement of licks of different fluids during repeated 10-second presentation periods, with presentation order randomized so that although the fluids enter the stomach normally, their mixture prevents the association of particular flavors with postingestive effects. Sham eating eliminates postingestive food stimuli altogether. It is done in rats with a surgically implanted gastric cannula, which when opened, causes liquid food to drain out rather than accumulate in the stomach or enter the intestines in appreciable amounts. Rats' brief-access and sham intakes of sweet solutions or of oil emulsions increase linearly over a wide range of concentrations, indicating the potent effect of flavor hedonics on eating (Fig. 1.17–4). Sham eating is done in humans simply by having subjects take food into the mouth and expel it without swallowing. This method has been used successfully with women with anorexia nervosa or bulimia nervosa. Interestingly, it revealed a greater propensity to sham eat in women with bulimia nervosa than in women without a history of eating disorders.

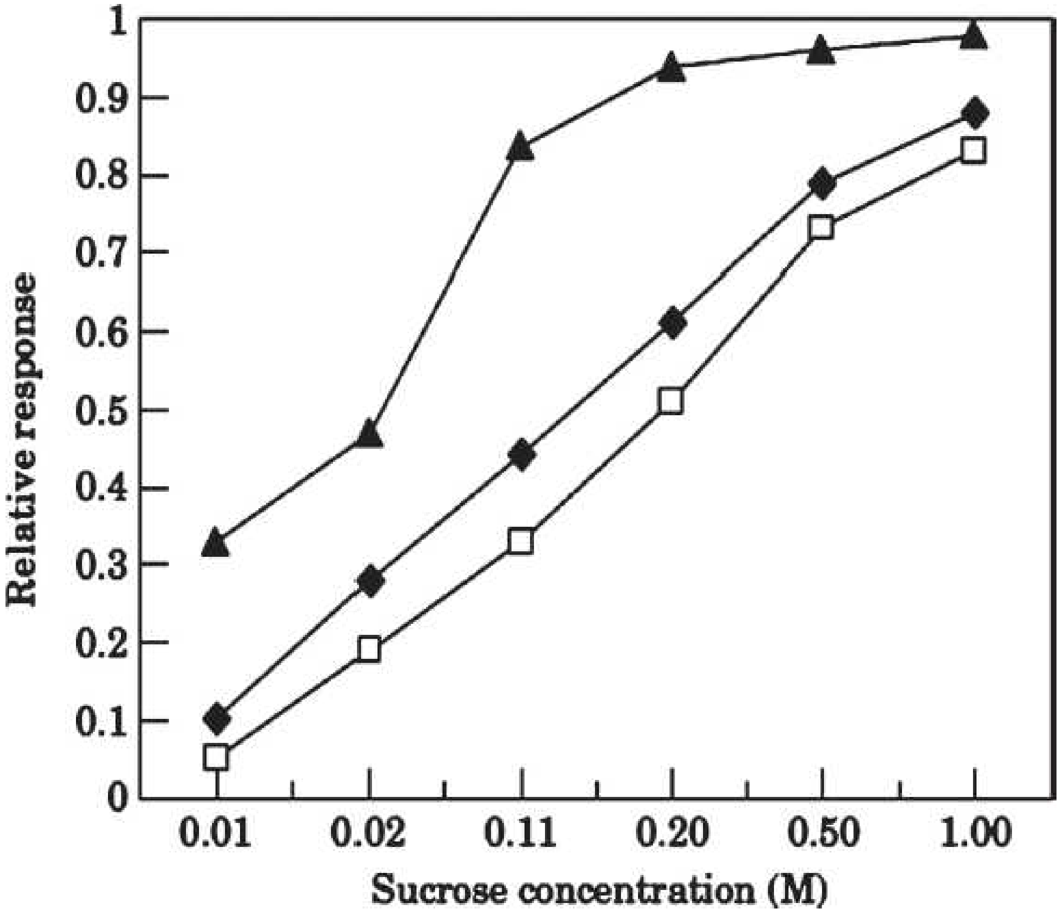

FIGURE 1.17–4. Flavor hedonics stimulates ingestion in rats. Rats' responses (expressed relative to maximal) to varying sucrose concentration in 30-minute sham-feeding tests (*open squares*), in 30-second brief-access licking tests (*filled triangles*), and from electrophysiologic recordings from the greater superficial petrosal nerve (a branch of cranial nerve VII, *filled diamonds*). (Reprinted from Smith JC. The history of the "Davis Rig." *Appetite*. 2001;36(1):93–98. Copyright © 2001, with permission from Elsevier.)

Eating in the Absence of Hunger. Eating in the absence of hunger (EAH) denotes eating driven by hedonics after satiation is achieved with less preferred foods (Table 1.17–2). Pediatric EAH, assessed by offering snack foods after a standard meal is strongly associated with overweight and obesity. Note that EAH refers only to the presumed absence of negative-reinforcement hunger; thus, "hedonic hunger" would be less ambiguous.

Innate and Learned Flavor Hedonics

Although some preferences (sweet) and aversions (bitter or sour) for basic gustatory stimuli appear to be innate, preferences and aversions for the vast majority of flavors are predominately learned. Foods' GI and metabolic consequences can reinforce such learning. This occurs in conditioned satiations, conditioned aversions (including the marked aversions for flavors associated with acute upper GI illness), and "specific hungers" (preferences for flavors associated with foods containing some, but by no means all, vitamins or minerals that can be learned during states of nutritional deficiency). Note that in these situations, with the exception of sodium appetite during sodium depletion, it is the discriminative rather than the hedonic aspects of flavor stimuli that are important, although increased or decreased hedonic responses are part of what is learned. Human flavor preferences also arise from the emotional, cognitive, and cultural associations attached to various foods, independent of their nutritional or physiologic properties. Most individuals endorse especially strong preferences, or *cravings,* for particular foods. Because they dramatically affect an individual's tonic level of food intake and their adherence to therapeutic dietary regimens, the origins and plasticity of human food preferences are important research challenges.

Table 1.17–2.
Two Demonstrations of "Eating in the Absence of Hunger"

	Meal	**EAH**
Standard meal (kcal)	861 ± 30	365 ± 20
Large-array meal (kcal)	1,309 ± 55*	295 ± 18

Adolescent subjects were first offered a midday meal consisting of either a large array of lunch foods in a buffet setting or a single standardized meal consisting of a subset of foods from the large-array meal (chicken nuggets, grapes, baby carrots, tortilla chips, cookies, 2% fat milk, etc.) served in excess. Subjects were instructed to eat until they were no longer hungry and to open the room when they were done. Note the effect of variety: subjects ate significantly larger meals in the large-array condition (*). To measure "eating in the absence of hunger" (EAK) subjects were offered unexpectedly an array of novel, highly palatable snack-food items 30 min after their meals. Note that they ate 300 to 400 kcal more regardless of the type of first course served, although there was a significant difference in the conditions ($^{+}$). Data are mean ± standard error of the mean. (Data from Shomaker LB, Tanofsky-Kraff M, Zocca JM, et al. Eating in the absence of hunger in adolescents: intake after a large-array meal compared with that after a standardized meal. *Am J Clin Nutr.* 2010;92:697.)

Variety. Variety is a strong hedonic control of eating. Offering a variety of nutritionally similar foods with different, preferred flavors leads to larger meals than does offering only one of the alternatives, even the single most preferred one. Table 1.17–2 shows an example. The effect of variety on intake is referred to as sensory-specific satiety, reflecting the decline in the preference for a consumed food in relation to preferences for foods that have not been recently consumed. Flavor variety can tonically increase rats' intake and increase body weight.

Familiarity. Familiarity is sufficient to condition flavor preferences. This phenomenon likely explains much of the marked cultural variety of preferred foods, the social contexts or times of day when they are eaten, and so forth. For example, children repeatedly faced with foods that they find unpalatable and with the sight of adults enjoying them learn to enjoy and eat them as well. This learning has to overcome the innate tendency to avoid novel flavors (neophobia), which is especially strong in young children.

Social Facilitation. Eating with acquaintances markedly increases intake in comparison with eating alone, whereas no facilitation is evident when eating with strangers. Given how often people eat with others, the characteristics and mechanisms of this effect deserve analysis.

Individual Differences. Heterogeneity in human gustatory capacity is a source of individual differences in hedonics. For example, the density of fungiform papillae on the anterior tongue is usually greater in women than in men, and this is associated with both individual and sex differences in bitter and sweet perception and hedonics. Furthermore, individual differences in sweet or bitter taste capacity are associated with the hedonic valence of a wide variety of flavors (Fig. 1.17–5). Such hedonic differences, in turn, are associated with body mass index (BMI*;* weight in kg/height in m^2), indicating that they tonically increase meal size and caloric intake. Recent work has indicated that the degree of sweet preference and the change following surgery can serve as a predictor of weight loss with Roux-en-Y bariatric surgery, suggesting that change in preference can play a role in modulating caloric intake.

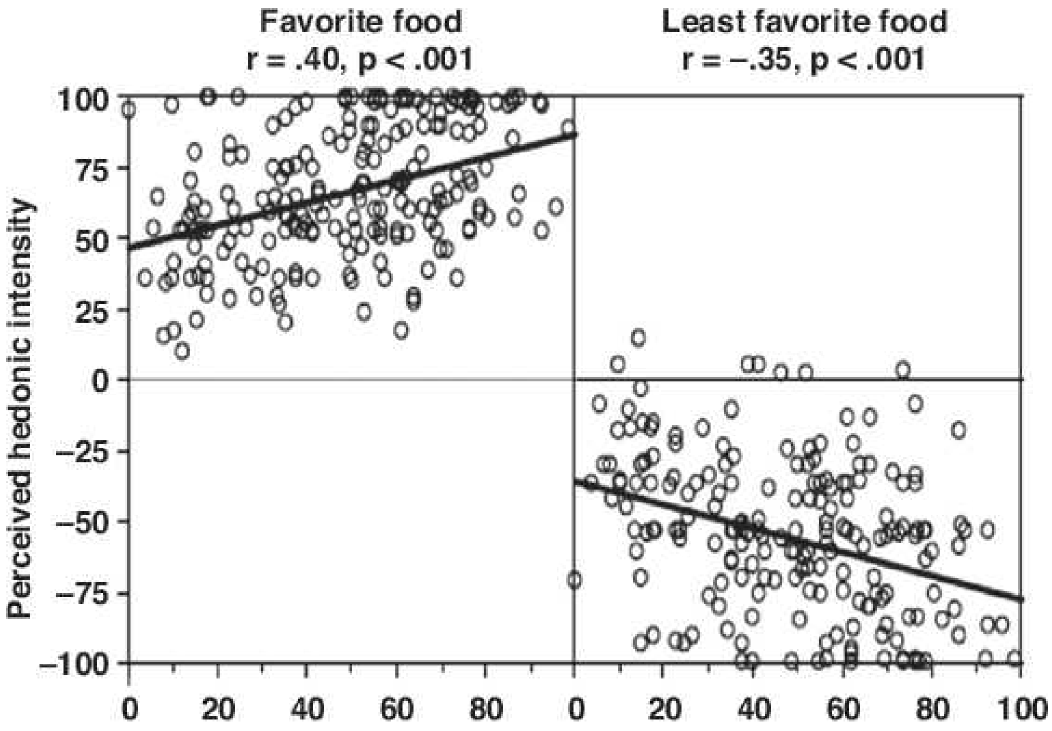

FIGURE 1.17–5. Individual differences in flavor hedonics. Hedonic intensities were rated with a general labeled magnitude, the gLMS scale, for favorite and least favorite foods as described in the text. Ratings are plotted against subjects' taste capacity, assessed by the average sensory intensity rating of four standard taste solutions (1 M NaCl, 1 M sucrose, 0.032 M citric acid, and 0.001 M quinine hydrochloride). Note the significant correlations between taste capacity and both positive (favorite food) and negative (least favorite food) flavor hedonics. (From Kalva JJ, Sims CA, Puentes LA, Snyder DJ, Bartoshuk LM. Comparison of the hedonic general labeled magnitude scale with the hedonic 9-point scale. *J Food Sci.* 2014;79(2):S238–S245.)

SATIATION AND POSTPRANDIAL SATIETY

Eating-inhibitory processes that occur during meals and contribute to meal termination are known as satiation processes. These are differentiated from longer-lasting processes that inhibit eating during the subsequent intermeal interval, known as postprandial or across-meal satiety processes. Because some signals appear to contribute to both, these processes are discussed together.

Gastric Mechanoreception

Although experimental dissection of gastric and postgastric signals in the control of eating is challenging, a variety of evidence indicates that gastric volume contributes directly to satiation via mechanoreceptors that are tuned to both tension and stretch or length. For example, (1) imaging studies have revealed significant correlations between fullness and gastric volume, (2) increasing a meal's volume by mixing in air decreased meal size, and (3) incorporating water into foods maintained gastric volume at higher levels, increased fullness, and decreased subsequent intake more than ingestion of the same amounts of food and water served separately. Gastric mechanoreceptors are linked to the brain mainly by vagal afferents.

Intestinal Nutrient Sensing

Food stimuli in the small intestine activate mechano-, osmo-, and chemoreceptors that initiate a number of potent satiation signals. Most important are the chemoreceptors tuned to detection of glucose, fatty acids, amino acids, and other digestive products. Negative-feedback signals generated by these nutrient sensors are relayed to the brain via endocrine and neural pathways, some of which are described below.

Oral preloads can be used to investigate the contributions of a food's metabolic energy content, nutrient composition, colligative and osmotic properties, and so forth to its satiating potency. When mixed nutrient preloads are used, decreases in eating are often proportional to the sizes of the preloads, that is, to their metabolizable energy contents. When the macronutrient compositions of the preloads vary, however, protein is typically more satiating on a calorie-for-calorie basis than carbohydrate or fat. Comparisons of intraduodenal and intravenous infusions indicate that intestinal signals inhibit eating more potently than postabsorptive signals. For example, in one comparison of intraduodenal and intravenous glucose infusions that produced identical increases in systemic glucose levels, intraduodenal glucose but not intravenous glucose decreased premeal hunger ratings.

The next sections describe just three of the many intestinal hormones thought to contribute to satiation and postprandial satiety. The probable existence of numerous signaling mechanisms for satiation raises the question of their interactions and their relative contributions in various normal and abnormal contexts. As yet, little is known about these questions. Finally, the peripheral origin and, in most cases, peripheral sites of action on the eating of GI hormones make them attractive targets for the development of pharmacologic therapies.

Cholecystokinin. Cholecystokinin (CCK) is secreted by enteroendocrine cells in the small intestines. CCK secretion is stimulated by glucose and other sugars, amino acids, and long-chain fatty acids. Secretion begins soon after meal onset and usually returns to basal levels during the intermeal interval.

CCK's role as an endocrine satiation signal is uniquely well established. Intravenous CCK infusions mimicking postprandial plasma levels reduced meal size without adverse physical or subjective effects in men and women (Table 1.17–1, criterion 3), intraduodenal lipid infusions stimulated satiation, which was reversed by a CCKA receptor antagonist (criteria 4 and 6), and infusions of the antagonist alone increased meal size (criterion 6) (Fig. 1.17–6). No comparable antagonist effects have been reported in humans for any other hypothesized endocrine control of eating. Finally, occasional individuals bearing null mutations of the CCKA (or CCK1) receptor are extremely obese, and more common CCKA receptor polymorphisms are associated with increased meal size, increased food intake, and obesity. CCK also fulfills the criteria for a normal physiologic satiation signal in animals. Indeed, CCK research in rats and mice has been paradigmatic for the study of the control of eating in animal models. CCK elicits highly specific, dose-related decreases in meal size. The specificity is indicated by: (1) CCK fails to inhibit water intake in water-deprived rats under conditions where it inhibits eating liquid food; (2) CCK elicits behavioral signs of satiation, including postprandial grooming and sleep, in rats that are sham feeding with open gastric cannulas, which otherwise sham feed essentially indefinitely; and (3) CCK can decrease food intake without signs of illness, such as pica or formation of conditioned taste aversions (of course, large doses can induce illness). In summary, a wide variety of data indicates CCK is an important part of the natural process of satiation. As well these data indicate that the physiologic system controlling satiation, however complicated, is not completely redundant.

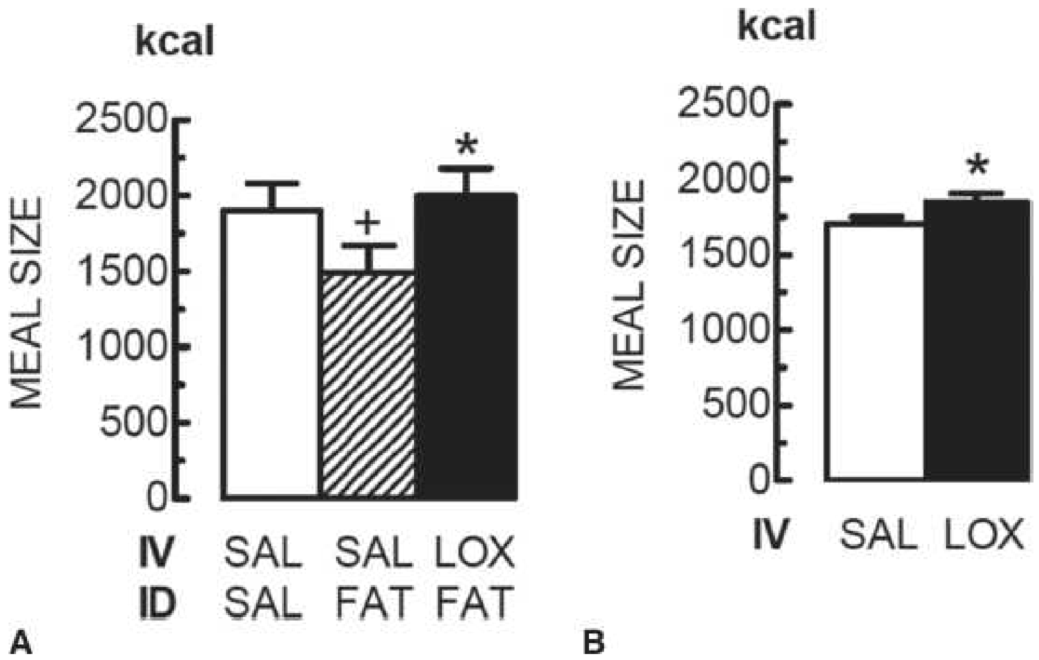

FIGURE 1.17–6. Evidence from CCKA receptor-antagonist studies that endogenous CCK is a physiologic satiation signal. **A:** The CCKA receptor antagonist loxiglumide (LOX) antagonized the satiating action of endogenous CCK stimulated by intraduodenal (ID) infusion of a fat emulsion. Healthy-weight adult males began a midday lunch buffet 4 hours after a standard breakfast, 90 minutes after the onset of an IV infusion of 10 $\mu mol \cdot kg^{-1} \cdot h^{-1}$ LOX or SAL, and 60 minutes after an ID infusion of 0.4 $mL \cdot min^{-1}$ corn oil (FAT) or SAL, and 20 minutes after an oral preload of 400 mL of a low-fat banana milkshake (bananas were used because they do not elicit CCK secretion). Infusions were continued throughout the meal. ID fat infusion significantly reduced the size of the lunch meal (+), and this was reversed by LOX (*); no physical or subjective side effects occurred in any condition. (Data from Matzinger D, Gutzwiller JP, Drewe J, et al. Inhibition of food intake in response to intestinal lipid is mediated by cholecystokinin in humans. *Am J Physiol.* 1999;277:R1718.) **B:** Antagonism of CCK signaling with the CCKA receptor antagonist LOX stimulated eating. Healthy-weight adult males began a midday lunch buffet 4 hours after a standard breakfast and 60 minutes after beginning an IV infusion of 22 $\mu mol \cdot kg^{-1} \cdot h^{-1}$ LOX or SAL. Infusions were continued throughout the meal. LOX significantly increased meal size (*) without physical or subjective side effects. (Data from Beglinger C, Degen L, Matzinger D, D'Amato M, Drewe J. Loxiglumide, a CCK-A receptor antagonist, stimulates calorie intake and hunger feedings in humans. *Am J Physiol.* 2001;280(4):R1149.)

CCK appears to act on CCKA receptors in the pyloric area, liver, and brain to elicit satiation. At least in rats, CCK also acts locally to elicit satiation, that is, in the intestinal lamina propria before absorption. For example, intravenous infusion of a small-molecule CCKA receptor antagonist, which presumably diffused from the capillaries into the lamina propria, increased food intake, but infusions of a CCK antibody, which would not escape the vasculature, did not. Activation of abdominal CCKA receptors stimulates vagal afferent neurons, which relay the feedback information to the NTS.

Glucagon-Like Peptide-1. Glucagon-like peptide-1 (GLP-1) is produced by enteroendocrine in both the small and large intestine and by a small population of neurons in the NTS. All three macronutrients lead to intestinal GLP-1 secretion. Secreted GLP-1 is rapidly inactivated by dipeptidyl peptidase-IV (DPP-IV), a proline/alanine-specific peptidase found on the luminal surface of capillary endothelial cells, in the liver, and in the blood. Despite this, and in contrast to CCK, GLP-1 secretion and plasma levels are elevated for hours after meals and return to basal only overnight. Thus, GLP-1 may function either as a satiation signal, a postprandial satiety signal (i.e., delaying onset of the next meal), or an across-meal satiation signal (i.e., decreasing the size of the next meal). GLP-1 receptors on abdominal vagal afferents and possibly in the brain mediate GLP-1 satiation.

Whether GLP-1 signals satiation in humans has not been fully established. Consistent with a satiating effect, intravenous infusion of physiologic doses of GLP-1 reduced meal size in the absence of adverse effects in normal-weight men (it has not been tested in women). In two tests, however, GLP-1 receptor antagonism failed to increase meal size, although the same antagonist had clear effects on insulin secretion and glycemia in other tests. GLP-1's status as a normal satiation signal deserves further study for several reasons: (1) GLP-1 antagonism stimulated secretion of glucagon and PYY(3–36, see below), which may have interfered with its desatiating effect; (2) the same antagonist increased eating in several tests in rats and mice; (3) the antagonist may not have reached GLP-1 receptors in the lamina propria that may be important for satiation; (4) the possibility that GLP-1 may function as an across-meal control of eating has not been explicitly tested; and (5) long-lasting GLP-1 agonists such as liraglutide (Victoza or Saxenda, Novo Nordisk) and semaglutide (Ozempic, Novo Nordisk) reduce eating and body weight in patients with obesity likely through both peripheral and brain sites of action.

Peptide Tyrosine Tyrosine. Intestinal enteroendocrine cells that secrete peptide tyrosine tyrosine (PYY) are located mainly more distal than CCK and GLP-1 cells, so plasma levels increase more slowly after meals. All three macronutrients stimulate PYY secretion, with long-chain fatty acids the most potent. DPP-IV acts on secreted PYY (i.e., PYY[1–36]) to produce the active form, PYY(3–36). Interestingly, in rats, peripheral administration of PYY(3–36) selectively stimulates Y2 receptors and inhibits eating, whereas central administration of PYY(1–36) stimulates other Y-receptor types and stimulates eating.

PYY(3–36)'s role in postprandial satiety has been tested using intermeal infusions that began after standard meals and ended before test meals. Although these tests led to reductions in eating without signals of illness, it was unclear whether the doses were physiologic. Infusions of supraphysiologic doses of PYY(3–36) during meals also reduced intake, but in this case, the subjects usually became ill. Thus, whether PYY(3–36) has a normal role in the control of eating is uncertain. It will be important for future research on this issue to focus on the possibility that PYY signals locally via neuropod signaling.

Vagal Afferent Signaling. A variety of peripheral eating-inhibitory feedbacks are signaled to the brain via vagal afferents. Vagal afferent nerve endings densely innervate the lamina propria in most of the GI tract and, less densely, the hepatic paraganglia, the portal vein, and the bile duct. Spinal visceral afferents of the splanchnic nerves have a similar innervation pattern, but their role in eating is less well understood. Abdominal vagal afferents are stimulated by glucose and other digestive products, by CCK, GLP-1, and other hormones, and by serotonin (5HT) and other signaling molecules that are released by food stimuli. Their importance in satiation is reflected in the increase in meal size that follows a selective surgical section of sensory abdominal vagal fibers in rats (Table 1.17–3). Total vagotomy may not result in increased meal size because of the impairment of GI motor function caused by loss of vagal efferents.

Vagal afferents integrate neural signals as well as relay them to the brain. For example, in rats, (1) some individual vagal afferent fibers are stimulated by both gastric fill and CCK infusion, and combinations of the two greatly amplify the vagal response (Fig. 1.17–7), and (2) other fibers are sensitive to both ghrelin and CCK, and the two functionally antagonist stimuli sum to determine the net vagal electrophysiologic response. Vagal afferent cell bodies in the nodose ganglion also demonstrate integrative properties in that patterns of mRNA expression of orexigenic and anorexigenic peptides and receptors vary depending on the nutritional state. Vagal (and spinal visceral) afferents project to the NTS, as described in the CNS section. Recent mouse work has suggested laterality in the function of vagal afferent fibers, with fibers arising from the left nodose mediating satiating feedback and fibers from the right nodose mediating reward or appetition aspect of ingestion.

Table 1.17–3.
Disconnection of Subdiaphragmatic Vagal Afferents Leads to Chronic Increases in Spontaneous Meal Size in Rats

	Control	SDA
Meal size (licks)	1,657 ± 109	2,309 ± 102*
Intermeal interval (min)	78 ± 6	92 ± 5*

Subdiaphragmatic vagal deafferentation (SDA) combines unilateral dorsal vagal rhizotomy at the brainstem and section of the ipsilateral abdominal vagal trunk, which arises from the contralateral side of the brainstem. Rats were maintained on a liquid diet (Ensure, Ross Laboratories). Control rats received sham surgery. SDA increased spontaneous meal size by ~1/3 (*) and increased intermeal interval by ~15%, likely in response to the larger meals. Data are averages over 3 day in the 3rd week after SDA surgery, when average postsurgical body weights and rates of body weight gain had reached their presurgical values, mean ± standard error of the mean. (Adapted from Schwartz GJ, Salorio CF, Skoglund C, Moran TH. Gut vagal afferent lesions increase meal size but do not block gastric preload-induced feeding suppression. *Am J Physiol.* 1999;276:R1623, with permission.)

Energy Homeostasis

Adiposity and Energy Homeostasis. The body contains both online and stored substrates for energy metabolism. Both are homeostatically regulated. Online energy substrates are metabolites circulating in the blood that can be taken up by cells and used to generate ATP. The most prominent is blood glucose, whose levels are actively regulated. Stored energy substrates include glycogen in the muscle and liver, which amounts to a few thousand calories and triacylglyceride stored in the adipocytes, which amounts to more than 70,000 kcal in people at healthy weights. The relative constancy of body weight displayed by most people through adulthood, during which one eats about 10 times as many calories per year as are stored in the adipose tissue, strongly suggests that adipose-tissue mass is physiologically regulated. The influences of energy stores on eating are mediated primarily via the control of meal size. Recent work indicates that the control of eating by energy stores can be accurately modeled by simple negative-feedback control systems. At the same time, the epidemic rates of type-2 diabetes mellitus and obesity in many societies indicate that lifestyles in these societies stress the capacities for glycemic and adipose tissue mass regulation beyond their capacities to handle surfeits. The feedback signals used by the brain to detect increases in the mass of adipose tissue have not been identified.

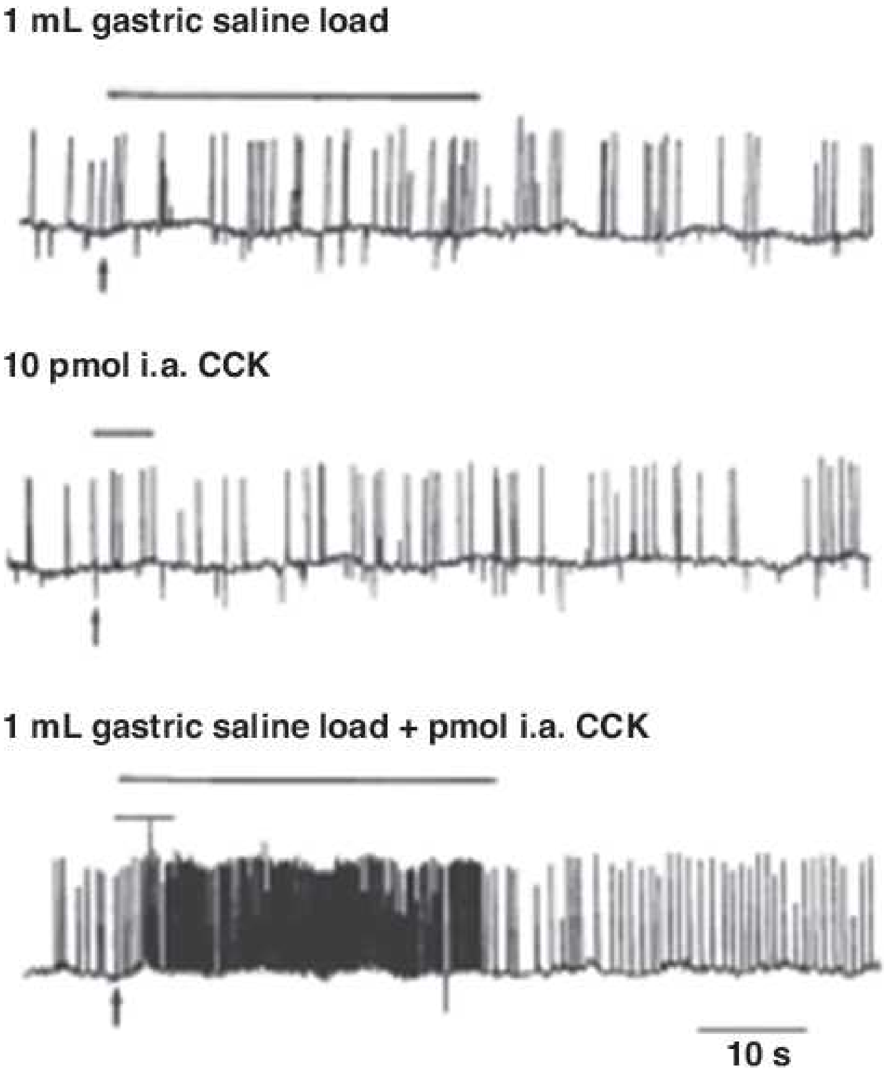

FIGURE 1.17–7. Synergistic effect of gastric mechanoreception and CCK on vagal afferent signaling in anesthetized rats. Data are extracellular recordings of action potentials in single vagal afferents in response to 1 mL intragastric saline loads and intraarterial (i.a.) infusions of 10 pMol CCK. (From Schwartz GJ, McHugh PR, Moran TH. Gastric loads and cholecystokinin synergistically stimulate rat gastric vagal afferents. *Am J Physiol*. 1993;265:R872–R872.)

Leptin. Leptin is a hormone secreted by adipocytes in proportion to their volume. Leptin's role in energy homeostasis is to defend against underweight, not to defend against overweight. That is, decreases in leptin levels below the usual level are sufficient to increase eating and decrease energy expenditure, but increases in leptin above the usual level have little effect. Note that "usual level" means the level to which the organism is adapted. Thus, long-term obese persons will increase their eating and decrease energy expenditure when leptin is reduced to levels that are still much higher than those in never-obese persons. How long a stable weight level must be maintained for such adaptation is unclear. Leptin physiology makes leptin monotherapy ineffective against obesity. Leptin has, however, shown promise in preclinical studies when administered in combination with other hormone-based therapies, such as long-acting forms of amylin, GLP-1, or CCK. With sustained weight loss, leptin levels fall below what would be predicted for the degree of adiposity. Restoring leptin levels with exogenous administration increase energy expenditure and decreases eating, suggesting that there could be a role for leptin therapy in maintaining a weight loss. Leptin is actively transported through the blood–brain barrier (BBB) and acts in a variety of brain loci to affect, among others, eating, energy expenditure, and reproductive-axis function.

BRAIN MECHANISMS OF APPETITE

Eating is mediated by a complex, anatomically diffuse neural network that extends from the caudal brainstem to the frontal lobes of the cerebral cortex. Figure 1.17–8 schematizes its general organization. A large number of interneuronal signaling molecules involved in this network have been identified and the application of increasingly powerful molecular-genetic and sophisticated behavioral methods has led to the construction of an at least rudimentary “wiring diagram.” It is no criticism of this demanding work to say that it approaches but does not quite attain the truly physiologic. That is, what normally leads to the excitation and inhibition of these neurons and under what condition the signaling molecules involved meet the criteria of Table 1.17–1 for endogenous neurocrine function are not yet clear.

Brainstem

The brainstem has vital sensory, motor, and integrative functions related to eating. As mentioned above, the NTS receives vagal and spinal visceral afferents. It also is the target of primary gustatory afferents. In addition, it expresses a variety of metabolite receptors and hormone receptors (e.g., ghrelin, GLP-1, and leptin) that directly sense eating-relevant information. The NTS is also the target of neural efferents from the area postrema, which, like other circumventricular structures, lacks a normal BBB and has receptors for a variety of circulating molecules, including: (1) receptors for the hormone amylin, which is a candidate satiation signal; (2) receptors for several toxins, which mediate conditioned taste aversion learning and elicit the emesis reflex; and (3) osmoreceptors. The brainstem also contains the lower motor neurons that produce eating and swallowing movements, upper motor neurons that drive lower motor neurons, and central pattern generators that coordinate these movements. Accordingly, difficulty eating and swallowing are signs of motor neuron diseases, such as bulbar palsy, that affect these motor networks. Finally, the NTS integrates a wide variety of information contributing to the control of eating. In addition to the sensory inputs described above, it is the target of projections from a variety of brainstem and hypothalamic areas, some of which are described below.

Tests of decerebrate rats, that is, rats bearing transections of the brain at the level of the midbrain, reveal the impressive integratory capacity of the caudal brainstem. When liquid food is infused into their mouths via oral catheters, they (1) ingest food in a meal-like pattern (which they end by food drain from the mouth) and, after meals, groom and become quiescent, similar to intact rats (2) eat progressively more of sweeter food (Fig. 1.17–9), (3) display the orofacial movements associated with preferred and nonpreferred foods in intact rats, (4) eat less after CCK injection, and (5) eat more after pharmacologic blockade of glucose metabolism. The caudal brainstem does not, however, have the capacity to initiate eating spontaneously or to increase eating in response to food deprivation; thus, these functions require the forebrain.

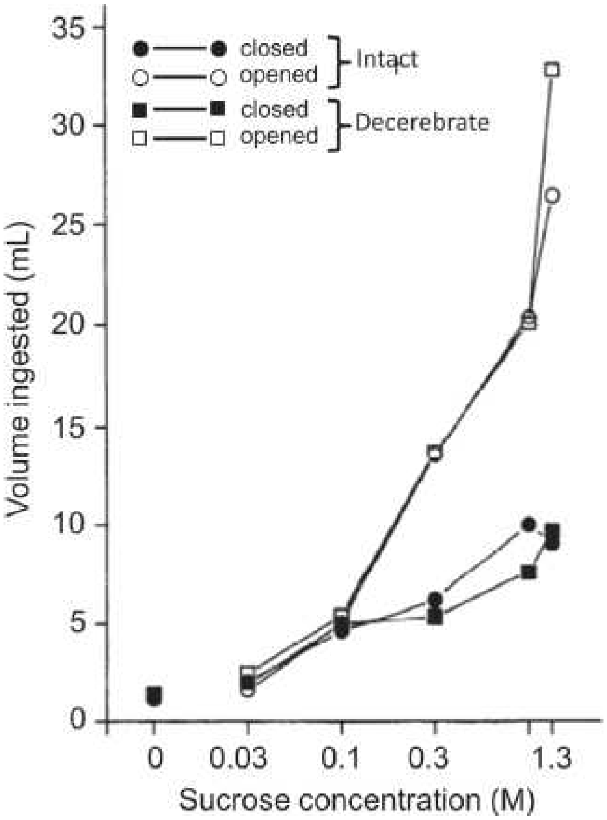

FIGURE 1.17–9. Eating behavior in intact and chronic decerebrate rats. Various concentrations of sucrose were delivered by intraoral catheters so that rats could either ingest it or passively reject it by allowing it to drip from the mouth. Intake was an increasing function of sucrose concentration in decerebrate rats that fed normally (closed condition). The gain of this function was dramatically increased in sham-feeding rats in which postingestive controls of meal size were minimized by opening a gastric cannula (opened condition). Note the close correspondence, in intact and decerebrate rats, of the stimulatory effect on eating of increasing sucrose concentration and the interaction of this stimulatory effect with the inhibitory effect of normal postingestive food stimuli. (Reprinted with permission from Grill HJ, Kaplan JM. Sham feeding in intact and chronic decerebrate rats. *Am J Physiol.* 1992;262(6):R1070. doi:10.1152/ajpregu.1992.262.6.R1070.)

Ascending Projections. Several ascending neural projections originate in the brainstem. Each contributes to a range of arousal, affective, and motivational functions related to eating.

A2 NORADRENERGIC NEURONS. A2 noradrenergic neurons have cell bodies in a region of the caudal medulla containing the NTS. They receive multiple inputs and project directly to the hypothalamus, cerebral cortex, and many other sites throughout the brain. They contribute to functions including vagovagal reflexes, satiation (including CCK satiation), and several aspects of affect and learning, especially related to stress or illness. Although noradrenergic neurons originating in the locus coeruleus (A4 and A6 cell groups) receive more attention in the study of stress, stress-related changes in eating are more likely to involve A2 noradrenergic neurons because these provide greater inputs to the paraventricular hypothalamic nucleus (PVN) of the hypothalamus, central nucleus of the amygdala (CeA) and NAc, and other sites mediating eating.

DOPAMINE. The VTA contains dopaminergic neurons that project via the mesocorticolimbic pathways to numerous hypothalamic and telencephalic targets as well as to the NTS and other caudal sites. Each of these areas is also reciprocally connected to the VTA. This network is important in food reward, as discussed further below, as well as having numerous other affective and cognitive functions. Importantly, dopamine in different brain areas can have very different influences on eating. For example, dopamine neurotransmission in the NAc stimulates eating, whereas dopamine in the perifornical hypothalamus inhibits eating (a phenomenon potentially explaining the clinical finding that neuroleptics that antagonize dopamine increase body weight, apparently by increasing food intake).

SEROTONIN. Serotonin (5-hydroxytryptamine, 5HT) neurons in the midbrain raphe nuclei give rise to another diffuse ascending projection system that is involved in affect and motivation, including the control of eating. For example, 5HT signaling via the 2C receptor has been implicated in the eating-inhibitory effects of CCK, GLP-1, leptin, and the bacterial toxin LPS. Some of these effects may involve melanocortin signaling in the ARC (discussed below).

Hypothalamus

The importance of the hypothalamus for the neural control of eating has been recognized since the classic descriptions by John Brobeck and his colleagues in the mid-20th C of the syndromes of hyperphagia and aphagia that result from lesions of the mediobasal (VMH and ARC) and lateral hypothalamus (LHA), respectively. Originally understood as functional centers, these and a number of other hypothalamic areas are now conceptualized as nodes in a distributed neural network. Figure 1.17–10 shows a network element based on two distinct neuronal populations in the ARC. One population expresses a precursor for α-melanocyte-stimulating hormone (αMSH). The second population expresses NPY, agouti-related peptide (AgRP), and GABA. Both sets of neurons express receptors to ghrelin and leptin (as well as receiving a variety of additional inputs), with the hormones' electrophysiologic effects opposite in sign within and between the two sets of ARC neurons. Studies in animals indicate that stimulation of AgRP neurons stimulates negative-reinforcement hunger, consistent with classic negative-feedback models of the homeostatic regulation of body weight. More recent studies, however, indicate that AgRP neuronal activity is reduced when mice view food before they consume it, suggestive of anticipatory, positive-reinforcement hunger. Current research generating gene-expression profiles of individual neurons so as to identify distinct subsets of neurons in these areas, will enable further insights into the organization and functions of the ARC and other hypothalamic and extrahypothalamic areas.

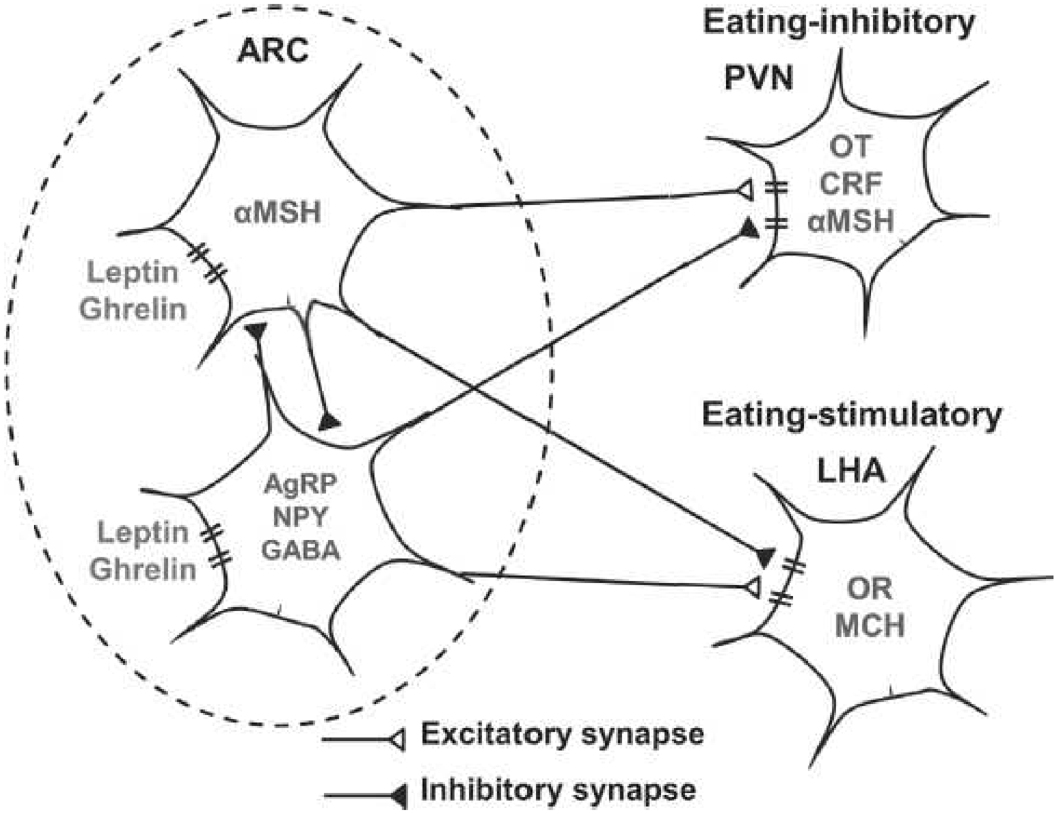

FIGURE 1.17–10. Schematic diagram of part of the hypothalamic component of the neural network controlling eating. Two populations of neurons in the hypothalamic arcuate nucleus (ARC) receive inputs from the hormones leptin and ghrelin as well as other humoral signals and neural afferents (not shown). One of these populations expresses α-melanocyte-stimulating hormone (αMSH) as a neurotransmitter; these neurons are stimulated by leptin and inhibited by ghrelin. The other population expresses agouti-related peptide (AgRP), neuropeptide Y (NPY), and γ-aminobutyric acid (GABA) as neurotransmitters; these neurons are inhibited by leptin and stimulated by ghrelin. The two populations of ARC neurons have mutually inhibitory connections. Among their principal projection targets are neurons in the paraventricular nucleus of the hypothalamus (PVN) that express oxytocin (OT), corticotropin-releasing factor (CRF), and αMSH as neurotransmitters and neurons in the lateral hypothalamic area (LHA) that express orexin (OR) and melanin-concentrating hormone (MCH) as neurotransmitters. αMSH neurons stimulate PVN neurons, and AgRP/NPY/GABA neurons inhibit them; in contrast, αMSH neurons inhibit LHA neurons, and AgRP/NPY/GABA neurons stimulate them. If the net balance of activity in this network is to stimulate the LHA neurons, eating is stimulated (thus, AgRP, NPY, OR, and MCH are often called orexigenic peptides; GABA is too widely expressed to have such a simplistic designation). If the net balance of activity in this network is to stimulate the PVN neurons, eating is inhibited (thus, αMSH, OT, and CRF are called anorexigenic peptides). Both these LHA and PVN neurons project to many sites in the brain to control eating.

Both αMSH and AgRP/NPY/GABA ARC neurons project to the PVN and the LHA, with electrophysiologically opposite effects in these sites. This suggests the model that if the net result of neural activity in this circuit is to stimulate PVN neurons and inhibit LHA neurons, then eating is inhibited; conversely, if the net effect is to stimulate LHA neurons and inhibit PVN neurons, then eating is stimulated. Interestingly, the effects of αMSH and AgRP are primarily mediated through their opposite effects on a single receptor, the melanocortin-4 receptor (MC4R). αMSH stimulates the receptor, and AgRP is an inverse agonist, that is, a functional antagonist. Loss-of-function mutations in *MC4R* or *POMC,* the gene expressing αMSH, are the commonest form of monogenic human obesity, occurring in 1% to 2% of patients with obesity. A melanocortin agonist, setmelanotide (Imcivree, Rhythm Pharmaceuticals), was recently approved for the treatment of obesity due to loss-of-function mutations in *POMC*, the leptin-receptor gene *LEPR,* or *PCSK1*, which encodes a serine endoprotease involved in neuropeptide synthesis.

Descending Projections. Forebrain eating-control signals are relayed to the integratory networks in the caudal brainstem rather than directly to the motor networks for eating. For example, (1) leptin administration in intact rats increased the satiating potency of both gastric loads and CCK; (2) leptin increased the neuronal activation produced by gastric loads and CCK in the NTS; (3) rats bearing mutations of the leptin receptor had reduced sensitivity to exogenous CCK; and (4) transgenic restoration of the leptin receptor function to these rats' ARC restored CCK's potency to inhibit eating and activate the NTS. Some of the neural pathways mediating these effects have been identified. As shown in Figure 1.17–11, ARC leptin-sensitive αMSH neurons project to oxytocin neurons, the PVN, which then project to NTS neurons that also mediate CCK satiation.

Telencephalon

The best-understood telencephalic contribution to appetite is the *telencephalic reward network,* which comprises a number of subcortical areas (e.g., NAc, ventral pallidum [VP]) and cortical areas (e.g., limbic, orbitofrontal, anterior cingulate, opercular, and insular cortex). Most of these structures receive dopaminergic, noradrenergic, and serotonergic inputs. In addition, opioid, cannabinoid, acetylcholine, orexin, benzodiazepine, glutamate, and GABA neurotransmission has been implicated in flavor reward. In addition to its roles in hedonics and reinforcement related to eating, this network is involved in other natural rewards, such as sex and in drug rewards.

Subcortical Reward Nodes. The NAc and VP have been extensively analyzed in rodents. Each has connections with the other and has numerous connections with more rostrally and caudally located structures. Dopamine is released in the NAc in a dose-dependent fashion as rats sham feed sucrose or liquid fat (Fig. 1.17–12), and local administration of dopamine-receptor antagonists into the NAc reduces sham feeding of sucrose solutions, indicating that NAc dopamine neurotransmission plays an important role in flavor reward. This is further supported by anatomical studies indicating that all the sensory modalities involved in flavor, that is, gustatory, olfactory, and somatosensory converge in the NAc. Furthermore, these projections are relatively direct; that is, they involve a minimal number of synaptic connections.

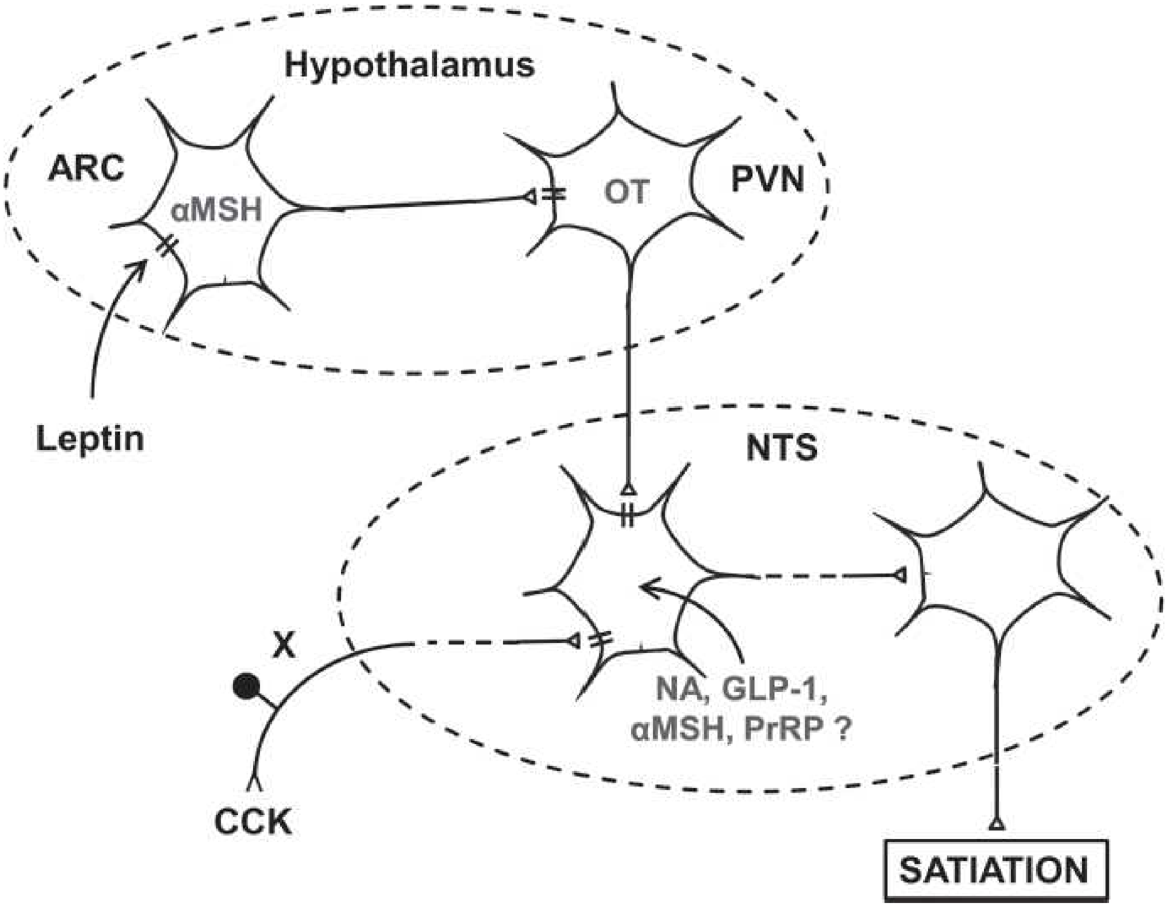

FIGURE 1.17–11. Schematic depiction of the neural network through which plasma leptin levels modulate the satiating potency of cholecystokinin (CCK). Increases in plasma leptin levels stimulate neurons in the hypothalamic arcuate nucleus (ARC) that express α-melanocyte-stimulating hormone (αMSH), and decreases in plasma leptin levels inhibit them (this appears to be the more physiologically relevant effect). ARC αMSH neurons project to neurons in the paraventricular nucleus of the hypothalamus (PVN) that express oxytocin (OT). These, in turn, project to neurons in the nucleus of the solitary tract (NTS) in the brainstem that also receive direct or indirect inputs from vagal afferent neurons (X) that are stimulated by CCK. Increases or decreases in the activity of this network lead to increases or decreases in satiation and meal size. The NTS network mediating CCK satiation appears to involve noradrenergic (NA), glucagon-like peptide-1 (GLP-1), αMSH, and prolactin-releasing peptide (PrRP) neurotransmission. Note: *broken lines* on the schematic axons indicate polysynaptic connections.

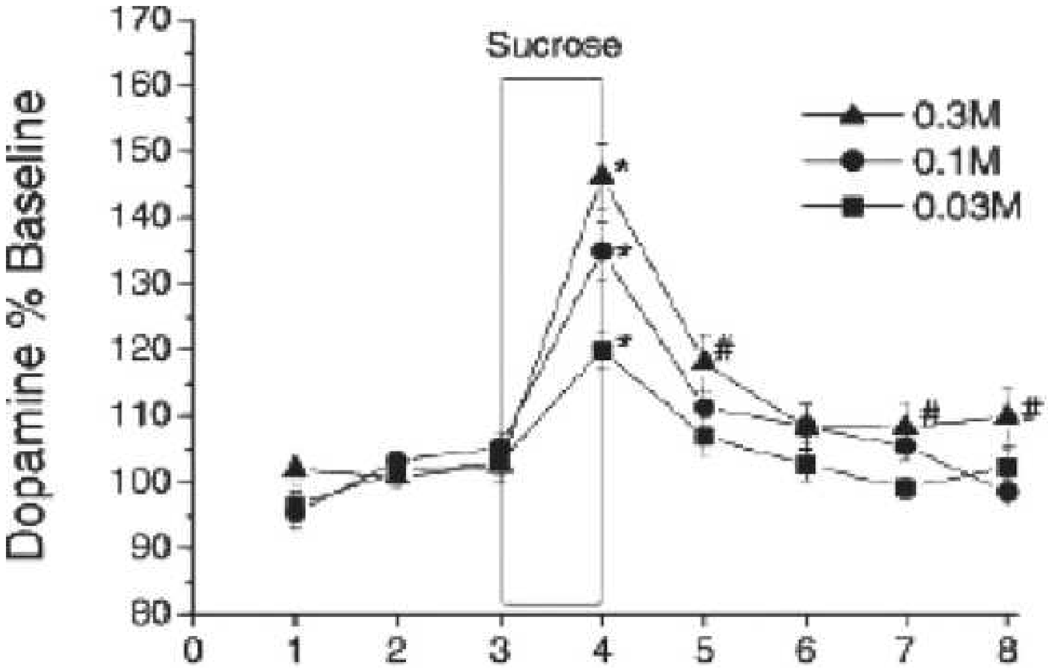

FIGURE 1.17–12. Evidence for the role of dopaminergic neurotransmission in the nucleus accumbens (NAc) in sweet-taste reward. Different molar sucrose concentrations were presented for 20 minutes per day to *ad libitum*-fed rats, which sham fed with open gastric cannulas to minimize postingestive negative feedbacks. Rats ingested increasing amounts of more concentrated sucrose (means of 18, 31, and 43 mL of 0.03, 0.1, and 0.1 M sucrose, respectively), and simultaneous extracellular microdialysis revealed a graded increase in the release of dopamine in the NAc during ingestion. Control tests (not shown) revealed that similar graded dopamine release occurred when the volume of sucrose ingested was held constant. Data are shown for 20-minute periods as mean ± standard error of the mean of baseline. *$P < .01$; #$P < .05$ versus baseline. (Reprinted with permission from Hajnal A, Smith GP, Norgren R. Oral sucrose stimulation increases accumbens dopamine in the rat. *Am J Physiol.* 2004;286(1):R31. doi:10.1152/ajpregu.00282.2003.)

A dense projection from the NAc targets the VP, a subdivision of the substantia innominata. Opioid neurotransmission via μ-opioid receptors appears to mediate reward in this area. In a fascinating rat study, lesion of the caudal VP caused rats to display aversive facial reactions to sucrose rather than positive reactions, suggesting that neural processing in this area is necessary for the generation of positive flavor hedonics.

Cortical Reward Nodes. Several areas of the frontal and temporal lobes of the cortex have been implicated in flavor reward. These include both evolutionarily older areas (e.g., the hippocampus and cingulate cortex) and evolutionarily newer or neocortical areas (e.g., orbitofrontal cortex and prefrontal cortex). Functional imaging studies in human subjects as well as single-neuron recording studies in monkeys indicate that flavor hedonics is mirrored by the activity of the midanterior orbitofrontal cortex. For example, orbitofrontal cortical activity is much higher if palatable foods are sampled when hungry than when satiated. In contrast, the medial orbitofrontal, ventromedial prefrontal, and middle anterior insula cortices may be less involved in generating the experience of flavor hedonics than in monitoring and predicting flavor rewards.

PHYSIOLOGIC MODULATORS OF APPETITE

Learning

Meal initiation, food selection, satiation, and meal size are all readily conditionable in animals and humans. Both classical (or Pavlovian) and instrumental (or operant) learning are involved. Environmental context and flavor usually provide the CS. For example, when a sound/light CS was presented to rats before each of six scheduled meals for several days and then tested during “extinction,” that is, when the rats had free access to the same diet, the CS elicited initiation of a very large meal on each daily presentation for 3 weeks. Thus, cues that predict food availability during food deprivation can provoke the initiation of a large meal in the absence of deprivation. The unconditioned stimuli (UCS) for such conditioned hunger have not been identified. Satiation and food selection are also conditionable, as shown by the extinction of conditioned controls of meal size during sham feeding (Fig. 1.17–13). In this case, the UCS is the postingestive consequences of eating. For example, rats that drink flavored water while nutrients are infused into the stomach, duodenum, jejunum, or liver subsequently eat less food with that flavor (flavor-nutrient conditioning). This is satiation, not aversion because when a choice of foods is offered, the rats choose the flavor associated with nutrient infusions. Studies in humans and rats indicate that food selection and amount eaten are often driven more by flavor-nutrient conditioning than by flavor hedonics. Recent work indicates that in the case of infused fats, vagal afferents relay the UCS signals centrally, leading to dopamine release in the striatum.

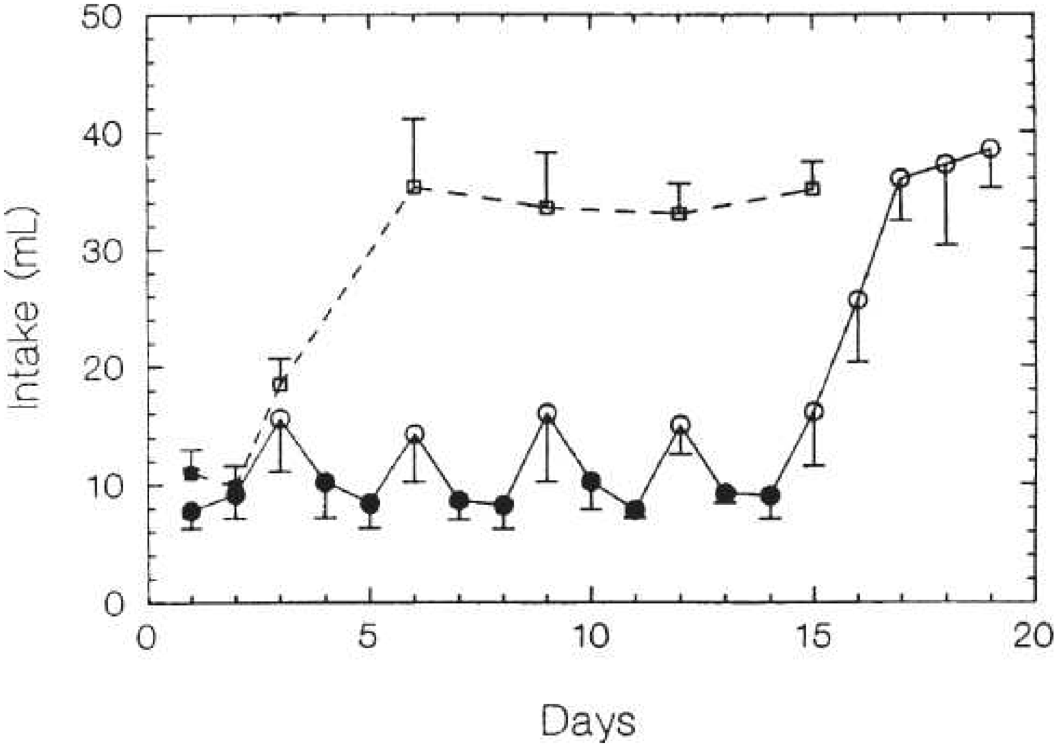

FIGURE 1.17–13. The role of conditioned satiation in eating in the rat. Data are 30-minute intakes of 0.8 M sucrose in two groups of rats in successive tests. Rats were prepared with steel gastric cannulas that were either closed for real-feeding tests (closed symbols) or open for sham-feeding tests (open symbols), during which sucrose did not accumulate in the stomach or enter the intestines. One group (*squares*) real-fed sucrose once and then sham fed. The other group (*circles*) alternated real- and sham-feeding tests. The progressive increase in sucrose intake during consecutive sham-feeding tests was prevented by interspersing two normal feeding tests between each sham-feeding test. When this was done, sham intake was significantly larger than real intake but significantly smaller than the asymptotic sham intake. These data indicate that normal feeding of sucrose produces a learned association between the taste of the sucrose and its postingestive effects, that this association limits intake, and that it extinguishes during consecutive sham-feeding tests. (Reprinted with permission from Davis JD, Smith GP. Learning to sham feed: Behavioral adjustments to loss of physiological postingestional stimuli. *Am J Physiol.* 1990;259(6):R1228. doi:10.1152/ajpregu.1990.259.6.R1228.)

Higher-order conditioning is likely to play important roles in human eating. For example, cultural socialization may result in the apparent positive hedonic response to and selection of the flavor of capsaicin (chili), which all infants avoid. Indeed, with the exception of a few unconditioned gustatory preferences and aversions (such as for sweet and bitter tastes), *all* food selection appears to be learned. Some forms of learned controls of eating are special forms of conditioning. Flavor aversions conditioned by upper GI food poisoning, for example, can be learned after only one CS–UCS pairing and, despite extraordinarily long CS–UCS delays (hours), are unusually long lasting.

Basic and clinical research on learned food preferences should be a high priority. For example, behavior therapy programs, because they are relatively highly structured and can present specific food stimuli, should provide excellent opportunities for the clinical use of conditioned physiologic controls of eating.

Interactions

This review emphasizes that different functional processes controlling eating and their physiologic bases interact in ways indicating that boundaries among them are merely heuristic. Fundamental learned interactions between flavor stimuli and GI or metabolic controls of eating were described in the previous section. There is also an unconditioned change in flavor hedonics related to physiologic state, such that flavor stimuli are rated as more pleasant by hungry than by full subjects ("alliesthesia"). There are also interactions between GI and adiposity signals. As described above, CCK satiation was reduced in rats with loss-of-function mutations in leptin receptors and was rescued by transgenic restoration of leptin receptors in the ARC. Similar interactions have been described between adiposity signaling and GLP-1 or other controllers of meal size.

Energy Expenditure

Resting Metabolic Rate (RMR). RMR, which is determined mainly by fat-free mass, is linearly correlated with daily energy intake, accounting for ~50% of the variance, and with meal size. Fat mass is not strongly correlated with daily energy intake. These data suggest that RMR tonically stimulates appetite. Teleologically, it seems sensible that organisms ensure sufficient energy to maintain the function of the brain, liver, kidneys, etc. The mechanisms involved are unknown. Note that RMR is unlikely to be a regulated variable; that is, although RMR drives appetite, there is no feedback loop maintaining RMR at a particular level.

Exercise. Energy intake also is related to habitual levels of exercise or physical-activity energy expenditure, but whether acute bouts of exercise affect eating is not clear. Recent research has delineated interesting relationships between exercise and food intake in an animal model of obesity, Otsuka Long Evans Tokushima Fatty (OTELF) rats, which lack CCK1 receptors and are hyperphagic and obese. When given access to running wheels, they are equally active to the control strain but they reduce their food intake within a day down to levels of the control rats and maintain this lower intake for as long as running wheel access is maintained. This results in the normalization of body weight. When they no longer have access to running wheels, food intake increases. Importantly, the magnitude and extent of the increase depend upon the developmental stage during which exercise is experienced. In mature rats, intake and body weight return to pre-exercise levels. However, when access to exercise is provided to young OLETF rats, the effects appear to be permanent. Food intake temporarily increases but not to levels in OLETF rats that did not have running wheel access and body weights are maintained at levels significantly below those of rats that did not have access to running wheels. Similar effects of exercise have been demonstrated for rats bred to be susceptible to dietary obesity and in mice lacking melanocortin-4 receptors. The mechanisms underlying such actions have yet to be determined.

Other recent work in rats has also demonstrated the effects of exercise on diet selection. Access to a running wheel reduced the selection of a previously preferred high-fat diet and can produce avoidance of a novel, normally preferred palatable diet.

Reproductive Axis

Ovarian cycling and other reproductive states affect eating. Adult women and female animals of many mammalian species decrease eating during the follicular and periovulatory phases of the cycle. In women, this decrease, which is not consciously appreciated, amounts to a few 100 kilocalories per day, which over the long term can affect body weight (Fig. 1.17–14). Studies of oophorectomy and estrogen treatment in rats and mice indicate that estrogens acting on estrogen receptor-1 (or α) in the medial NTS mediate these effects. Estrogen levels are also high in the midluteal phase. It is thought that progestins counteract the eating-inhibitory effects of estrogens and maintain higher levels of food intake during the midluteal phase of the cycle.

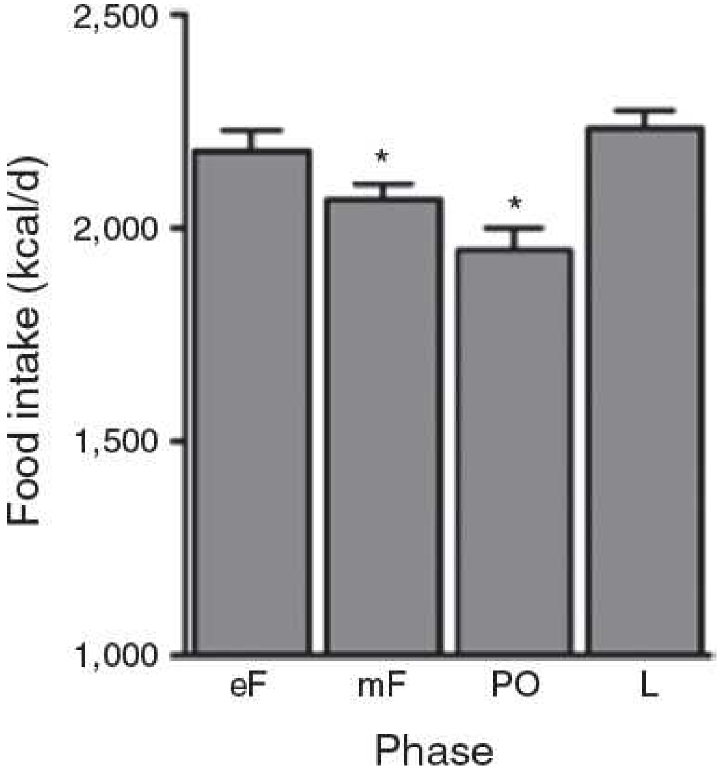

FIGURE 1.17–14. Daily food intake during the ovarian cycle in women averaged across the early-follicular (eF; 4 days), mid-follicular (mF; about 9 days), periovulatory (PO; 4 days), and luteal (L; about 11 days) phases. Note the progressive decrease in food intake during the follicular phase. Old-world monkeys, whose cycle is apparently identical to the human cycle, show a similar follicular decrease in daily food intake and also a high, constant level of food intake during most of the luteal phase which has not been verified in women. *Significantly different from luteal phase. (From Asarian L, Geary N. Sex differences in the physiology of eating. *Am J Physiol Regul Integr Comp Physiol*. 2013;305:R1215–R1267.)

In rats and mice, the periovulatory decrease and the postoophorectomy increase in food intake are caused by selective changes in meal size; meal frequency does not contribute. Indeed, when the hyperphagia of oophorectomized rats abates after they have increased body weight ~20%, it is because meal frequency decreases; the oophorectomy-induced increase in meal size is permanent. This is a good example of the importance of meal pattern analysis in understanding the controls of eating. Estrogens decrease meal size during the periovulatory phase in rats at least in part by selectively increasing the satiating potency of CCK.

Both human and animal research indicates that there is a sex difference in the avidity for sweets, with females preferring them more than men. One reflection of this is that women more frequently endorse sweets as their most preferred or craved foods, whereas men more frequently endorse savory foods. The mechanisms underlying this sex difference are unknown.

Reproductive axis function also seems to affect binge eating, as described below.

Illness Anorexia

Anorexia of varying intensity and duration is a common element of both innate and acquired immune responses to infection, trauma, neoplasm, and other challenges. The transient anorexia of the acute phase response of the innate immune system, like fever, is an unpleasant but adaptive response that can facilitate recovery. More chronic illness anorexia, however, is a maladaptive response that can increase illness severity and interfere with therapy.

A number of cytokines, including interleukin-1 and TNF-α, as well as prostaglandin-E_2 and other immune signaling molecules are involved in illness anorexia. Peripheral immune signals apparently affect the brain both directly and indirectly via endocrine and peripheral neural responses and converge on the same neural networks that mediate normal eating. For example, serotonergic neurons in the dorsal raphe nuclei (DRN), which project into the hypothalamus and telencephalon, have been implicated in both the normal control of eating and illness anorexia. In animals, illness can lead to reduced meal size, reduced meal number, or both. Illness anorexia in humans remains poorly understood.

PSYCHIATRIC EATING DISORDERS

Laboratory Studies in Patients with Eating Disorders

Subjective Appetite in Patients with Anorexia Nervosa. The study of disordered subjective appetite around meals in patients with eating disorders provides important insights into disordered eating. Patients with anorexia nervosa display marked individual differences in subjective appetite. It seems that physiologically rooted perceptions of appetite are often outweighed by psychological influences related to body image, fear of losing control of eating, conditioned food preferences, etc. Figure 1.17–15 shows an example. Disentangling these disparate factors remains challenging.

Eating in Patients with Bulimia. Binge eating is accessible to laboratory study. In a residential-laboratory setting in which subjects had free access to a variety of foods, patients with bulimia nervosa and control subjects usually took similar numbers of meals and, usually, similarly-sized meals (40 to 980 kcal). But about a quarter of the meals taken by the patients were much larger (1,058 to 6,728 kcal). These meals occurred mainly late in the day and consisted largely of sweet and snack foods. Remarkably, experimentally manipulated cognitive stimuli, that is, an invitation to binge if possible, are sufficient to induce binges in the laboratory in patients with bulimia that exhibit spontaneous binges. This opens the possibility of within-individual studies of the behavioral and neural differences between normal and binge meals.

Postingestive negative-feedback satiation signals are less potent in patients with bulimia. (1) Equivalent preloads of food decrease intake less in patients with bulimia nervosa than in controls, particularly when the patients are eating large meals. (2) Patients with bulimia must eat larger amounts of food to produce equivalent self-reports of fullness during a meal. (3) Volume distention of the stomach produces a decreased perceptual and mechanical response in patients with bulimia, presumably because their stomachs are larger than normal as the result of accommodation to the frequent ingestion of large meals. (4) Meal-stimulated CCK release is less in bulimic patients than that in controls (Fig. 1.17–16). These abnormalities appear to resolve as binging decreases, suggesting that they are not the initial cause of bulimia. Nevertheless, it is possible that they facilitate the development of the disorder once it has begun and impede recovery from it.

Binge eating is also associated with ovarian cycling. Binge frequency is maximal during the mid- and lateluteal phases of the cycle in women with bulimia nervosa and least during the follicular phase. Binge frequency and emotional eating (the tendency to overeat or binge eat in response to negative emotions) show similar cyclic effects in community samples with greater tendencies for disordered eating associated with high levels of both estradiol and progesterone and lessor tendencies associated with high levels of estradiol and minimal levels of progesterone.

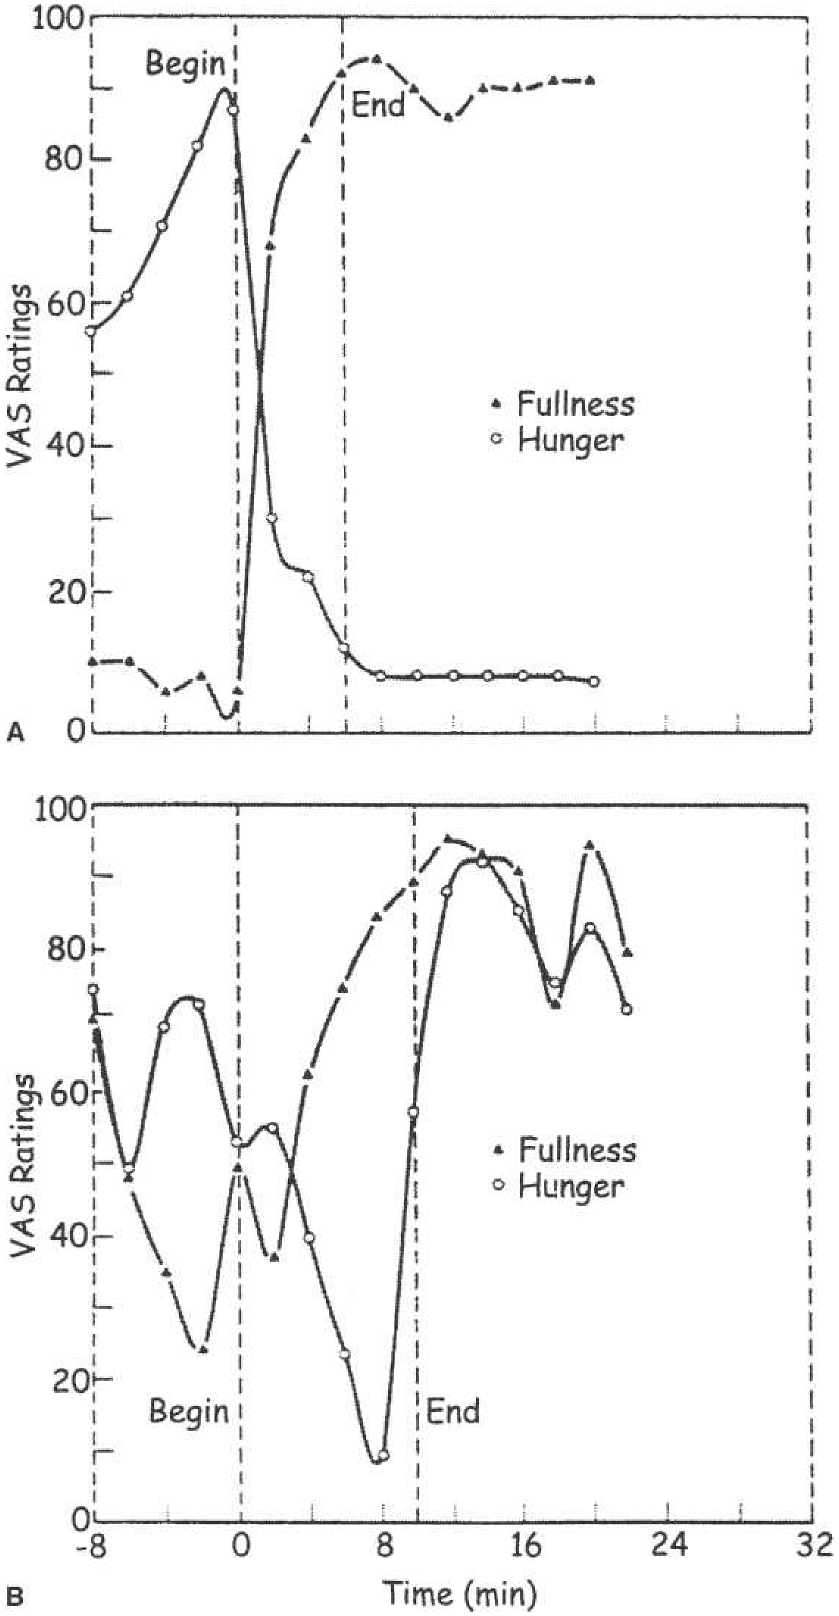

FIGURE 1.17–15. Disturbed subjective appetite in a woman with anorexia nervosa. Momentary intensities of hunger and fullness around a meal were rated by (**A**) a healthy woman and (**B**) a woman with anorexia nervosa using

visual analog scales. In the healthy woman, hunger is high before the meal, fullness is low before the meal, and the two percepts change in a reciprocal fashion before, during, and after eating; this is typical of most healthy normal subjects. In contrast, in this patient with anorexia nervosa, hunger and fullness change irregularly before, during, and after the meal and are often not reciprocally related; other patients with anorexia nervosa showed a variety of responses, some more and some less like the usual responses of healthy women than these. Note that the figure does not show other experiences associated with meals, such as pleasure and tranquilization. The challenge for this research is to disentangle the various psychological and physiologic influences producing these percepts. (Reprinted from Owen WP, Halmi KA, Gibbs J, Smith GP. Satiety responses in eating disorders. *J Psychiatr Res.* 1985;19(2–3):279–284. Copyright © 1985, with permission from Elsevier.)

Serotonin and Eating Disorders. Functional brain imaging, often involving radiolabeling methods to identify neurotransmitter function, is a major research focus in eating disorders. The most progress to date involves the study of serotonergic mechanisms. (1) Women with bulimia nervosa displayed reductions in $5HT_{2A}$ receptor binding in the orbital frontal cortex following recovery, suggesting that this might reflect a trait difference underlying vulnerability for this disorder. (2) Women who recovered from anorexia nervosa also displayed reduced $5HT_{2A}$ receptor binding, albeit in different brain areas.

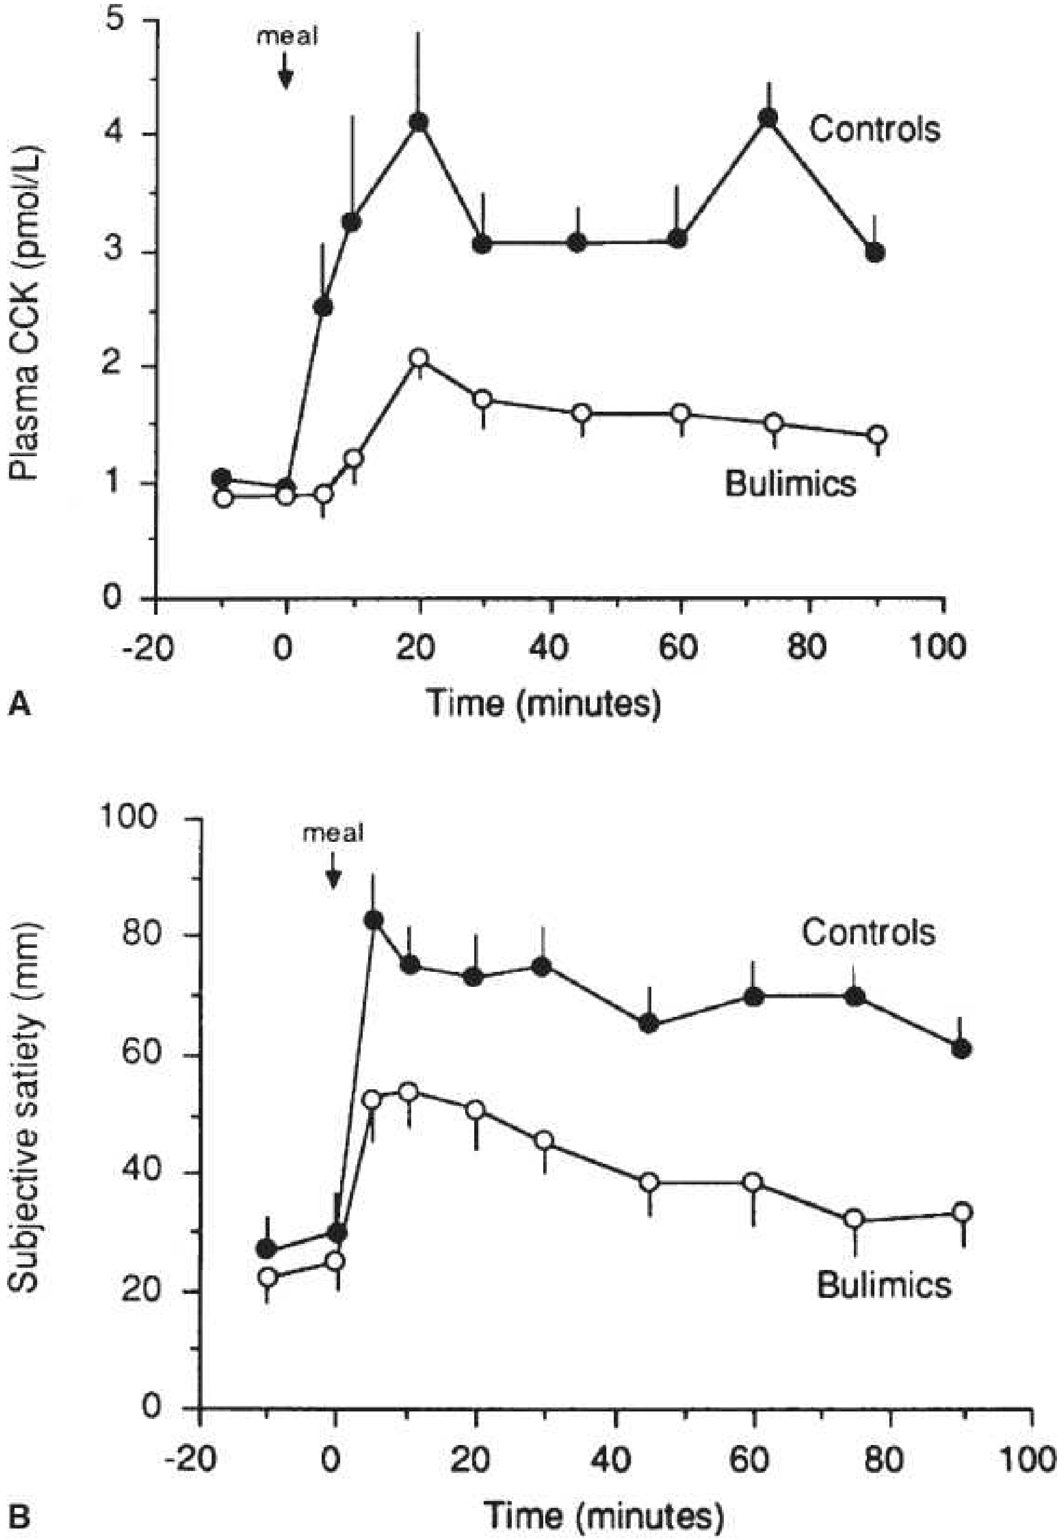

FIGURE 1.17–16. Prandial concentrations of cholecystokinin (CCK) (**A**) and the subjective experience of postprandial satiety (**B**) are reduced in patients with bulimia nervosa. Fourteen patients and 10 control women matched for age and weight were offered a 400-mL liquid meal after an overnight fast (*arrows*) and ate it in 1 to 2 minutes. Plasma CCK was measured with a

selective bioassay. Satiety was measured by a 100-mm visual analog scale (0 = empty; 100 = full). Both the peak CCK concentration and the integrated CCK response (area under the curve) were significantly reduced in patients with bulimia nervosa, and this correlated with reports of significantly less satiety beginning 5 minutes after meal onset. (From Geracioti TD, Jr., Liddle RA. Impaired cholecystokinin secretion in bulimia nervosa. *N Engl J Med*. 1988;319:683–688, with permission.)

A key challenge in research of this type is to identify the causal factors contributing to vulnerability. For example, serotonergic changes might be related to anxiety disorders, which occur in the majority of patients with anorexia nervosa and bulimia nervosa, rather than being specific to the disordered control of eating. Unfortunately, relatively few brain-imaging studies of eating disorders in patients occur in the context of eating. More work of this type might reveal state or trait differences related to the physiology of appetite between eating disorders and suggest new targets for improved treatment.

The acute tryptophan depletion (ATD) test has been used to investigate the role of serotonin in eating disorder behaviors. The test involves ingestion of a tryptophan-free protein load, which diverts plasma tryptophan into peripheral protein synthesis, leading to a decrease in central serotonin synthesis. One study indicated that ATD decreased mood in both patients with bulimia nervosa and healthy controls and increased the urge to binge in patients who were medicated with serotonin-reuptake inhibitors (SSRI) at the time of testing but not in patients who were not so medicated and not in controls. These data are consistent with a specific role of serotonin in acute binge urges. Further research is warranted to determine why ATD affected binging only in the medicated group (perhaps that group had a more severe disorder or perhaps ATD reversed the beneficial effects of SSRI treatment but that serotonin is not involved in the binge disorder itself), where in the brain the critical effect on serotoninergic neurotransmission occurred, and what functional system it influenced.

Animal Models of Psychiatric Eating Disorders

Anorexia Nervosa. Activity-based anorexia (ABA) is a widely used model of anorexia nervosa. In this model, rats or mice are given access to running wheels for most of the day and access to food for only 1 to 2 hours per day. Over the course of several days, animals run progressively more and eat progressively less, to the point of self-starvation. In some, but not all studies, signs of anxiety and anhedonia occur. ABA also elicits many endocrine and neurotransmitter changes similar to those associated with anorexia nervosa. Additionally, as in anorexia nervosa, adolescence is a period of increased vulnerability. Individual differences also play a role in ABA. For example, in a recent study of adult female C57BL/6N mice, only about half the animals displayed progressive weight loss, while the others maintained their initial weights. When mice with transgenic knockdown of the dopamine transporter and increased dopamine levels were tested, however, more mice were vulnerable due to exaggerated increases in wheel-running activity.

Binge Eating. Binge-like eating can be produced in rats and mice by a variety of methods. Restricted access to a highly preferred food (usually 1 to 2 h/day for 3 day/wk) increases intake in comparison with 1 to 2 hours of access every day. Intake of preferred foods is also increased if the food is offered 1 to 2 h/day following electric shock or other physical stressors. Psychogenic stress, produced by placing the preferred food just outside the cage, also suffices to elicit binge-like eating.

Several studies have addressed the influences of the reproductive axis on binge-like eating. Estradiol treatment reduced binge-like eating in oophorectomized rats, similar to the effect found in women, but, unlike in women, the effect did not vary cyclically and was not reversed by progesterone. Female rats are markedly more vulnerable to displaying binge-like eating than are male rats (Table 1.17–4). The development of this “binge-eating proneness” trait was pursued to follow up on a report that girls with lower levels of estrogen during puberty have increased heritability of binge eating. Rats that were prepubertally oophorectomized failed to show normal pubertal development and displayed an increased risk of binge-like eating as adults (Table 1.17–4). These data, consistent with the human data, suggest that normal pubertal estrogens levels are protective against the development of binge eating (note that this apparent organizational effect of estrogens contrasts with the activational or acute effect of estrogens to reduce binge eating in women and binge-like eating in animals). Finally, another recent study indicated that estrogens act on serotonergic neurons in the DRN to inhibit binge-like eating in adult female mice.

Table 1.17–4.
Influences of Sex and Pubertal Development on the Propensity for Binge-Like Eating in Rats

A. Sex	**BER**	**BEP**
Female (%)	3*	47*
Male (%)	37	3
B. Prepubertal oophorectomy	**BER**	**BEP**
Likelihood of BEP (odds ratio)	0.6	2.4*
	(0.3–1.3)	(1.0–5.7)

A. Male and female rats were offered standard chow *ad libitum* and a palatable commercial cake frosting for 4 h/day, 3 day/wk for 2 weeks, a procedure that leads to increased palatable food intake in comparison to *ad libitum* access to the same food. Palatable-food intakes in six tests were ranked across all rats, and propensity for binge-like eating was scored as binge-eating–prone phenotype (BEP; scored in the highest tertile of palatable-food intake in three or more of the six tests and never scored in the lowest tertile) or binge-eating-resistant phenotype (BER: scored in the lowest tertile of palatable food intake in three or more of the six tests and never scored in the lowest tertile). Females were significantly more likely to develop the BEP phenotype than males (*) and significantly less likely to develop the BER phenotype than males (*). Data are percent of rats of each phenotype (rats with intermediate scores are not shown). (Adapted from Klump KL, Racine S, Hildebrandt B, Sisk CL. Sex differences in binge eating patterns in male and female adult rats. *Int J Eat Dis.* 2013;46(7):729, with permission.) **B.** Prepubertal female rats were oophorectomized and phenotyped as described above as adults. Oophorectomy prevented normal pubertal development, as assessed by vaginal opening, and significantly increased the odds of developing the BEP phenotype (*). Data are odds ratios (95% confidence intervals) of the likelihood of developing BER or BEP phenotype following oophorectomy relative to non-oophorectomized rats. (From Klump KL, Sinclair EB, Hildebrandt BA, et al. The disruptive effects of estrogen removal before puberty on risk for binge eating in female rats. *Clin Psychol Sci*. 2020;8:839–856, with permission.)

SUMMARY

The behavioral and subjective aspects of eating are generated by a widely distributed neural network extending from the caudal brainstem to the frontal lobes. The fundamental output of this network, and therefore the focus of behavioral neuroscience of appetite is the meal. Physiologic stimuli for meal initiation include circadian rhythms, metabolic signals, and endocrine signals, of which ghrelin has received the most attention.

Conditioned signals, however, are usually more important. After eating begins, flavor hedonics increase or decrease eating. Other than the preference for sweet taste, these are mainly conditioned with a variety of mechanisms ranging from postingestive nutrient sensing to social and cultural factors, contributing. Meal-ending satiation is controlled by physiologic signals involving gastric mechanoreception and gastrointestinal hormones, such as CCK and GLP-1, as well as by conditioned influences. Some of these mechanisms maintain satiety after meals. A great deal of progress has been made in delineating nodes in the underlying neural network in the hypothalamus, mainly in the context of energy homeostasis and the ventral forebrain, mainly in the context of food reward. AgRP, NPY, GABA and αMSH are important mediators of the hypothalamic contributions to energy homeostasis. Reduced leptin in underweight appears to activate this system to stimulate appetite, but the extent to which overweight engages a regulatory compensatory influence remains in doubt. A number of subcortical (NAc, VP, etc.) and cortical sites (hippocampus and cingulate, insular, orbitofrontal, and prefrontal cortices) contribute importantly to hunger, satiety and, especially, food reward. Ascending projections from the brainstem and midbrain α-adrenergic, serotoninergic, and dopaminergic neurons provide important inputs to most of these areas. A general principle is that the functional divisions of appetite are increasingly understood to result from interactions among all of the physiologic mechanisms mentioned. Subclinical disordered eating and psychiatric eating disorders are accessible to direct experimental study as well as to study in animal models.

1.18 Genome, Transcriptome, and Proteome: The Molecular Genetics, Biochemistry, and Multi-Omics Underlying the Neurobiology of Mental Disorders

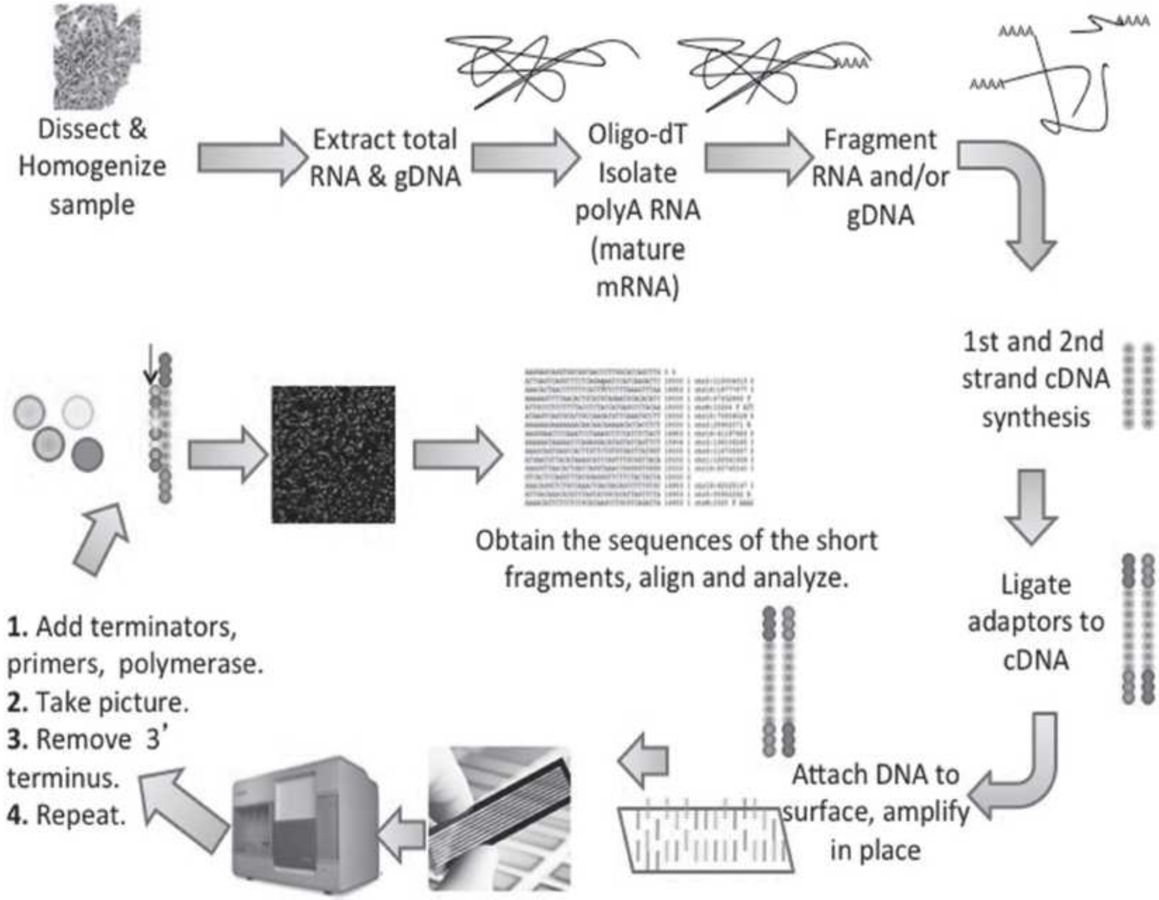
EVAN E. AFSHIN, M.D., AND CHRISTOPHER E. MASON, PH.D.

This is an era in which the global study of the DNA, ribonucleic acid (RNA), and protein-building blocks of cells has become feasible, accessible, and increasingly routine. Genome-wide association studies (GWAS) of a million or more common genetic markers from large populations are now relatively inexpensive and conducted routinely. The same can be said for studies that sequence the exome, that is, the DNA of expressed genes as well as the entire genome. The growing understanding of genome variation provided by the International HapMap Consortium and continued major advances in genotyping technology together have made it possible to conduct high-throughput, cost-effective GWAS in large numbers of individuals with detailed information on phenotypic traits and environmental exposures. The resulting data will be used to identify genetic variants potentially related to mental disorders, assess the prevalence of these variants in large and diverse samples, and examine possible modifiers of gene–disease relationships. Soon, the 1,000 genome project followed, organizing a comprehensive database of SNPs, copy number variations (CNVs), insertions and deletions (indels), as well as large structural rearrangements. ENCODE project (described later in this chapter) expanded these studies further into functional genomics. Functional genomics is already becoming routine in brain research and is being applied to the study of postmortem human brains from individuals with mental illness and to animal models of relevance to clinical neuroscience.

These exciting molecular genetic approaches permit the study of biologic information from a global perspective. This information is contained in the **human genome**, the three billion base sequence comprising the full complement of DNA in human cells. The genome of each individual is contained within every cell in the body that carries a nucleus and represents the raw material necessary to allow for normal development. This genetic material also plays a causal or contributory role in much of human disease, including mental illness. **Genomics** is the study of the full complement of genetic material of an organism. The ability to consider humans in this light is a fairly recent development, one that has been energized by the sequencing of the human genome and the subsequent large-scale efforts to identify and characterize human genetic variation and all functional and regulatory elements. The **transcriptome** is a term that can be applied to the sum total of RNAs transcribed from genes in an organism, a process often referred to as gene “expression.” Studies of gene expression usually focus on **messenger RNA** (mRNA), the intermediate between genes and proteins. They also vary depending on the experimental design and may include only mature, polyadenylated mRNA or total RNA (mRNA plus ncRNAs) in the cell. Global studies of gene expression compose the field of **functional genomics** and may use such tools as **next-generation sequencing** (NGS), a methodology that relies on the power of massive parallel sequencing of short reads derived from genomic DNA or RNA. A simplified diagram of NGS workflow is shown in Figure 1.18–1.

The **proteome** denotes the full panoply of proteins expressed in an organism and studied globally by proteomics. As the general understanding of these biologic domains in humans and many other organisms has grown, so too has the appreciation of its complexity. The deeper we delve into its structure, function, and complex interactions, the more we are pressed to reconsider basic concepts. For instance, the amount of genetic variation in apparently normal healthy people is underestimated. While it has long been appreciated that the sequence of the DNA varies slightly between individuals, it has recently been found that as much as 20% of the human genome can possess large-scale structural variation as well. Hundreds of thousands to millions of nucleotides of the genetic code may be missing, duplicated, or have multiple copies within a single individual without obvious adverse effects. These variations, which are referred to as **copy number polymorphisms**

(CNPs) or CNVs are just beginning to be cataloged and studied in depth. In addition, there are extremely large numbers of common differences between individuals on a single nucleotide level, known as SNPs. Understanding the importance of these many forms of genetic variation promises to revolutionize the current thinking about the role of genetic structural variation in normal development, shed light on the heritability and biology of traits associated with psychiatric disorders, and perhaps ultimately reshape psychiatric diagnostic schema.



Dissect & Homogenize sample
Extract total RNA & gDNA
Oligo-dT Isolate polyA RNA (mature mRNA)
Fragment RNA and/or gDNA
1st and 2nd strand cDNA synthesis
Ligate adaptors to cDNA
Attach DNA to surface, amplify in place
1. Add terminators, primers, polymerase.
2. Take picture.
3. Remove 3' terminus.
4. Repeat.
Obtain the sequences of the short fragments, align and analyze.

FIGURE 1.18–1. Overview of the NGS workflow. Tissue is being dissected and homogenized, and genomic DNA and/or RNA are extracted. In case of studying mature coding mRNAs, oligo-dT purification is performed. Next, DNA and/or RNA is fragmented into short pieces (~200 nt) and cDNA library is derived. Next adaptors are ligated, who help anchor the cDNA to a hard surface, and sequencing by synthesis is performed. The final results are the sequences of the short fragments of DNA or RNA.

The notion of a “gene” is evolving as well. It was long thought that a single gene led to the production of a single protein. However, by 1977, it was discovered learned that one gene may code for multiple versions of a protein that differed functionally. Recent data challenge the conventional definition of the boundaries of an individual gene, findings which will likely lead to a major reappraisal of genomic function and regulation. For example, most genes have multiple 3′ and 5′ termini and various splicing sites and harbor various regulatory elements within their gene bodies. In addition, elements called enhancers can control gene expression long-range, and transcription factor binding site’s (TFBSs) can regulate the ability of genes to be activated, attenuated, or silenced.

In addition to forcing a reconsideration of fundamental genetic concepts, the sequencing of the entire human genome also set the stage for a far deeper understanding of how genetic variation alters the regulation of gene expression and how variation either in functional or regulatory domains of genes affects brain structure and function, and how this variation contributes to the risk for mental disorders.

This chapter will review fundamental concepts, including the nature of DNA, chromosomes, RNA, proteins, and the concept of coding and noncoding genes. This chapter will then review what is currently known about the sequence characteristics of the human genome on a global scale and consider how this sequence varies between individuals and among populations. Subsequently, this chapter will consider how the genome is regulated and the manner in which the study of proteomics and systems biology promises to leverage these recent advances in functional genomics to enhance the general understanding of normal and pathologic brain development and functioning.

THE ORGANIZATION AND STRUCTURE OF THE HUMAN GENOME

A **genome** is defined as the total complement of DNA replicated in a living organism. The sequencing of genomes of free-living organisms began in 1995 with bacteria and progressed to larger and more complicated organisms, such as yeast (1996), worms (1998), and fruit flies (2000). A critical milestone was reached in 2001 with the completion of the first draft of the human genome. Currently, there are thousands of genomes sequenced. In 2011, the Genome in a Bottle Consortium was established with the goal of providing an entire technical infrastructure that will enable data from genome sequencing to be used in translational medicine.

As these data became available, four curious patterns emerged: (1) the number of genes is lower than expected. Estimates prior to the completion of the draft human sequence ran as high as 160,000. As of the last issue of GENCODE annotation, the official annotation of the ENCODE project, there are 60,155 genes, with 19,881 of them being protein-coding genes. It is now evident that there are, in total, about 20,000 protein-coding genes in *Homo sapiens;* (2) gene number is not a predictor of organismal complexity. For example, amoebas are simple, single-celled organisms but are predicted to have many more genes than humans (Table 1.18–1); mice and humans have been found to have approximately the same number of protein-coding regions; (3) genome size is not a predictor of organismal complexity. An amoeba (*Amoeba dubia)* has the largest known genome (670 gigabases)—more than 200 times larger than the human genome; humans and chimpanzee genomes are essentially the same size but they hold obvious and important differences with respect to the development of the cerebral cortex; and (4) a small percentage of eukaryotic genomes codes for proteins. Only 2% of the human genome encodes proteins. The vast majority is comprised of intronic and repetitive sequences, some of which are clearly functional and much of which remains a mystery. Apart from protein-coding genes, there are a substantial number of actively transcribed genes that don't code any proteins (ncRNAs, to be discussed below), sometimes called the "dark matter" of the genome. Some of this "dark matter" is known to be functional, although the functional significance of much of ncRNAs is yet to be resolved.

Table 1.18–1.
Number of Genes and Genome Sizes across Different Organisms

Organism	Gene Count	Genome Size (base pairs)	Number of Chromosomes
Amoeba	50,000	670,000,000,000	13
Plant (Fern)	37,500	100,000,000,000	90
Human	25,000	3,000,000,000	46
Chimpanzee	25,000	3,000,000,000	48
Mouse	25,000	2,500,000,000	40
Honey bee	15,000	300,000,000	32
Fruit fly	14,000	130,000,000	10
Worm	19,000	97,000,000	12
Fungus	6,000	13,000,000	32
Bacterium	3,000	5,000,000	1
Mycoplasma genitalium	500	580,000	1
DNA virus	450	50,000	0
RNA virus	20	10,000	0
Viroid	1	500	0

Sorted by Genome Size. All numbers are approximate.

Cumulatively, these observations pose a central question for psychiatry: if the genome of humans is not very distinctive from an evolutionary perspective, how has it produced the unique qualities of the human CNS? Recent developments have begun to shed light on this critical question.

DNA and Chromosomes

DNA is made of four **nucleic acids**, also known as **nucleotides** or **bases**, adenosine (A), cytosine (C), guanine (G), and thymine (T). In total, human genomic DNA is comprised of approximately 3 billion nucleotides, and this full complement is found in every cell in the body that contains a nucleus. Within the nucleus, the genome is organized into 46 strands of DNA that complex with multiple proteins to form **chromosomes** (23 inherited from mother and 23 inherited from father). In the nuclei of cells, the strands of DNA are combined with **histone proteins** that enable DNA to be wound tightly into histone-DNA complexes called **nucleosomes** and then organized into a super structure called **chromatin**.

From the first observations of chromosomes under the light microscope, chromatin has been divided into two types corresponding to the familiar light and dark banding patterns: **euchromatin** (lighter, less dense material) and **heterochromatin** (darker, more dense material). In one sense, chromatin acts simply as a spool around which DNA is wound, ensuring that the entire genome fits within the nucleus. This property enabled cells to remain small, a property that influenced the evolution of multicellular organisms. However, it also plays a key role in coordinating the function of the genome. The histone protein cores around which the DNA is organized may be altered by chemical reactions, including **acetylation, phosphorylation**, and **methylation**. The addition or subtraction of these and other chemical modifiers are able to dictate the conformation of regions of DNA within the nucleus, a process that helps coordinate the regulation of gene expression. A field of study, epigenetics has emerged to study the way that gene expression is altered by modifying chromatin or DNA methylation but not altering the DNA sequence (see the section on Epigenetics in this chapter). Finally, the organizational structure of chromatin creates scaffolding that helps guide the movement of DNA necessary for chromosomal replication and during cellular division (**mitosis**).

The darker staining of heterochromatin is due to the very tight packing of nucleosomes, making the DNA largely inaccessible to cellular machinery, whereas the light color of the euchromatin reflects a more open, unfolded, and usually active state. Euchromatic regions were found to be distinct in other ways as well: they hold many more genes and contain less repetitive sequences. However, heterochromatic regions of the genome can become active and some heterochromatic regions are modified back and forth, becoming active only when needed. These processes will be discussed in more detail subsequently when epigenetic mechanisms are considered at the conclusion of this chapter.

Genes, RNAs, and Proteins

Gregory Mendel first discovered genes in 1866 when he identified hereditary units he called “factors” and elaborated the principles of their inheritance through his experiments with pea plants. However, he had no physical or mechanistic understanding of what constituted a gene. The first medical application of genes came in 1902 when Archibald Garrod found that alkaptonuria, a rare disorder characterized in part by the urine turning black when exposed to air, followed Mendel laws of inheritance. He identified that the transmission of this condition followed an autosomal recessive pattern. However, while it was clear that genes were passed from one generation to the next and carried disease liability, it was still unclear precisely how or in what substance.

In 1910, Thomas Morgan demonstrated that genes were discrete units on chromosomes through his work with fruit flies, and he first proposed the idea of genetic linkage due to chromosomes exchanging material in a process called **crossing over** (Fig. 1.18–2).

In 1941, experiments in bread molds (*Neurospora crassa*) by Edward Tatum and George Beadle showed further that certain enzymes were functionless if the genes were mutated. This led to the widely accepted notion that specific genes make specific proteins, commonly referred to as the “**one gene, one enzyme**” hypothesis.

Despite these remarkable discoveries, the physical substrate for the transmission of genetic information was still a matter of debate. Early in the 20th century, proteins were favored, as they were known to be comprised of 20 different amino acids. As DNA was the product of only four different nucleotides, it was thought that the former was most likely to allow for the diversity required to make the complex instructions necessary for sustaining life. However, in 1944, genes were shown to be composed of DNA by Oswald Avery, through his demonstration that DNA could create a heritable transformation in bacteria, but proteins could not.

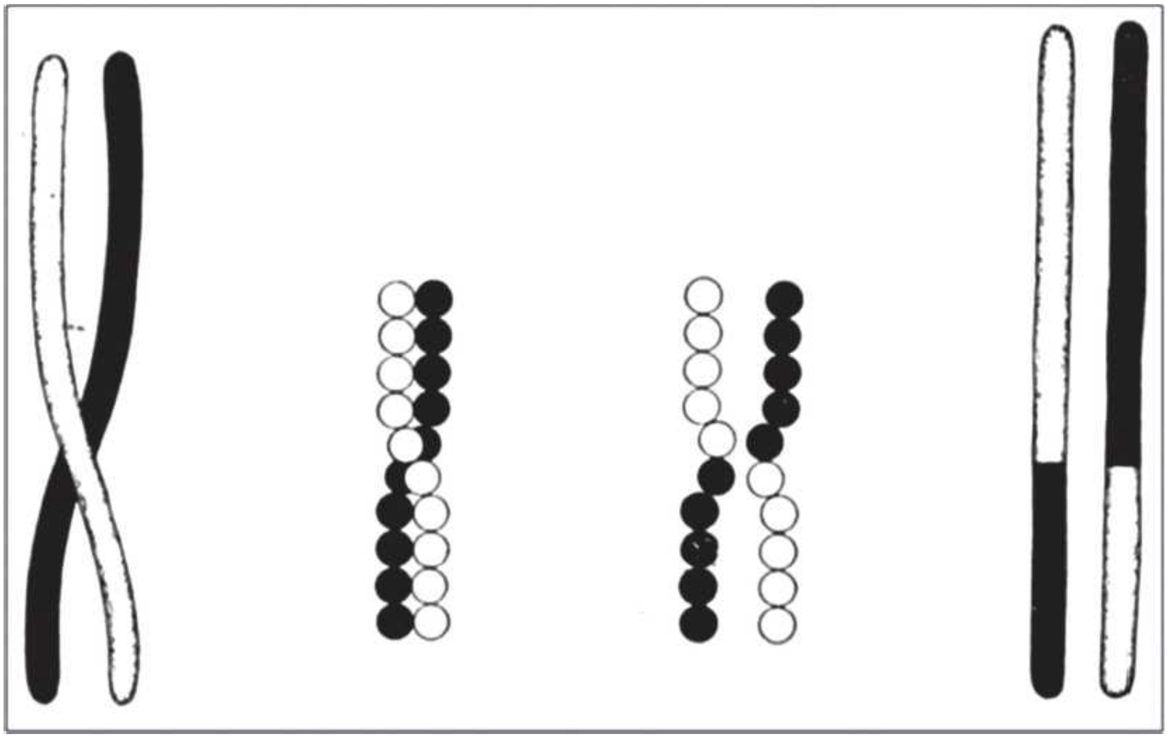


FIGURE 1.18–2. Crossing Over. A schematic of genes positioned along chromosomes (*circles*) and exchanging information (crossing over) with a different series of genes (*black circles suddenly with white circles*) during meiosis. The farther apart genes are on a chromosome, the more often they cross over—a phenomenon known as recombination.

Finally, in 1953, Watson and Crick published the chemical structure of DNA, showing that it was a **double helix** formed by two sugar-phosphate backbones supporting the four nucleotides. These, in turn, were recognized to form specific pairs between them, such that an “A” on one strand paired with “T” on the other and “C” on one paired with “G” on the other.

Coding Genes

The last several decades of progress have now led to an appreciation that there are, in a broad sense, two classes of genes: those that lead directly to the production of proteins (**coding genes**) and those that do not (**noncoding genes**). Coding genes are stretches of DNA that are **transcribed** by an enzyme (RNA polymerase) into a temporary mRNA, which is then **translated** into a protein (made of peptides), following what is known as the central dogma of molecular biology: DNA → RNA → Protein (Fig. 1.18–3).

In the 1960s, it was discovered that coding DNA is “read” in three-letter segments called **codons** (see Fig. 1.18–3), each of which becomes an amino acid in a peptide or protein. However, unlike simpler prokaryotic organisms, human coding genes are transcribed initially as sequences that require editing. Coding genes have segments that are read as codons (called **exons**) and also noncoding sequences that are transcribed but not translated into a protein (called **introns**). Noncoding sequences can be present in three areas of a gene: in front (**upstream** with respect to the sequence of transcription) of the gene, inside the gene, and behind (**downstream**) the gene. Those sequences upstream of the gene are called the **5′ UTR**. The noncoding region downstream of the coding interval is the **3′ UTR**. Mature mRNA contains a polyadenylation signal (i.e., AAUAA) that directs transcriptional machinery to insert a long string of adenosines, known as a poly-A tail, at the 3′ terminus of the mRNA. A single gene may contain several polyadenylation signals in series in its 3′ UTR, but the mechanism of determining which one is going to be used has yet to be established. In turn, multiple polyadenylation signals allow for transcripts with variable 3′ UTR length to be produced from a single gene. Transcripts with longer 3′ UTRs are relatively prevalent in the brain, giving rise to higher numbers of miRNA binding sites that enable fine-tuning of RNA regulation. In addition, longer 3′ UTRs are known to harbor protein-binding motifs that shuttle proteins to a specific subcellular location. The BDNF gene is known to possess a form with long 3′ UTR with a binding motif for BDNF that enables it to be transported to dendrites. Thus, the nascent mRNA transcript produced from a coding gene must be first processed to lead to the coherent set of instructions necessary to produce a protein product at the appropriate subcellular location. The removal of introns, through a process called **gene splicing**, is one critical step in determining a gene’s function, and it will be addressed in more detail when considering the function of each part of the genome.

Since gene transcripts are read in three-base codons, and DNA is made up of four nucleotides, there are 64 possible codons (4 × 4 × 4). In most organisms, mRNA that are translated into proteins possess a three-base sequence, called a **start codon** (AUG), delineating where the reading or translation of the codons should begin. Three **stop codons** (UAA, UAG, UGA) signal the last amino acid in the growing polypeptide chain. Start and stop codons are the punctuation needed for reading a gene, while the other 60 codons determine which amino acids are included in the peptide or protein. Since the cell uses only 20 different amino acids to make proteins, there exists some redundancy in the genetic code such that different codons can encode for the same amino acid (Fig. 1.18–4). This redundancy in codon usage may have a specific function. There is a so-called codon usage bias, where translation favors some codons over others. Differences in codon translation efficiency are related to the concentration of tRNAs that correspond to those codons, thereby implying that there is a complex interplay in-between them. Such complex evolutionary changes may fine-tune the translation process, especially in tissues with an extremely broad repertoire of expressed genes, such as neurons.

The processed RNAs are shuttled through the cell to organelles called **ribosomes** to be turned into a protein chain, which then folds into increasingly complex levels of organization (Table 1.18–2).

The total of all the proteins made by the genome is called the proteome. Many proteins serve as subunits for larger protein complexes (including the large enzyme that performs transcription, RNA polymerase II), and the study of many proteins at once is known as proteomics, a topic that will also be addressed in more detail later in this chapter.

Table 1.18–2.
Protein Structure Definitions

Name	Definition
Primary	A chain of amino acid (peptides), making a polypeptide
Secondary	The amino acids are bound within a chain by hydrogen bonds
Tertiary	The polypeptide forms entire sheets and helices for a 3D structure
Quaternary	Multiple polypeptide chains bond together for a macromolecular structure

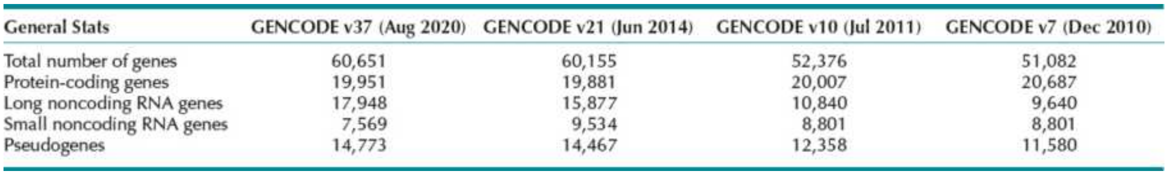
Noncoding Genes (or Noncoding RNAs)

General statistics of the GENCODE annotation for the past 4 years show a very interesting trend: the total number of annotated genes is rising; however, the number of protein-coding genes decreases at the expense of a rising number of ncRNAs, especially pseudogenes and long intergenic noncoding RNAs (LINCs), as shown in Table 1.18–3.

While coding genes conform most closely to early notions of how hereditary information is stored and processed, over time, it has become clear that these represent only about 2% of the genome. Moreover, an alternative set of instructions contained within the DNA governs transcription that is not followed by the production of a protein. Over 30,000 noncoding genes have so far been cataloged in the human genome. These are comprised of RNA (and consequently are also called **noncoding RNAs**, or **ncRNAs**). Table 1.18–4 lists several types of RNAs. Some are involved in regulating normal cellular processes of gene transcription and protein translation, whereas others have only recently been discovered and their functions are not as well understood. Moreover, some ncRNAs can function all by themselves, catalyzing reactions and acting autonomously in the cell.

Some of the best-characterized ncRNAs are called **siRNAs**. These are transcripts coded for in the DNA that are complementary (or antisense) to another transcribed sequence from the genome. Once a siRNA binds to the complementary mRNA sequence, the cell degrades the transcript, thus functionally silencing the gene that produced the mRNA without altering the DNA or mRNA sequence. Similarly, a different subset of noncoding genes, called micro-RNAs (miRNAs), are short (18–22 bp) sequences that bind most often to the 3′ UTR of a transcript and most commonly lead to a decrease in the level of the resulting protein. Both siRNAs and miRNAs operate post-transcriptionally to regulate gene expression. Thus, the multiple extremely important ways along the process from DNA to protein in which gene expression may be altered is of major importance to scientists seeking to understand the function of the genome. This topic will be addressed in the second section of this chapter. The recognition that ncRNAs are widespread and play a key role in the regulation of gene expression strongly suggests that they may also confer risk for mental disorders and other complex diseases. Moreover, it was quickly realized that siRNAs could be useful to assess the consequences of loss of expression of a particular gene at the level of the cell or the model organism; as a result, siRNAs have quickly become an indispensable research tool.

Table 1.18–3.
Distributions of Annotated Genes by Their Coding Capacity and Biotype for GENCODE 2010–2020



General Stats	GENCODE v37 (Aug 2020)	GENCODE v21 (Jun 2014)	GENCODE v10 (Jul 2011)	GENCODE v7 (Dec 2010)
Total number of genes	60,651	60,155	52,376	51,082
Protein-coding genes	19,951	19,881	20,007	20,687
Long noncoding RNA genes	17,948	15,877	10,840	9,640
Small noncoding RNA genes	7,569	9,534	8,801	8,801
Pseudogenes	14,773	14,467	12,358	11,580

Two other important classes of ncRNAs are pseudogenes and LINCs. Pseudogenes are ubiquitous in the brain transcriptome and encompass several types of transcripts, transcriptionally active genes that lost their coding potential—unitary pseudogenes (GULO-vitamin C–producing enzyme), duplicated genes that lost their coding potential, and reverse transcribed genes (processed pseudogenes). The reason their number keeps growing in each subsequent annotation is because they share a substantial portion of their sequence with the functional genes, which makes them extremely hard to identify. Bioinformaticians have developed highly sophisticated algorithms to be able to distinguish pseudogenes from functional genes. The "sponge" hypothesis suggests that pseudogenes may compete with functional genes for a limited pool of miRNAs. If so, then pseudogenes may influence overall gene regulation without possessing intrinsic function.

LINCs also appear to influence neural function. Most LINCs alter transcription (H19, XIST, AIR, HOTAIR) in various ways (i.e., direct effect on transcription, changing the epigenetic signature). Others exert their function on the translational level (GAS5).

While a significant amount of ncDNA is transcribed to functional ncRNAs (see Table 1.18–4), it has not been clear how much of the genome was actively processed nor how much of this transcription might contribute directly to biologic function. To answer this question, the National Human Genome Research Institute (NHGRI) launched a project in 2003 to identify all the functional elements in the genome called ENCODE (the Encyclopedia Of DNA Elements). By the second phase of the ENCODE project, it appeared that 75% of the human genome was transcriptionally active. However, 70% of the genome showed extremely low expression levels, raising questions regarding functional significance. Also, 11% of the genome was associated with motifs in transcription factor-bound regions or high-resolution DNase footprints in one or more cell types. Promoter-associated histone modifications or enhancers marked ~20% of the genome, while as much as one-third of the genome was marked by modifications associated with transcriptional elongation. Taken together, it appears that the vast majority of the genome is either transcribed or harbors regulatory elements (Fig. 1.18–5).

These observations strained the ability to classify genetic material. While there is a clear distinction between coding and noncoding genes, a large amount of transcriptionally active DNA produces RNAs that do not fit into current functional categories. For clarity, the term ncRNA will be used to describe noncoding genes such as siRNAs and miRNAs, whose general structure is well characterized. The additional transcribed material is referred to as **transcripts of unknown function (TUFs)** or **transcriptionally active regions (TARs).**

TUFs and TARs may represent (1) new protein-coding genes that were missed by previous experiments and gene-finding algorithms; (2) new noncoding genes; (3) novel antisense transcriptional units (siRNAs and miRNAs) that may regulate other genes; (4) alternative isoforms of known genes that include intronic regions in the final mRNA product; (5) misannotated genes that should be longer or shorter, divided into two genes, or merged into one larger gene; (6) biologic artifacts representing aberrant transcription or accidental transcriptional read-through; or (7) experimental artifacts due to small amounts of genomic DNA contamination.

Table 1.18–4.
Types of RNA

Name	Abbrev	Year	Function
Messenger	mRNA	1956	Carries the transcribed message from the DNA
Ribosomal	rRNA	1958	Components of the protein-making machinery, the ribosome
Transfer	tRNA	1962	Function in translation to bring amino acids to the ribosome
Small nuclear	snRNA	1977	Help the splicing of immature mRNAs to reach their final form
Small nucleolar	snoRNA	1986	Direct chemical modifications of rRNAs and other RNAs
Micro	miRNA	1993	Single-stranded RNA that regulates gene expression
Small interfering	siRNA	1999	Small, double-stranded RNAs that interfere with transcription
Piwi-acting	piRNA	2006	Germ-line acting RNA that stops parasitic genetic elements
Virus-derived, small interfering	viRNAs	2011	Virus-derived, small interfering RNAs that mediate trans-generational inheritance of viral silencing

Future experiments will be needed to clarify the role of these TARs, but some conclusions are already possible. For instance, the majority (93%) of the euchromatic genome is functional in some capacity (either transcribed or regulating another sequence). Also, gene regulation is symmetrical along the genome, with no bias for upstream or downstream placement of regulatory structures. This contrasts with previous notions that regions 5′ or upstream to the starting codon of a gene were most likely to modulate the regulation of that transcript. Finally, surprisingly, many of these regulatory or active regions of the genome are not highly conserved across species. Taken together, these data show that any search for genes and genetic mechanisms contributing to brain development and mental disorders must extend far beyond the horizon of coding sequences.

FIGURE 1.18–5. Summary of the ENCODE Project. The discovery and annotation of TARs was performed by sequencing RNA from a diverse range of cell lines, followed by comparative genomics, integrative bioinformatic methods, and human curation. Investigation of the regulatory elements involved DNA hypersensitivity assays, assays of DNA methylation, and chromatin immunoprecipitation (ChIP) of proteins that interact with DNA, including modified histones and transcription factors, followed by sequencing (ChIP-Seq).

Repetitive DNA

With the sequencing of the human genome and the recognition that only a small proportion is present in the form of coding DNA or ncRNAs, interest in the remainder of the genome has increased, and much of this material is present in the form of repetitive elements.

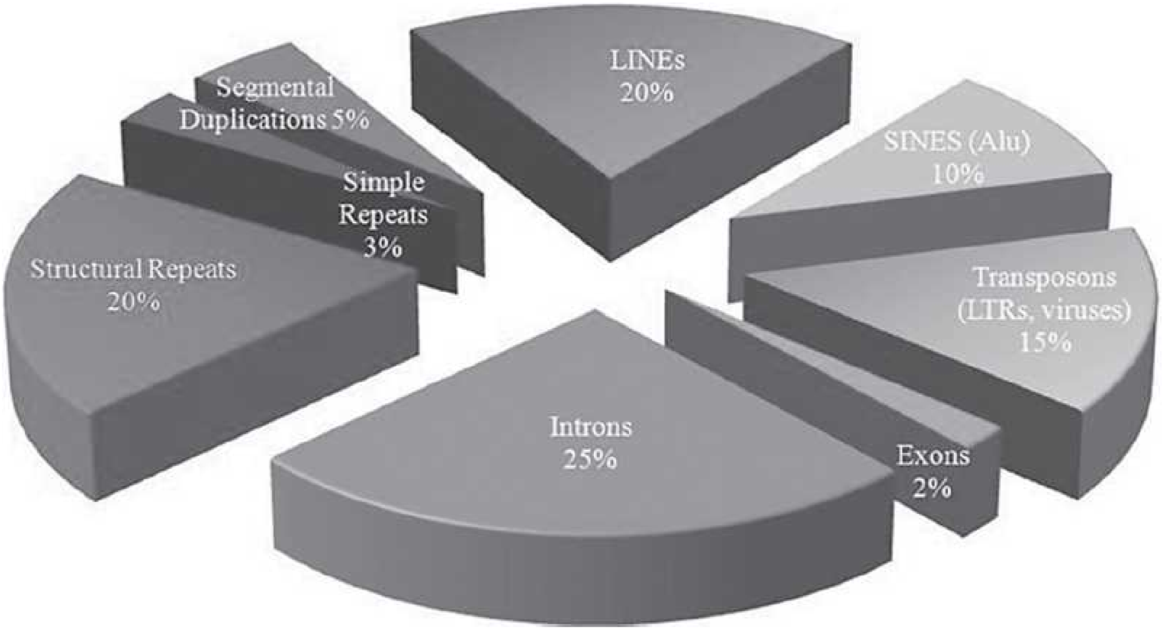

FIGURE 1.18–6. Structural Organization of the Human Genome. Most of the human genome is repetitive DNA sequences and transposable elements (LINES, SINEs, LTRs, and viruses). Very little of the genome is coding sequence (exons) but there is great room for gene flexibility and change with many of the gene's long intron sequences (introns).

The structural organization of the human genome is shown in Figure 1.18–6. Nearly one-third of the genome consists of repeated elements. Some repeated sections of the human genome serve structural purposes at the end or middle of chromosomes. However, many types of repeats are of unknown function, including **simple sequence repeats** (SSRs) and **segmental duplications** (SegDups). SSRs are small sequences (2 to 6 bp) that are tandemly repeated in the genome. A short trinucleotide repeat (CAG) in the coding part of the HGG gene responsible for coding the Huntingtin protein is known to be the cause of Huntington disease, a progressive neurodegenerative disorder that is ultimately fatal. While healthy individuals have 10 to 35 repeats in the HGG gene, affected individuals can have as many as 120. The onset and severity of the disease correlate very strongly with the number of repeats. This is one of the few neuropsychiatric diseases with a clearly defined genetic etiology that can be diagnosed prior to the onset of symptoms with a simple test. Children of a parent with Huntington disease have a 50% risk of developing this disorder. Thus, the capacity to diagnose an illness in presymptomatic individuals raises important ethical issues related to the role of genetics in neuropsychiatric clinical practice. SegDups are sequences of 1,000 bp or greater that appear at least twice throughout the genome. Interestingly, some of these SegDups contain extra copies of entire genes.

The most ubiquitous repeated genetic elements in the genome are transposable elements (TEs or **transposons**), which can jump from one place to another in the genome. This process may lead to new forms of genes that may be useful to humans, but it also poses a danger of disrupting essential genes. TEs are divided into several subgroups: **long interspersed elements** (LINEs), **short interspersed elements** (SINEs), and the small 300 bp *Alu* element (considered a SINE). The *Alu* element is present in 75% of introns and accounts for 10% of the entire genome, whereas the 6,000 bp (6 kb) LINEs account for 20% of the human genome and can be found in thousands of genes (in 5′ UTRs, exons, 3′ UTRs, and introns). Almost all genes in the human genome have at least one TE.

Alu elements are both TEs and retrotransposons, which alter DNA through reverse transcription in the manner of retroviruses, such as the 7SL RNA-derived primate-specific repeat family. Their distribution throughout the evolution of primate lineage has resulted in as many as 1.1 million copies in the human genome. Insertions of the Alu elements occurred in a few major waves, deriving the old *AluJ* subfamily (including *AluJo* and *AluJb*; about 81 million years ago), the middle-aged *AluS* subfamily (including *AluS*, *AluSx*, *AluSg*, *AluSq*, *AluSp*, *AluSc*, and *AluSb*; about 48 to 19 million years ago), and the young and still active *AluY* wave (including *AluY*, *AluYa5*, *AluYa8*, and *AluYb8*; starting about 6 million years ago and continuing to the present) (M7). Albeit ubiquitous in the genome, Alu repeats (as any other repeat or low-complexity sequence) are extremely hard to map accurately using the current short-read sequencing. This fact, along with the limited RNA sequence data derived from primates, explains the lack of proper mapping of these elements. The body of the *Alu* element is approximately 300 bp bases in length, formed from two diverged dimers, separated by a short A-rich region. Such structure enables them to fold perfectly into double-stranded structures, thereby being substrates for a process called RNA editing (discussed below).

Novel findings demonstrate that *Alu* elements are actively transposing in neurons in culture as well as in neurons in vivo. These changes in the neuronal genomes might generate neurons with unique genetic, transcriptomic, and proteomic makeup, increasing the complexity of the brain.

Since the human’s divergence from the common ancestor with the chimpanzee, approximately 98,000 viruses have invaded the human genome. These viruses, called **endogenous retroviruses**, total 8% of the human genome and are made up of **long terminal repeats** (LTRs) that reverse transcribe themselves from RNA to DNA, DNA TEs, and some viruses that lay dormant and can no longer replicate (about 4% of the human genome). Some of these sequences are essentially dead genomes that have incorporated into human DNA and are now replicated along with the genome, whereas others are still actively infecting humans by retrotransposition.

The large volume of repetitive noncoding DNA present in the human genome totals 98% of the human genome. These regions were thought to be nonfunctional, earning the misnomer “junk” DNA. However, in light of the many functions ascribed to noncoding DNA, it is generally thought that the functions of this “dark matter” in the genome remain to be discovered. Even if a function for a specific sequence has not been identified, it may still be critical to the functioning of other genes, either nearby or surprisingly remote. Even if a sequence is a repetitive TE that is present in thousands of places in the genome, the location of a single TE may be needed for the correct activity of that specific gene that now possesses the element. In a complete reversal from only a decade ago, every sequence of the genome is now considered putatively functional, opening the door for a better understanding of the genomic biology of psychiatry and revealing a much larger genome that requires critical examination.

The Mitochondrial Genome

All eukaryotes, including humans, possess two fully functional living genomes, that is, the DNA particular to that species and the genomes of mitochondria (in animals) or chloroplasts (in plants). The theory of endosymbiosis suggests that in the early days of evolving life on Earth (1.5 to 2 billion years ago), multicellular life forms merged with respiratory bacteria, which were able to produce cellular energy in a more accessible form (ATP). This relationship proved to be mutually beneficial for both the protoeukaryotes and the respiratory bacteria since the bacteria could evade prey, and the protoeukaryotes had a new source of energy. This theory is supported by the fact that mitochondria have their own genome and separate replication cycles and that the closest living relatives of mitochondria (rickettsia bacteria) are parasites of eukaryotic cells.

The human genome and the mitochondrial genome now have a completely intertwined coexistence. Nearly 300 genes from the mitochondria are present on the 23 human chromosomes. These are referred to as **nuclear DNA of mitochondrial origin** (NUMTs), and they are produced by the nuclear genome to support the function of mitochondria. Further, 27 of these NUMTs do not appear in the chimpanzee or other genomes and have therefore been incorporated into the human genome within the last 4 to 6 million years. Most of them (23/27) are present within known or predicted human genes, indicating that the symbiosis between these two genomes is significantly gene-centered, perhaps ensuring stronger protection against transposable elements and/or protect mitochondrial DNA (mtDNA) from damage inflicted by **reactive oxygen species** (ROS). Moreover, some neuromuscular diseases and metabolic defects arise from mutations or errors specific to mtDNA or NUMTs (Table 1.18–5), underscoring the importance of the mitochondrial genome in influencing the risk of mental disorders. Finally, recent studies have shown how integral the mitochondria are to human physiology, particularly the body's response to stress. A multi-omics and systems biology approach to profiling astronauts revealed significant enrichment for mitochondrial processes as a consistent phenotype of spaceflight.

Exosomes

Exosomes are a type of extracellular vesicle that contains DNA, RNA, and protein of the cells that secrete them. The physiologic purpose of exosomes remains largely unknown and needs further investigation. Some theorize exosomes play a role in maintaining cellular homeostasis by removing excess or unnecessary molecules, while others believe exosomes are integral to regulating complex intercellular and intertissue communication. Indeed, studies have shown exosomes are associated with cardiovascular diseases, viral pathogenicity, cancer progression, inflammatory diseases, and CNS-related diseases, including neurodegeneration. Findings have suggested that the molecular mechanisms and intrinsic properties of exosomes may have potential utility in the therapeutic control or diagnostic evaluation of these diseases. Also, exosomes can be engineered or programmed to deliver therapeutic agents and immune modulators to specific targets. Moreover, they have been reported in all biologic fluids and found to be readily accessible via liquid biopsies, making them a potentially useful diagnostic and prognostic marker for clinicians. Exosomes have been shown to both promote and limit the aggregation of misfolded proteins in the brain, making them a potential player in both the pathogenesis and treatment of neurodegeneration and other neurologic disorders. Their unique intrinsic property of being able to efficiently pass through the **blood–brain-barrier**, a vascular network functioning as a selective filter to keep drugs or toxins from reaching the brain, make exosomes a key therapeutic agent of interest for researchers and clinicians.

Table 1.18–5.
Human Diseases Arising from Mitochondrial-Encoded Genes

Disorder	Affected Gene(s)
NARP (Neuropathy, Ataxia, Retinitis, Pigmentosa)	ATPase6
MELAS (Mitochondrial Encephalomyopathy, Lactic Acidosis, Stroke)	tRNA (Leu), Cytochrome C
MERRF (Myoclonic Epilepsy; Ragged Red Fibers)	tRNA (Lys), tRNA (Ser)
LHON (Leber hereditary optic neuropathy)	MTND4
Friedrich ataxia	FRDA
Leigh syndrome	ATPase6, MTND5

HUMAN GENETIC VARIATION

The whole-genome sequencing of a reference human in 2001 set the stage for intensive studies of genetic variation between individuals and among populations. Generally, between any two unrelated persons, differences are present at approximately 1 in every 1,000 base pairs, that is, 0.1% of their genomes. It also appears that not everyone has two copies of every part of the genome. These larger regions of variability (>1 kb) occur in heterochromatic and euchromatic regions and are estimated to cover 5% to 20% of the total human genomic sequence. The prevalence of these variants has dramatically altered thinking about the total burden of variation within the human species. The search for disease susceptibility genes in psychiatry may be more precisely thought of as the hunt for that small proportion of genetic variation that is either causal or contributing to psychopathology.

Sequence Variation

DNA sequences of individuals vary in terms of the genetic code at the nucleotide level. Such changes may involve the substitution of one nucleotide for another or, in some cases, the insertion or deletion of one or a small number of bases or **indels.** In addition, short repetitive sequences in the DNA may differ in terms of the number of nucleotides present in these regions, variations that are known as **short tandem repeats** (or STRs) and **small sequence repeats** (SSRs).

There are varying thresholds for classifying a variant as common. Typically, if a sequence variation is found in less than 1% of the population, it is considered rare, though some authors use a threshold of 5%. Specific genetic variants found above this frequency in a given population are typically referred to as **polymorphisms**, but this term may also be applied to any change in the genome regardless of its frequency and regardless of whether or not it is deleterious to the function of the RNA or protein that it encodes or regulates. Similarly, any permanent change in the DNA nucleotide sequence can be called a **mutation,** although this term is most commonly applied to disease-related genetic variation.

Common single-base substitutions with a population frequency greater than 1% are often called **SNPs**. These have been intensively studied and proven critical to gene discovery efforts. SNPs are thought to have occurred spontaneously in human history, to have only happened at one point in that history, and to have distributed subsequently throughout a population over time. SNPs are generally stable from generation to generation, and a very large number have accumulated in the genome as the human species has evolved. Currently, 30 million known SNPs have been identified. These individual SNPs, or the arrangement of SNPs on a single chromosome (called **haplotypes**), allow scientists to trace inheritance within families or to identify variations that may carry risks for disease within a population. In addition, the distribution of SNPs and haplotypes among various populations has provided critical insight into human evolution. For instance, this type of data along with other genetic and archeologic evidence has provided strong evidence for the theory that humans originated from African hominids.

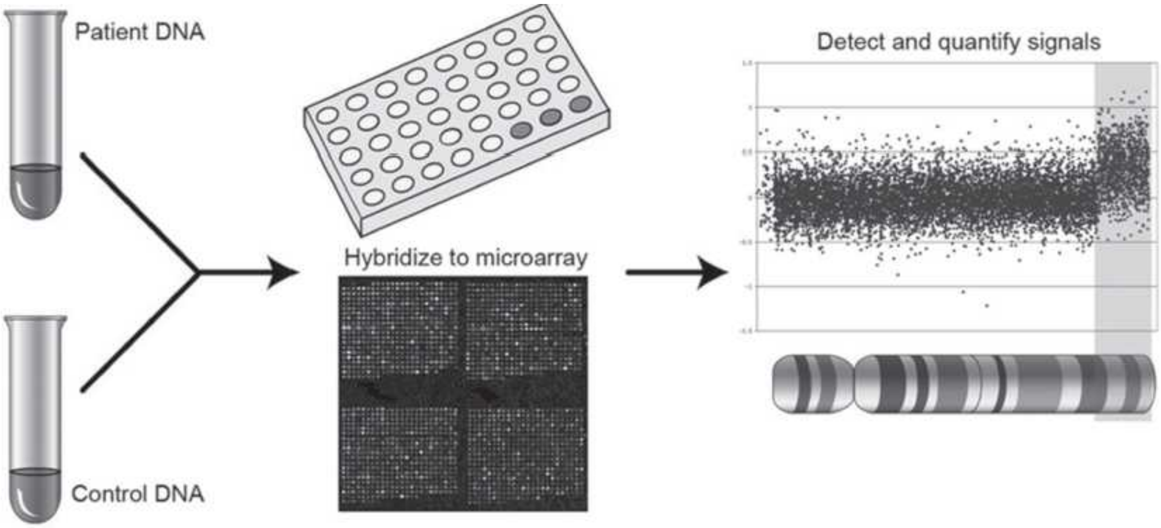

FIGURE 1.18–7. Detecting Structural Variation in the Human Genome. Using microarrays, which hold thousands of spots of DNA from the human genome, a comparison between amount of patient DNA and control DNA along the genome can be made. If a region of a chromosome is altered (upward shift in intensity, in red along the chromosome), it is then defined as a CNV.

Structural Variation

While large microscopic variations including balanced and unbalanced translocations, large deletions or inversions, and extra chromosomes, have been studied for decades, only recently has it become apparent that there is also a tremendous amount of submicroscopic structural variation in the genome.

In the late 1990s, several labs developed tools to identify chromosomal aberrations that were below the resolution of the light microscope. Given the known relationship between chromosomal abnormalities and various human disorders including cancer and mental retardation, it was anticipated that the ability to identify formerly unseen chromosomal anomalies would lead to the identification of additional disease susceptibility genes. The surprising result of these efforts was the identification of differences in the number of copies of chromosomal segments found among the control samples used to validate the technology. Given the clear evidence that these changes were widespread among individuals without any obvious phenotype, these changes became known as **CNPs** or **CNVs.**

Subsequent studies have widely replicated these initial results and the development of higher resolution technologies has demonstrated that deviations from the expected two copies of each genetic locus are common throughout the genome. These variants are not replacements or changes in sequence (like mutations or SNPs) but are more comparable to indels, where regions of the genome are missing a copy (**heterozygous deletions**), missing both copies (**homozygous deletions**), or have extra copies (**amplification**). Healthy human beings possess from several dozen to several hundred CNVs and may carry as many as a thousand total CNVs. When the sum total of all the identified variants is considered (SNPs, CNVs, and larger DNA deletions and/or amplifications), as much as 20% of the genome has been shown to vary between individuals (Fig. 1.18–7).

Gene (and large genomic segments) duplications have resulted in many evolutionary changes during the evolution of hominid lineage. Trichromatic vision was developed in the primate lineage around 40 million years ago as a result of gene duplication. Such rearrangement was facilitated by the Alu repeats, which flank the opsin genes, allowing the duplication to occur. The genes coding for cytochrome P450 enzymes frequently contain CNVs in humans. They are key enzymes in drug metabolism and, as such, extremely important in the novel field of pharmacogenomics (discussed below).

The discovery of CNVs has had an enormous impact. Approximately 10% of the genes in the human genome, including genes influencing development, overlap common CNVs, suggesting that the human genome is able to tolerate haploinsufficiency (the loss of one of two haploid copies) to a far greater extent than previously anticipated. Several mechanisms lead to CNV formation. Some CNVs appear to have developed once in human history with subsequent distribution among populations. Other CNVs appear to be more dynamic. In this case, a region of the genome may be primed to lead to CNVs, but this process may occur randomly among different individuals and lead to multiple different CNVs in a single chromosomal region.

The relationship between CNVs and human disease is a topic of intense study. It is now clear that the relationship between genotype and phenotype with regard to structural variation is quite varied. Previously, if a deletion was identified in a patient being evaluated for mental retardation, it was presumed that the deletion was the likely cause of the clinical problem. Presently, the identification of a loss of a gene in such a patient, even one known to be involved in brain development, is no longer *prima face* evidence of causality. At present, it is generally presumed that: (1) some CNVs have no phenotypic consequences; (2) as with other forms of variation, some common CNVs will be found to contribute incrementally to complex, multigenic disease; and (3) some copy number changes, particularly those that are rare and or *de novo* (newly created in a single person), may carry large risks for some disorders. Given that the characterization of these types of variation in the human genome is in the early stages, distinguishing among these alternatives in a given patient or population remains a formidable challenge.

Common versus Rare Genetic Variation

Irrespective of whether a genetic variant is sequence-based or structural, once it is introduced into the human genome, one expects that it will be subject to natural selection. That is, changes that do not alter reproductive fitness may be readily passed from generation to generation and, over time, have the potential to become common. Alternatively, changes that result in reduced fitness are likely to be subject to purifying selection, leading the frequency of that variant to decline over time in the population.

The impact on fitness is only one of several forces that influence the frequencies of genetic variants. For instance, a new mutation is, by definition, rare until it has had time to disseminate into a population and be subject to selective pressures. Moreover, the history of ethnic populations and migration patterns can dramatically influence the dynamics of genetic variants over time. However, it is important to note that as social constructs, race, and ethnicity can complicate genetic studies involving common variance, oftentimes leading to spurious findings and conclusions.

One would presume that rare variants contribute to disorders that are lethal early in development and those that reduce fertility or otherwise lead to decreased reproductive fitness. One would conversely presume that common genetic variants contribute to disorders that appear later in life or for which there is not a negative impact on fitness. Common variants are also presumed to be implicated in conditions (e.g., sickle cell trait) where a positive effect (malaria resistance in this case) of a given genetic variation might counterbalance negative consequences. The competing impacts of positive and negative effects of a gene variant are called **balancing selection.**

The field of human genetics has a record of tremendous accomplishment in those disorders in which a single rare genetic change causes or dramatically increases the risk for a disease or syndrome. However, the task of clarifying disorders in which multiple gene variants contribute to the manifestation of disease has remained a daunting challenge. Two alternative, but not mutually exclusive, paradigms have emerged to account for the genetics of common complex disease: a common variant: common disease model and a rare variant: common disease alternative.

The former has been largely favored in mental disorders; for example, it is widely held that schizophrenia, major depression, bipolar disorder, and autism result from the combined effect of multiple common genetic variants, each with modest effect and interacting with environmental factors to exceed a biologic threshold. For these and other complex disorders, both modeling and early experimental evidence have essentially ruled out the contribution of a single gene of major effect, assuming that there is a single phenotype (with relatively little variation) for a particular illness. As most of the variation within a population is carried in common variants, it is thought that common disorders will likely reflect this underlying genetic architecture.

An alternative model posits that many individually rare variants with relatively large effects contribute alone or in combination to the risk for common disorders. This hypothesis seems intuitive for disorders with early-onset and those that alter reproductive fitness. In the absence of balancing selection, one would expect that alleles with large effects, even if these are contributory and not causal, would be likely to be rare. In addition, one would expect a significant burden of rare mutations for disorders in which so-called sporadic or *de novo* variation played an important role. Indeed, recent studies show that *de novo* mutations (mostly *de novo* missense and *de novo* likely gene-disrupting mutations) in children affected by autistic spectrum disorder (ASD) may account for more than 10% of the diagnosed cases.

These two possibilities are not mutually exclusive. As more research is completed, it is likely that both common and rare variants will be found to contribute to the variable manifestation of many common mental disorders. However, the distinction is of tremendous importance with respect to current genetic studies because the methodologies employed to show a causal or contributory role for genes differ tremendously in terms of their ability to detect the contribution of rare versus common genetic variation. In addition, diseases with complex and extremely variable phenotypes, such as schizophrenia or ASDs, may be caused by various combinations of rare and common variations, which would, at least in part, explain the large spectra of pathologies seen in the aforementioned conditions.

THE FUNCTION OF THE GENOME

Now that the sequence of the human genome has been elaborated, research now focuses on how its 3 billion nucleotides work in a coordinated fashion. Given that the human genome appears largely unremarkable compared to other species in terms of size, gene number, or percentage of the genome devoted to protein-coding, one must presume that the capabilities of the human brain must be powerfully influenced by variation in a relatively limited number of genes or influenced by factors other than raw DNA sequence. The characterization of brain-specific functional components of the genome and the consequences of genetic variation in these elements will undoubtedly become a prime concern for psychiatric genetics in the coming era. More broadly, such an understanding will identify those unique molecular changes that define *Homo sapiens* as a species.

As recently as the early 1970s, the importance of gene regulation for shaping the development of the human brain remained in question. Several hypotheses were entertained regarding the origin of the differences between humans and other closely related species. It was thought that speciation might be the result of small-scale sequence changes (DNA or protein sequence chances), regulatory changes (from controller genes or other similar elements), or large-scale sequence changes (gene and genome duplication). In 1975, Mary-Claire King and Allan Wilson published a paper in which they sequenced and compared 44 human and chimpanzee genes. To the surprise of many, the vast majority of these sequences were found to be nearly identical among chimp and human and virtually all of the small-scale changes identified were synonymous. Moreover, the gene and genomic organization of the transcripts was essentially unchanged between the two species. These data demonstrated for the first time that neither coding sequence nor genomic organization was likely to account for the differences between the two species.

King and Wilson's work supported the alternative conclusion, that is, the sequence surrounding genes that regulated gene expression accounted for key evolutionary changes that include dramatic differences in cortical architecture. This work also implied that sequencing of the human genome and that of closely related species would not be sufficient for understanding key differences in their biology. These conclusions largely have been borne out: it is clear that in order to understand brain function, the question of whether a gene sequence is present is often not as important as determining *when* and *how* the transcript is active in that organism. In cases of highly divergent neurodevelopmental disorders such as autism, it has been shown that there are distinctive spatiotemporal expression patterns of the ASD-associated genes in early developmental stages of the brain. Aberrant spatiotemporal expression of these genes could easily contribute to developmental impairments, resulting in autism.

Yet another confirmation of King and Wilson's work came up recently with obtaining the genomes of the Old World Apes. Namely, several genomic regions that underwent rapid evolution in humans were identified —human accelerated regions (HARs). While HAR1 is a gene expressed during the development of the neocortex, and HAR2 (also known as HACNS1) is a human-specific developmental enhancer, another 721 HARs were identified by comparing conservation scores of the sequences. Surprisingly, 92% of them are noncoding genes, emphasizing the likely importance of regulatory sequences in recent human genome evolution.

REGULATION OF TRANSCRIPTION AND THE TRANSCRIPTOME

Perhaps the largest contribution to the complexity of eukaryotes comes from **RNA splicing**, the process by which the exons of a gene can be combined in multiple ways (Fig. 1.18–8).

The discovery that genes were transcribed as both exons and introns came from studying the adenovirus gene *hexon* in 1977. The implications of this discovery for human evolution were quickly recognized: a single region of DNA could lead to a variety of transcripts and multiple versions of a protein. These, in turn, could become targets of evolutionary selection that might generate new functions without having to sacrifice the utility of the original transcript. Thus, the “universe” of the transcriptome suddenly became much larger.

During RNA splicing, exons can either be retained in the mature message or targeted for removal in different combinations to create a diverse array of mRNAs from a single pre-mRNA, a process referred to as **alternative RNA** splicing. By 1994, estimates of the number of human genes exhibiting alternative splicing ranged from 1% to 5%. However, these estimates were known to be imprecise due to the sparse availability of sequence data. Interest in resolving this issue led to a portion of the HGP being devoted to studying the relationship between gene structure and gene expression, and two methods were utilized: **complementary DNAs** (cDNAs) and **expressed sequence tags** (ESTs). Both methods depend on the mRNA being processed first, which removes all the introns and then adds a long polyadenosine (poly-A) tail to the initial transcript. The presence of these poly-A tails provides a means for transcripts to be bound and isolated in the laboratory by running the total extracted RNA through columns packed with complementary poly-T sequences. Once isolated, the single-stranded mRNAs serve as a template in a reaction to create the complementary sequence, using an enzyme called reverse transcriptase. This creates the cDNAs, which can then be sequenced. ESTs are small fragments of cDNAs and they are slightly different because they use cloning techniques to digest the cDNA and merge the sequence with a bacterial fragment in order to discern the sequence. Once created and analyzed, these EST and cDNA libraries confirmed a massive amount of alternative splicing in the genome and showed that within genes, some exons are always used (constitutively spliced) while others are very rare and specific to a certain time or place in the body (alternatively spliced).

As these sequence libraries were being created, other technologies simultaneously emerged to allow researchers a clearer view of gene expression and splicing. In 1995, Pat Brown and colleagues first measured expression for 45 genes in parallel in the plant *Arabidopsis* by creating a microarray. They placed complementary sequences to the 45 genes in small spots on a glass microscope slide and then isolated mRNAs from two different *Arabidopsis* samples. The relative expression of each of the 45 genes could be determined between the two samples based on the fluorescence intensity determined at each spot on the slide.

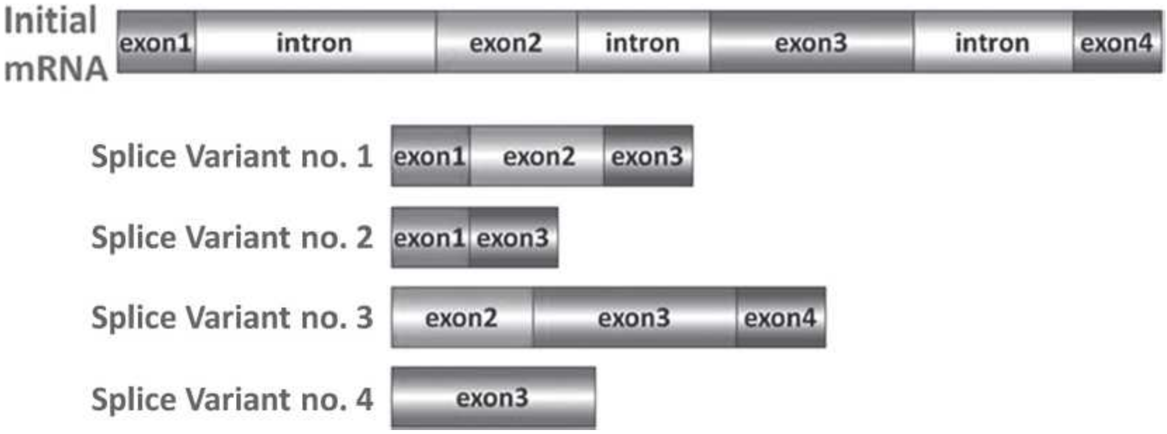

FIGURE 1.18–8. **Alternative Splicing in Eukaryotic Genes**. Different variations of certain multi-exon genes can be generated by the cell, depending on environmental conditions or developmental stage. These different splice variants will then create a slightly modified version of the gene's protein.

Since this time, a series of technical and methodologic developments have led to an astonishingly rapid increase in the density and specificity of the probes (spots) that may be placed on microarrays. Current technologies allow for millions of sequences to be arrayed on a single slide, providing the basis for comprehensive and global studies of gene expression within and among organisms. With hundreds of thousands of cDNAs and ESTs isolated, the current estimate is that at least 80% of human genes undergo alternative splicing.

While the size and gene number found in an organism do not generally correlate with the biologic sophistication of an organism, such is not the case for alternative splicing. At the most fundamental level, this distinction is made clear by the contrast between prokaryotes (which have no alternative splicing) and eukaryotes (which do). There is also some evidence that within higher organisms increases in splicing rates correspond to greater complexity. For instance, in yeast, most genes (~96%) have no introns and very few splicing events have been discovered. Moreover, recent evidence shows that invertebrates have fewer genes undergoing alternative splicing (50% to 60% in the fruit fly) than do vertebrates (80% in humans).

While the total amount of alternative splicing in the human genome remains a question, it is already clear that the brain shows the largest amount of any tissue in the human body. This observation suggests that alternative splicing and its regulation may be quite important for understanding what makes the human brain so different from other closely related species and in understanding the neurobiology of mental disorders.

Indeed, the process of alternative splicing bestows an opportunity for genes to undergo accelerated evolutionary change. Most genes are under strong negative selection pressure, meaning that it is difficult for them to change, especially if they are critical to the early development of an organism. Alternative splicing leading to the formation of a gene's less common products can be an evolutionary shortcut that relaxes this negative selection pressure. Since enough of the major (or more common) form is still present, the new, minor splice form would not be subject to the same degree of negative selection and may even create a "neutral space" for the novel gene product to acquire a new function for the organism.

Ample evidence of this process can be found within the DNA sequence. The exonic constituents of the major versus minor forms of a given gene are largely conserved between the mouse and human genomes. The major-use exons typically show higher degrees of sequence conservation than minor-use exons, suggesting stronger negative selection on the former. Cross-species comparisons demonstrate that minor-use exons are a more recent addition in evolutionary time, supporting the hypothesis that the basic biologic functions of a gene can be augmented through the addition of new splice variants. There is strong evidence that when a minor-use exon subserves a new important function, its level of conservation quickly approaches that of more ancient exons. These phenomena take place even if the new splice variant is highly restricted temporally or spatially, and this is amply demonstrated in the human brain.

It has often been the case that researchers have focused on changes that affect the most highly conserved regions of a gene or the most highly conserved amino acids in a protein sequence based on the notion that these underpin the most vital functions of the transcript. Recent cross-species comparisons and the enhanced knowledge of splice variation suggest that it is also possible that changes in less-conserved sequences or those that alter only minor splice variants that are spatially or temporally restricted could be quite relevant.

An appreciation of the importance of splice variations points to the critical nature of its regulation. As with many other aspects of the genome, the mechanisms of the process are incompletely understood. It has long been appreciated that there are canonical splice sites that define the boundaries of introns: the 5′ splice site typically has the sequence GT and the 3′ site most often has the sequence AG. However, these are not absolute as they are absent in approximately 2% of known introns. It has been appreciated that regulation of gene splicing is also influenced by sequences nearby or within the gene. These include **exonic splicing enhancers** (ESEs) and **exonic splicing silencers** (ESSs), which are specific sequences contained within exons that regulate splicing proliferation or attenuation. Changes in these sequences can have a profound impact on gene function without altering the amino acid composition of a protein. Synonymous sequence mutations, that is, those that alter the nucleotide sequence but do not change the amino acid sequence, involving these motifs have been shown in some cases to lead to serious developmental disorders.

In addition to the accumulating knowledge on gene splicing, several other aspects of regulating the transcriptome have been well characterized. Individual genes are regulated by transcription factors, which determine the timing and degree of a gene's activity. Transcription factors bind to specific sequences upstream of genes called TFBSs or **response elements** (REs) (Fig. 1.18–9). Most transcription factors consist of a DNA-binding domain that confers some target specificity and an activation domain that confers its regulatory function.

RNA Editing

Another way of regulating and diversifying the transcriptome is RNA editing. RNA editing is one of the most unusual post-transcriptional RNA modifications since it can modify the information content of an organism without changing the underlying DNA in the genome. It is mediated by the ADAR type of enzymes, deaminating adenosine (A) and turning it into inosine (I), which is then recognized as guanosine (G) by both the spliceosome and the ribosome (Fig. 1.18–10). This type of transcriptome diversification contributed to evolutionary changes in many cases instead of gene duplication/mutation or alternative splicing, possibly due to its efficiency and low energy consumption. RNA editing may produce changes in the coding sequence, miRNA binding sites, and may create novel splicing sites. Until recently, only a small number of edited human genes were discovered and most of them have important roles in the CNS. Brain shows the most versatile repertoire of RNA editing events, including AMPA, HTR2C receptors, sodium channels, and calcium channels. Humans have the highest amount of A to I editing as compared to rodents, rhesus macaque, and chimp, which may contribute to human traits.

FIGURE 1.18–9. **Gene Regulation by Transcription Factors**. Once a transcription factor is activated in its activation domain, usually by phosphorylation (the P sites on the TF), the DNA binding domain is then activated and finds the binding site in front of the appropriate gene (TFBS). Once bound, the gene is then activated.

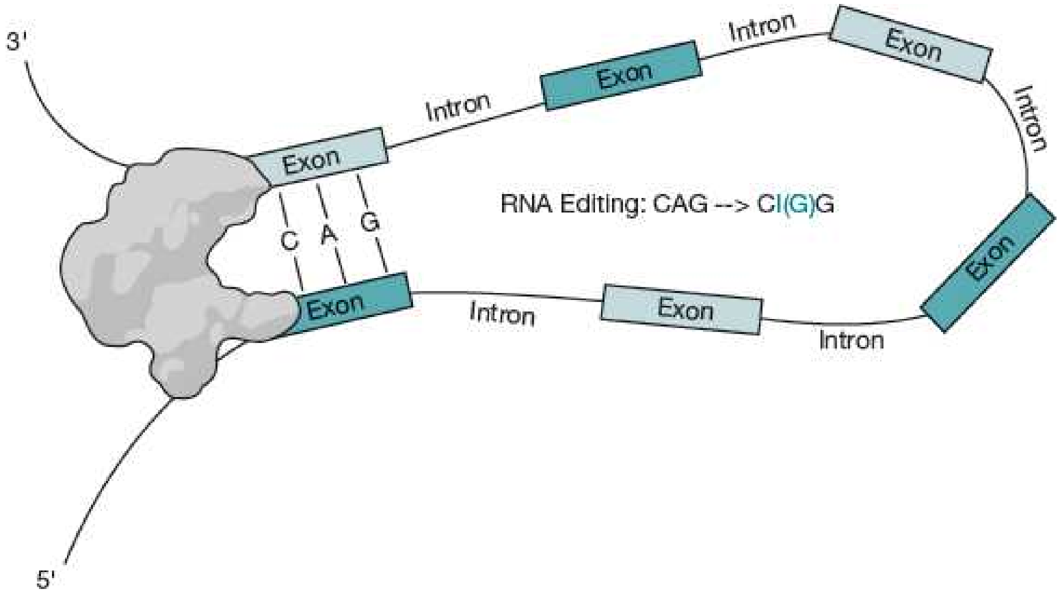

FIGURE 1.18–10. ADAR-Mediated RNA Editing. Double-stranded secondary structure of the RNA (*black line*) enables ADAR binding and deamination of the adenosine in the exon. Deamination derives inosine, which is then acts like guanosine in each interaction that requires Watson-Crick base pairing. Nascent CAG codon showed on the scheme, has been changed to CI(G)G. Created with BioRender.com.

RNA editing occurs almost exclusively on RNAs that form double-stranded secondary structures (dsRNA). Alu elements, due to their specific sequence, are a perfect target for RNA editing. Due to the fact that so many genes involved in brain functions undergo editing (calcium, sodium, potassium channels; GABA, serotonin, glutamate receptors), it is thought that RNA editing is a “fine tuner” of the brain transcriptome.

One of the best known eukaryotic regulatory elements is the TATA box, so named because the sequence TATA is present upstream of a gene. This motif binds a protein complex that allows for the initiation of transcription. The core promoter of individual genes need not contain all elements. Many promoters lack a TATA box and use instead of the functionally analogous **initiator element** (INR). These sequences are related to the number of protein-coding genes in the genome. Determining the number of coding genes in an organism is simply a matter of counting the number of TATA boxes and INRs in promoters that are nearby coding regions. Sequences like the TATA box, which are immediately upstream of a gene, are called **cis-regulatory** (meaning “on the same side”) due to their presence nearby the gene and on the same strand of DNA. Regulatory elements, TFBSs, or gene products that act on a gene from the other strand of DNA or from a distant region of the genome are called **trans-regulatory elements.**

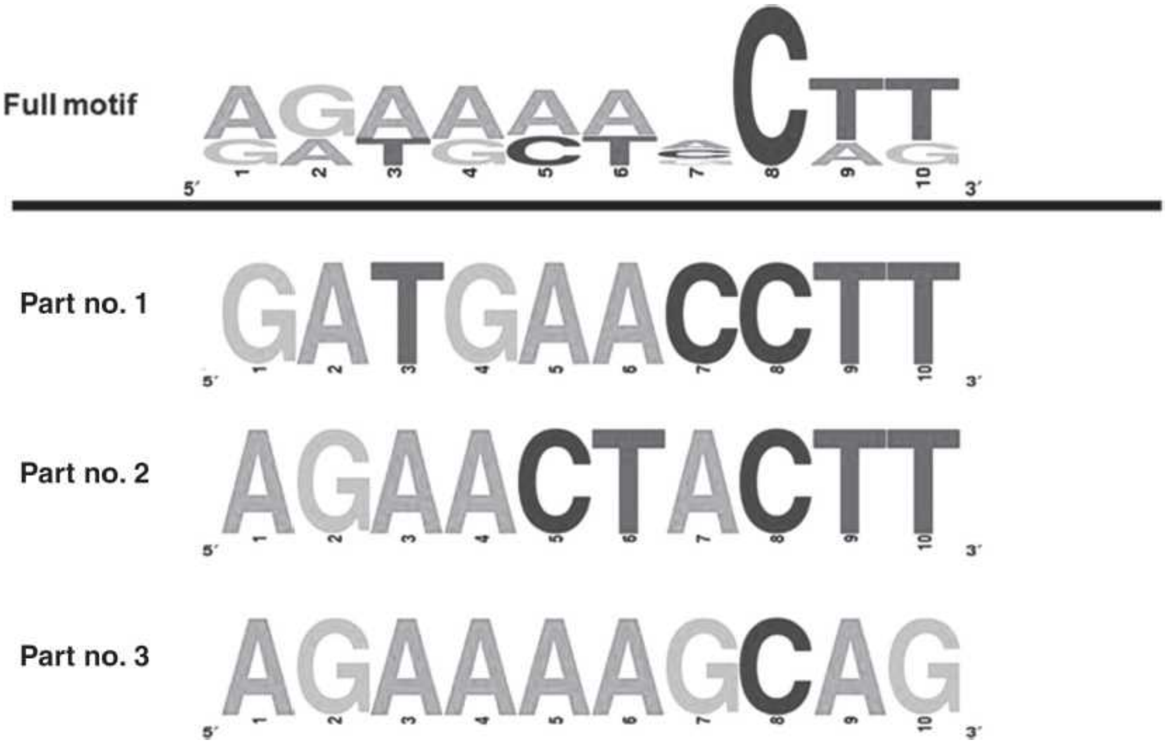

FIGURE 1.18–11. Building a Consensus Sequence for a Transcription Factor Binding Site (TFBS). For any TFBS upstream of many genes, there are often several different functional motifs (**Part #1, #2,** and **#3**) that allow for binding of that specific TF. When merged, these three 10bp sequences create a consensus motif that is degenerate across all nucleotides except for position 8, which is always a cytosine (C).

After the human genome was sequenced, this simple dichotomy of the regulation (cis- and trans) has become more complicated. The most well-understood promoter elements (TATA box and INR) are only present in the promoter regions of 54% of human genes, where promoters are defined within 100 bp in either direction of the **transcriptional start site** (TSS). This suggests that unknown promoter sequences exist to regulate the expression and function of these genes, or much of gene regulation occurs in trans-regulatory elements. A great deal of bioinformatics research is now focused on this very question.

Over 10 other core promoter elements are now predicted, but there is no longer an expectation that these elements will be universally present in all or even most genes. Rather, genes are activated in large simultaneous groups or come in multiple waves of activation, and these coexpressed genes can have a specific set of regulatory elements and modules that restrict expression to a certain time or place. Once a large set of coexpressed genes is found, an examination of the upstream regions of those genes can be performed to ascertain the sequences of the regulatory elements.

For a set of coexpressed genes, it is not typical to identify precisely the same regulatory sequence upstream of all of these transcripts. Due to the flexibility in the TF's DNA binding domain, there is often some sequence variability that is tolerated in gene regulation. Studies of many TFBSs have demonstrated that certain nucleotides in the binding site are critical, while others may vary. Aligning these sites across many genes results in the identification of a consensus sequence or consensus motif for a TFBS (Fig. 1.18–11).

Hundreds of transcription factors have now been studied with a technique called ChIP (Chromatin Immunoprecipitation). The dynamic process of TF binding to regulatory elements is frozen in a moment in time by fixing bound TFs to their cognate regulatory site via a chemical process known as **crosslinking**. Genomic DNA, some of which is now bound by TFs, is then fragmented in a manner that preserves this crosslinking. Using antibodies specific to the known TFs, the bound genomic sequences can be identified, separated from the rest of the genome (the unbound fragments), and then characterized. These bound fragments can be sequenced directly to identify where precisely a specific TF is functioning or may be labeled with different dyes and studied on a microarray. This latter method has become known as **ChIP-chip** (chromatin immunoprecipitation on a chip).

Table 1.18–6.
Effects on Gene Expression of Mono-, Di-, Tri-Methylation, As Well As Acetylation of Lysine for the Most Prominent Histone Markers

	Histone Modification Type			
Histone Marker	Mono-methylation	Di-methylation	Tri-methylation	Acetylation
H3K4	Activation		Activation	
H3K9	Activation	Repression	Repression	Activation
H3K14				Activation
H3K27	Activation	Repression	Repression	Activation
H3K79	Activation	Activation	Activation	
H3K36			Activation	
H4K20	Activation			
H2BK5	Activation		Repression	

These experiments identified a large amount of regulatory complexity in the human genome. The position of the TSS, where the beginning of transcription occurs for a gene, can sometimes be found hundreds of thousands of bases (>100 kb) away from the first exon. Also, many of these regulatory elements, TSSs, and TFBSs for genes are not found beside their respective gene but within introns or within different genes altogether. Sometimes these regulatory elements allow for genes to behave as discrete elements; however, at times, these regulatory motifs allow for a group of genes to merge together. There have been observations of trans-splicing, whereby exons from one gene can combine with exons from a completely different gene, creating chimeric mRNAs and chimera proteins that contain some or all of the elements from the two independent proteins.

Important points in understanding gene regulation include the following: any regulatory element in the genome should not be presumed to be regulating the gene to which it is adjacent; multiple genes may be activated in concert by a single, distant regulatory element; and a single gene is not always a single gene, and can (if needed) merge with some or all of the parts of another gene, even at relatively great distances.

Epigenetics

One additional realm of genetic regulation rests outside of the genomic sequence in the **epigenome**. Epigenetic regulation is any heritable change in the genome that does not change the nucleotide sequence. These changes can occur by either a chemical modification to the DNA known as methylation or by chemical changes to the protein complexes of histones. Histone modifications are far more numerous, with phosphorylation, acetylation, methylation, and ubiquitination modulating the activity of a gene or group of genes by altering DNA-protein complex conformation. This, in turn, has an impact on DNA availability to transcription factors and the recruitment of other molecules that inhibit or enhance gene expression.

Epigenetic marks on DNA consist of methylation of cytosine by specific methyltransferases, thereby deriving 5-methylcytosine (5 mC). 5 mC presence is predominant at regions of the genome that contain neighboring CG tandems—CpG sites. Cytosine methylation of CpG sites located at the gene promoters is a hallmark of transcriptionally silenced genes. DNA methylation is a reversible process and it is thought that the oxidative product of 5 mC, 5-hydroxymethylcytosine (5hmC), is an intermediate in the conversion of 5mC back into cytosine. The presence of 5hmC in germ cells is in favor of this model, as demethylation (resetting of the epigenetic code) is needed for the production of gametes. In addition, 5hmC shows high concentrations in CNS, with novel data suggesting roles of 5hmC in regulating splicing and gene expression in the brain.

Important histone modifications and their effect on the gene expression are presented in Table 1.18–6.

Probably the most reliable signs of gene repression are the presence of H3K27Me3 at gene promoters as well as H3K9Me2/3, which is a strong mark for the presence of heterochromatin at the specific location. In contrast, H3K4Me3 presence at the promoters is a sign of open, actively transcribed chromatin regions, while H3K36Me3 marks during the length of the gene body are also an indication of an actively transcribed region.

Epigenetic programming allows for tissue-specific regulation of gene function and structural and functional specialization throughout the body. Epigenetics also clearly helps explain differences between identical twins who share the same DNA sequence. This nonsequence-based heritable change can also lead to parent-specific effects during fertilization, known as **epigenetic imprinting**. These epigenetic markers are established or “imprinted” in the germline (sperm or egg cells) of the parents and are maintained through mitotic cell divisions in the somatic cells of an organism. Each person, when making eggs or sperm, imprints the epigenetic characteristics of their own sex since they must reprogram the epigenetic signature that was given by their own parents. Prader–Willi and Angelman syndromes are examples of diseases attributable to abnormal epigenetic imprinting.

Epigenetic programming not only regulates single genes but also can alter the behavior of entire chromosomes. X-chromosome inactivation is a normal process that occurs in every human female, in which one X chromosome is genetically silenced in every cell. This allows for dosage compensation, in which the amount of expression of any gene mapped to the X chromosome is essentially the same for males and females (even though males carry only a single X). The choice of which chromosome is active (X_a) and inactive (X_i) within a given cell is typically a random process. However, in some cases, a particular chromosome is more likely to be inactivated, contributing to aspects of Rett syndrome and other X-linked disorders.

Parent of origin effects, defined as the transmission of a risk for disease based on whether an autosome has been transmitted by the mother or father, has been hypothesized to play a role in several common mental disorders. The strongest evidence that this may be the case is the observation that duplications of chromosome 15q inherited from the mother, but not the father, accounts for a small but significant proportion of cases of autism.

Epitranscriptome

Another layer of complexity arises from modifications to the bases in RNA—the epitranscriptome. The current database list 112 forms of RNA modification. One type, methyl-6-Adenosine (m^6A), is found in all kingdoms of organisms. m^6A is enriched within 3′ UTRs and long exons in both mice and humans. Sequences enriched with m^6A are evolutionary conserved. Preliminary analysis showed that m^6A may hinder RNA editing. Also, as m^6A can be demethylated back into adenosine, it may constitute a mechanism for regulating RNA editing. m^6A is implicated in the modulation of the circadian rhythm, perhaps by influencing the trafficking of circadian cycle regulatory genes through the nuclear envelope. In addition, it may play a role in the regulation of translational dynamics for transcripts enriched with m^6A. These functional relationships suggest that post-transcriptional modifications of RNA may modify a transcript's properties and function, generating the so-called epitranscriptome.

PROTEIN REGULATION AND THE PROTEOME

Just as gene expression is regulated at multiple steps, so too can the protein products specified by coding genes (Table 1.18–7). Over 20 known modifications may occur to proteins. These modifications include chemical modification of specific amino acids, exchanging one amino acid for another, attaching other biochemical functional groups, attaching larger molecules (e.g., lipids or carbohydrates), or making structural changes to a protein. Even after a protein is fully formed and biochemically active, it can still be selectively targeted for degradation.

These types of protein modifications play an important role in neurotransmission since most neurotransmitters are shuttled across synaptic membranes and clefts by proteins that have been specially created to accomplish this task. For example, the protein that transports dopamine across synaptic membranes, the DAT, undergoes a range of posttranslational changes that are specific to its needed function in each cell.

Table 1.18–7.
Regulatory Mechanisms across the Genome, Transcriptome, and Proteome

	Regulatory Mechanism
Epigenetic	Allelic exclusion (imprinting one allele of a gene, so only the other is expressed)
	X chromosomal inactivation
	Chromatin re-modeling and chemical alteration (methyl, acetyl, phosphate)
	Short-range cell-to-cell signaling
Pretranscriptional	Binding of tissue-specific transcription factors
	Binding of competing, inhibitory factors
	Hormones binding to response elements in inducible genes
	Use of different transcription start sites, stop sites, and promoters
Post-Transcriptional	Alternative splicing within the same gene
	Tissue-specific RNA editing
	Translational control mechanisms
	Interference and degradation by siRNAs
	Trans-splicing between different genes
Post-Translational	Proteolytic cleavage
	Protein merging into a larger protein complex
	Glycosylation
	Targeted for degradation (ubiquitination)
	Chemical alteration (methyl, acyl, phosphate, or sulfate groups)
	Addition of heavy metals

To measure and understand these changes for each protein, a new discipline, **proteomics**, has emerged that examines each individual protein's various chemical modifications and how those proteins interact with each other to create larger cellular complexes and machinery. Components of the proteome have been the focus of intensive study, for example, all the active and interacting proteins in a synapse are dubbed the **synapse proteome,** and those in the brain are termed the **brain proteome**. All of these protein characterizations and interactions require extensive experimental support, large datasets and overlapping experimental methods.

Mass spectrometry is useful for rapid cataloging of all proteins present within a sample, such as the ~1,000 proteins in the synapse proteome (~1,000 proteins). High-pressure liquid chromatography (HPLC) coupled with mass spectrometry has the capability of resolving the full proteome of the brain. Two-dimensional (2D) electrophoresis is used to study protein interactions. In this approach, proteins are pushed across each other's path in a gel with a change in the migration pattern suggesting a direct interaction. Yeast two-hybrid experiments are another approach to characterizing protein binding partners. In this case, two proteins of interest are cloned into a yeast cell. Each protein is a hybrid, one containing the first protein and the DNA-binding domain of a specific transcription factor, while the other contains the second protein and the activation domain of the same transcription factor. If the two proteins interact, the transcription factor will have both necessary components to activate its target reporter gene, which is typically designed to be easy to assay. More recently, **protein chips**, which are similar to expression microarrays, have been created. These chips place thousands of proteins on a microscope slide and then they are washed over by a single sample, thus detecting every interaction between a protein and the rest of the queried proteome.

All these methods have enabled the discovery and characterization of the proteins made by the ~25,000 genes in the human genome. Current estimates suggest that from this relatively small number of coding genes, as many as 2 million distinct proteins may result. Several groups have emerged to tackle the task of accurately cataloging all of these proteins, including the Human Proteome Initiative (HPI) and the Human Proteome Organization (HUPO).

In summary, the complex machinery that regulates the genome can be thought of as encompassing four levels: pretranscriptional regulation (exemplified by the functioning of transcription factors), post-transcriptional regulation (exemplified by miRNAs and siRNAs), post-translational regulation (exemplified by chemical modification and processing of proteins), and epigenetic regulation.

If the notion of understanding how these processes contribute to the complex functioning of the human brain and how they might contribute to mental illness was not sufficiently daunting, one need only consider the astronomical potential for diversity inherent in the transcriptome and proteome: Though the human genome is only 3 billion letters long, for every gene with more than one exon, the number of possible transcripts increases at the rate of $2^n - 1$. Consequently, a two-exon gene can be spliced into a product containing each one of the two exons, or both combined, totaling three possible transcripts. Similarly, a three-exon gene can be spliced into one of the three exons, or four other combinations (1–2, 2–3, 1–3, 1–2–3), totaling seven, and so on. When this formula is applied to the gene with the most exons in the human genome (*titin,* with 234 exons), one can see that this one coding unit could theoretically combine into 2.76×10^{70} different transcripts. In addition, given about 2 million proteins in the human proteome, there exist 4 trillion possible protein–protein interactions. In total, this becomes about 7.0×10^{82} possible gene products and subsequent interactions to examine. As a comparison, the number of atoms in the universe is estimated to be around 4.0×10^{80}. Though these numbers are theoretical approximations, they illustrate the vast potential complexity of the human genome and the need for sophisticated methods to understand it.

PHARMACOGENOMICS IN NEUROPSYCHIATRIC DISORDERS

Pharmacogenomics is the effort to characterize gene variants that influence the response to medications with the long-term goal of optimizing the treatment of individual patients. Pharmacogenomic tests are already established in several different fields of clinical practice including oncology, infectious disease, anesthesiology, gastroenterology, cardiology, gynecology, rheumatology, neurology, and psychiatry. The Federal Drug Administration (FDA) maintains a table of pharmacogenomic biomarkers in drug labeling that covers over 350 drug-gene combinations across over 75 genes.

In psychiatry, pharmacogenomics has had its greatest impact through characterizing gene variants coding for P450 microsomal enzymes that influence the rate of metabolism of psychotropic medications. These tests have been applied clinically as an alternative to measuring drug–blood levels in order to identify whether a lack of clinical response could be attributed to rapid drug clearance, necessitating treatment with higher medication doses. They might identify slow metabolizers, who might be more suspectable to medication side effects. To date, pharmacogenomics studies related to the pharmacodynamics actions of psychotropic medications do not yet have sufficient validity or explanatory power for routine clinical use but may become more common in the future.

THE BRAIN AS A SYSTEM

The field of **systems biology** focuses on the emergent properties of biologic systems. There is increasing interest in developing sophisticated computational approaches that enable scientists to evaluate the interplay of genome, transcriptome, proteome, and other emergent properties of the brain, such as behavior.

Systems biology is a particularly powerful approach to extraordinarily large datasets generated by large-scale international collaborations aiming for a complete functional annotation of the human genome, transcriptome, and proteome. These efforts have been made possible by technologic advances that have allowed for the accumulation of very large datasets that encompass all of the types discussed in this chapter: regulatory sequences, the transcription factors that bind them, the expressed genes (coding and noncoding), their subsequent modifications by other enzymes, the final protein product(s), and the interaction of that protein with any other protein (**protein–protein interactions** [PPIs]). These data are derived from three sources: (1) computational predictions of transcriptional activity, splicing potential, or protein interactions; (2) experimentally based observations extracted from published scientific reports and databases; and (3) the use of algorithms that scan all of the world's published scientific literature and report any interaction with a specific gene or protein of interest (**text mining**). In addition, large databases of protein sequences have been compiled and curated, such as UniProt.

Over the past several years, major advances in bioinformatics and computational biology have allowed an entire biochemical or neurologic pathway to be modeled and a change in one segment of the pathway (from a mutated exon to a drop in synaptic plasticity) to be traced to every other possibly interacting biologic entity. This technique—known as **pathway analysis**—creates predictions for expected changes to other genes or proteins in the same pathway. Already, several such tools are publicly available online, including Ingenuity, DAVID, KEGG, and Interactome, an effort at Cold Spring Harbor Laboratory to build a working model for every interaction (gene–gene, gene–protein, protein–protein) that exists in the human body.

An extraordinary public resource has recently been created that catalogs region-specific expression analyses in the mouse brain, known as Allen Brain Atlas. This database currently contains a three-dimensional rendering of almost every gene's expression pattern. The mouse model serves as a good proxy for understanding region-specific brain expression in humans, and as a result of this comprehensive resource, essentially any gene of interest can be analyzed with all the others, for instance, to investigate the spatial and temporal correlation among groups of genes or across the entire genome. These and other resources are publicly available on the World Wide Web (Table 1.18–8).

FUTURE PROSPECTS

The brain is the most complex organ in the human body and perhaps the most complex structure known to humanity. Scientists have never before had so many tools and technologies to bring to bear to study the brain. These approaches create an unparalleled ability to gather and merge information about a biologic system, but the exact methods by which clinicians and researchers can merge patient data and abstract predictions is a work in progress.

Though sequencing, microarrays, and cloning have been indispensable techniques, they are already being eclipsed by newer, faster, and more high-throughput technologies. All of the methods currently used for analyzing and understanding an individual patient's genome are restricted to specific regions, but this is only because of the limitations of the current technology. Once each patient's genome can be sequenced cheaply and quickly, another revolution in the postgenomics era will begin. Instead of searching for mutations or structural abnormalities only in genes or places where a change is suspected, every small- and large-scale genetic variation will be detected for every location in the genome.

Clearly, the availability of a complete picture of each patient's DNA will vastly empower efforts to identify that proportion of genetic variation that contributes to mental disorders, influences therapeutic response, and mediates the results of environmental stressors. There is no doubt that recent discoveries have already heralded the first steps toward the development of personalized genomic medicine. The <$1,000 genome is a major step toward realizing this potential. The tremendous payoff from molecular genetics will greatly enhance the understanding of DNA sequence and structural changes; these important first steps will be critical in dissecting the molecular neurobiology of mental disorders and in developing novel therapeutics.

1.19 Gene Mapping Investigations of Psychiatric Disorders

SCOTT C. FEARS, M.D., PH.D.

The field of genetics essentially started from the rediscovery of Gregor Mendel's basic concepts at the turn of the 20th century and has matured into an essential cornerstone not only of the biologic sciences but also of all of medicine. The discovery of the basic structure and properties of DNA in the middle of the century led to an exponential acceleration in the current understanding of all aspects of the life sciences, including deciphering the complete sequence of the human genome and those of myriad other species. Massive databases of such sequences now provide 21st-century biologists with the task of decoding the functional significance of all this information. In particular, attention has turned to determining how sequence variations contribute to the phenotypic variation between species and between individuals within a species; in humans, it is hoped that discoveries about the relationship between genotypes and phenotypes will revolutionize the understanding of why and how some individuals but not others develop common diseases. This hope is particularly strong for psychiatry, as current knowledge of the pathogenic mechanisms of psychiatric disease remains sparse.

With a few notable exceptions, the field of psychiatric genetics struggled for many decades to identify and confirm genetic linkages and associations for mental health disorders. Recently, advances in high-throughput sequencing and organization of well-powered sample sizes through large-scale collaborations have started to deliver long-awaited results. Prior to 2010, no confirmed genetic variants influencing risk for schizophrenia had been discovered, but since then, over 250 risk variants have been identified and replicated in rigorously designed gene-mapping investigations. Similar success is beginning to emerge for other mental health disorders, including Alzheimer disease, autism, bipolar disorder, and depression. The growing list of genes associated with psychiatric disorders promises to redefine the current understanding of the biologic basis of mental disorders. The emerging catalog of gene-mapping findings does not support the popular theories of the last 50 years that have focused on alterations of monoaminergic systems as fundamental to the development of mood and psychotic disorders. Rather, genetic findings indicate that the etiologies of psychiatric disorders are linked to a complex network of partially overlapping cellular processes, including neurodevelopment, synapse functioning, ion regulation, immunity/inflammation, and intracellular signaling. Further, genetic analyses are confirming what has long been suspected; that there is substantial heterogeneity within categorically defined diagnostic groups and significant genetic overlap between different categories of disorders. In contrast to traditional genetic approaches that aimed to identify one or a few rare genetic variants with a large impact on the development of disease (i.e., Mendelian genes), much of the recent success has been gained by focusing on the identification of common genetic variants, each of which contributes only a small increase in disease risk. There are still major issues to be resolved, for example, deciphering the relative contributions of common versus rare genetic mutations; however, as a whole, the field is finally able to begin building an empirically rigorous foundation upon which many of the deep unknowns regarding the pathophysiology of mental disorders can begin to take shape.

Genetic mapping studies aim to identify the specific genes and sequence variations implicated in heritable diseases based on their chromosomal location. These studies are carried out by investigating affected individuals and their families through two approaches: linkage and association (Figs. 1.19–1 and 1.19–2). The two approaches have distinct advantages and are discussed in more detail below. Briefly, linkage methods are implemented within samples composed of related family members and are well suited for mapping genes with large effects on disease traits (high penetrance), whereas association methods are usually implemented in outbred populations (nonfamily members) and are designed to identify genes with small effects on the disease (low penetrance). It is now straightforward to use linkage methods to genetically map large-effect Mendelian traits, which are traits for which a specific genotype at one particular locus is both necessary and sufficient to cause the trait. Psychiatric diseases, however, do not follow simple Mendelian inheritance patterns but rather are examples of etiologically complex traits. Etiologic complexity may be due to many factors, including the following:

1. *Incomplete penetrance* in which the phenotype is expressed in only some of the individuals carrying the disease-related genotype.
2. *The presence of phenocopies*, which are forms of the disease that are not caused by genetic factors.
3. *Locus heterogeneity,* which occurs when different genes are associated with the same disease in different families or populations.

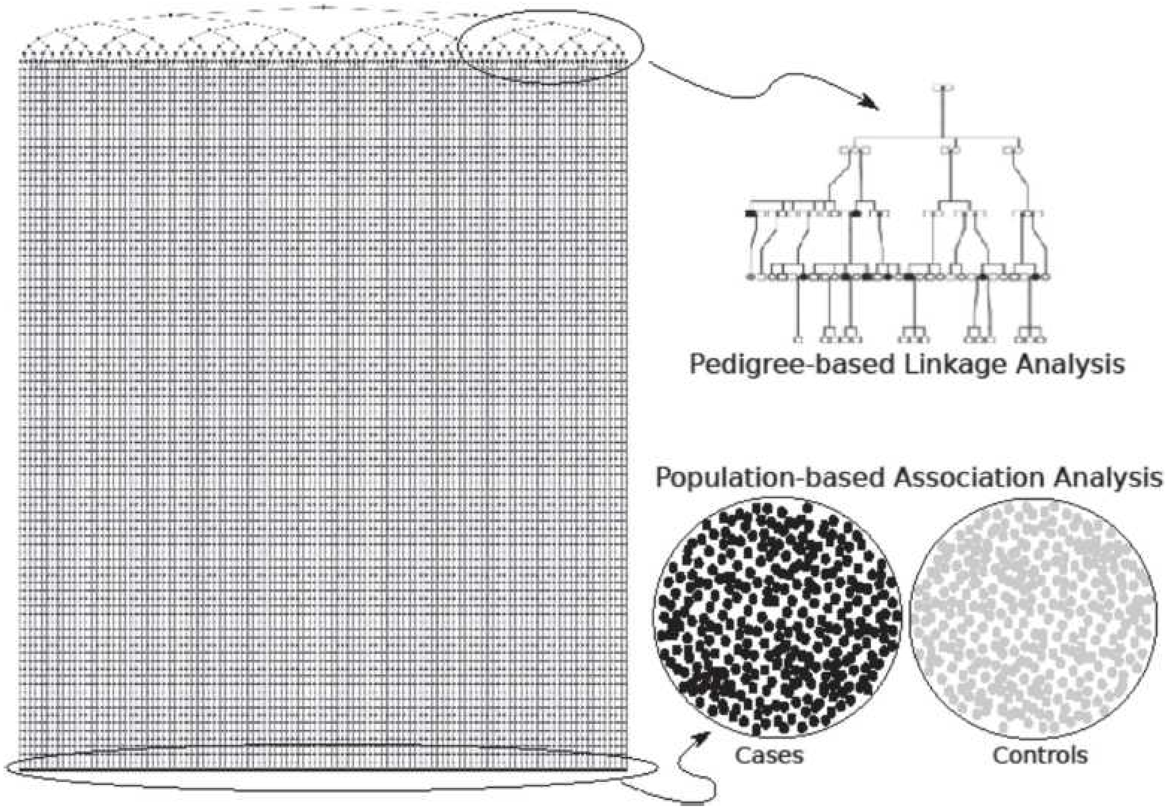
4. *Polygenic inheritance* in which risk for disease increases only if susceptibility variants at multiple genes act in concert.

Mapping a complex disorder involves several component steps, including the definition of the phenotype to be studied, epidemiologic studies to determine the evidence for genetic transmission of that phenotype, choice of an informative study population, and determination of the appropriate experimental and statistical approaches. This chapter will start with an overview of the epidemiologic methods used to identify genetically influenced traits and disorders and then describe the various approaches that are used to map the specific genetic variants associated with complex traits. The final part of this chapter will review the progress to date in mapping genes for several key psychiatric disorders.

EPIDEMIOLOGY

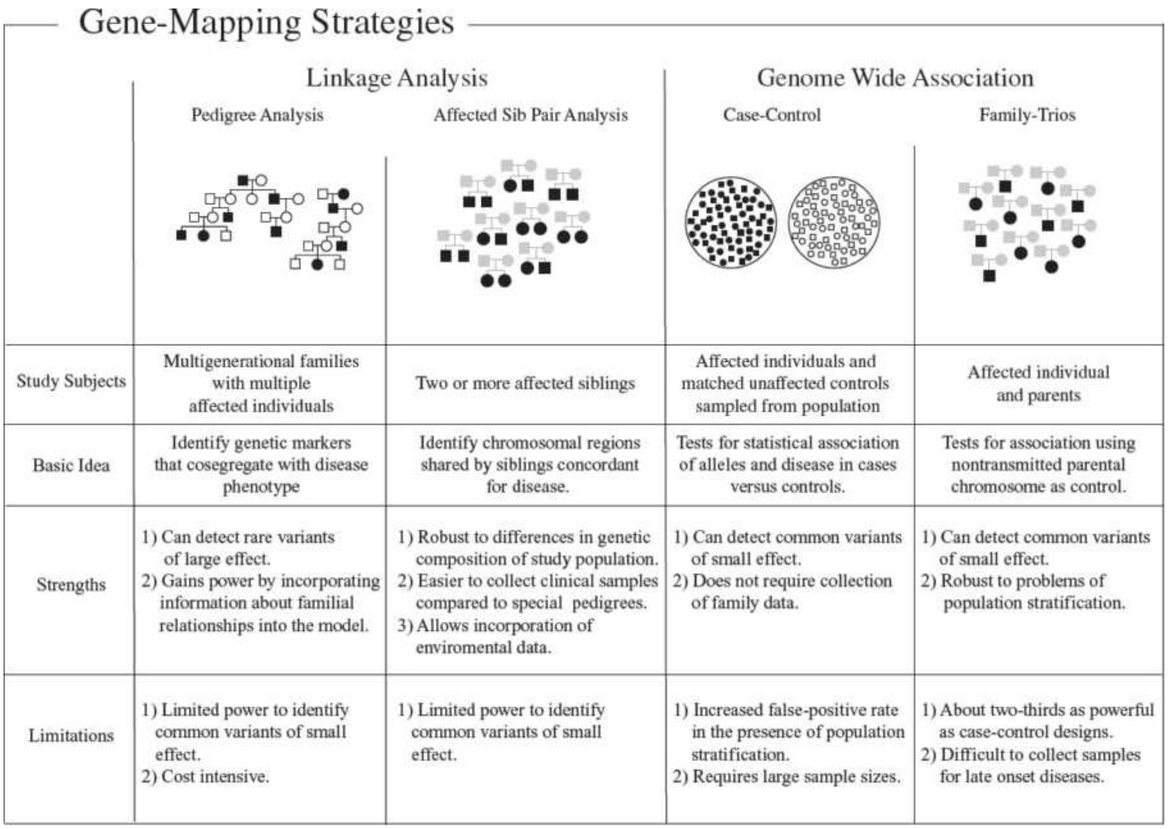
Genetic Epidemiologic Approaches

Prior to mapping specific genes, genetic epidemiologic investigations provide quantitative evidence regarding the degree to which a given trait aggregates in families and, furthermore, can suggest to what degree such aggregation reflects a genetic contribution to the etiology of the trait. Family studies compare the aggregation of disease among the relatives of affected individuals compared to control samples. Because these studies do not differentiate between genetic and environmental contributions to such familial aggregation, they provide only indirect evidence regarding the heritability of a trait. Often these studies measure the familial relative risk (λ), defined as the rate of occurrence of a disease among specified categories of relatives of an affected individual compared to the rate of occurrence of the disease for the general population. A relative risk of >1 suggests a genetic etiology and the magnitude of the measure gives an estimate of the genetic contribution to the disease. Relative risks can be calculated for sibling pairs, parent–offspring pairs, and various other types of family relationships. Likely modes of transmission can be assessed by comparing the degree of relative risk for each type of relationship. Multiple family studies have been carried out for many of the major psychiatric disorders, including major depression, bipolar disorder, schizophrenia, and obsessive compulsive disorder (OCD). While these studies have consistently reported familial aggregation for all of these disorders, the degree of such aggregation has varied substantially across studies, largely reflecting differences in phenotype definition and how study samples were ascertained and assessed (see "The Phenotype" section below for more details).



Pedigree-based Linkage Analysis
Population-based Association Analysis
Cases
Controls

FIGURE 1.19–1. There are two basic approaches to mapping genes: linkage (**top right**) and associations (**bottom right**). All gene-mapping approaches are based on identifying genetic mutations that are inherited identical by descent (IBD). The left side of the figure shows a schematic representation of a founder at the top center of the figure and all of their descendants inheriting the risk allele IBD. Linkage analysis (**top right**) samples multiple generations of individuals within a family and aims to identify cosegregation of genetic markers of known location with the disease trait in affected individuals. Linkage analysis is optimal for detecting genes of large effect in family members relatively close to the origination of the genetic mutation (before natural selection results in the removal of the mutation). In contrast, association analysis (**bottom right**) samples generations very distant from the founder and attempts to identify enrichment of specific genetic variants within affected individuals compared to controls. Genetic mutations that have survived for many generations tend to confer a relatively small increase in disease risk (which is generally expected to lower fitness), which is reflected in the small effect sizes of variants identified by association studies.



Gene-Mapping Strategies

	Linkage Analysis		Genome Wide Association	
	Pedigree Analysis	Affected Sib Pair Analysis	Case-Control	Family-Trios
Study Subjects	Multigenerational families with multiple affected individuals	Two or more affected siblings	Affected individuals and matched unaffected controls sampled from population	Affected individual and parents
Basic Idea	Identify genetic markers that cosegregate with disease phenotype	Identify chromosomal regions shared by siblings concordant for disease.	Tests for statistical association of alleles and disease in cases versus controls.	Tests for association using nontransmitted parental chromosome as control.
Strengths	1) Can detect rare variants of large effect. 2) Gains power by incorporating information about familial relationships into the model.	1) Robust to differences in genetic composition of study population. 2) Easier to collect clinical samples compared to special pedigrees. 3) Allows incorporation of enviromental data.	1) Can detect common variants of small effect. 2) Does not require collection of family data.	1) Can detect common variants of small effect. 2) Robust to problems of population stratification.
Limitations	1) Limited power to identify common variants of small effect. 2) Cost intensive.	1) Limited power to identify common variants of small effect.	1) Increased false-positive rate in the presence of population stratification. 2) Requires large sample sizes.	1) About two-thirds as powerful as case-control designs. 2) Difficult to collect samples for late onset diseases.

FIGURE 1.19–2. Genetic mapping approaches can be divided into those that rely on linkage analysis and those that rely on association analysis. Linkage studies can be further categorized as either focused on investigation of pedigrees or focused on investigation of sib pairs. Association studies can be categorized as either case control or family based. Some of the key features as well as advantages and disadvantages of these different approaches are shown in the figure.

Twin studies examine the concordance rates of a particular disorder (the percentage of twin pairs where both twins have the disorder) in monozygotic (MZ) and dizygotic (DZ) twins. For a disorder that is strictly determined by genetic factors, the concordance rate should be 100% in MZ twin pairs (who share 100% of their genetic material) and 25% or 50% in DZ twin pairs (who are no more closely related than any siblings), depending on whether the disease is recessive or dominant, respectively. For a disorder where genetic factors play a role in disease causation but are not the exclusive cause of disease, the concordance rates should be greater for MZ twins than those for DZ twins. The higher the degree of concordance of MZ twins, the higher the trait heritability or the evidence for a genetic contribution to disease risk. When genetic factors do not play a role, the concordance rates should not differ between the twin pairs, under the simplifying assumption that the environment for MZ twin pairs is no more similar than that for DZ twin pairs. The twin studies that have been conducted for traits such as autism, bipolar disorder, and schizophrenia have consistently suggested high heritability and have therefore spurred efforts to genetically map loci for each of these conditions. Different twin studies may, however, generate varying estimates for the heritability of any given disorder. When evaluating the results of twin studies, it is therefore important to scrutinize how the phenotype was ascertained because, as with family studies, the different heritability estimates are likely due to differences in the mode of assessing and defining phenotypes. For example, early twin studies of psychiatric disorders often relied for their phenotypes on unstructured interviews by a single clinician. In contrast, modern studies generally utilize standardized assessments and review of diagnostic material by a panel of expert clinicians. Similarly, part of the apparent variation in heritability between different twin studies can be attributed to the fact that some studies employ narrow definitions of affectedness for a given phenotype, while other studies employ broader phenotype definitions (e.g., considering a twin with major depressive disorder (MDD) to be phenotypically concordant with a cotwin diagnosed with bipolar disorder). Because of such differences in approach across studies, it is usually prudent to view such investigations as providing a rough estimate of the genetic contribution to trait variability. Nevertheless, even such estimates are useful in deciding which traits are likely to be mappable.

BASIC CONCEPTS OF GENE MAPPING

Introduction

Once genetic epidemiologic studies of particular phenotypes have suggested that these phenotypes are heritable, genetic mapping methods are implemented to identify the specific genetic variants that contribute to the risk of the disorder. The fundamental essence of gene mapping is to identify the order of genetic loci along a chromosome and determine the distance between them. Prior to the discovery of DNA as the molecular basis of genes, mapping studies typically sought to identify patterns of transmission in families between disease phenotypes and enzymatic or physiologic phenotypes like the ABO blood group to establish linkage. Current mapping studies start with an extensive set of DNA polymorphisms of known location and methodically traverse through the genome to identify the location of an unknown disease locus. There are two basic approaches to mapping genes: linkage and association (Figs. 1.19–1 and 1.19–2). Linkage analysis uses information from family members to identify loci that are transmitted together across generations more often than would be expected by chance. In contrast, association designs do not make explicit use of family information and aim to identify nonrandom co-occurrence of genetic variants of known location with disease traits. Linkage analysis is ideally suited to identify rare genetic variants that have a relatively large effect on the disease trait, whereas population-based association methods are designed to identify common genetic variants that have modest effects on the disease trait. The following sections will provide an overview of the basic concepts of gene mapping, starting with the phenomena of recombination and linkage upon which all mapping methods are based.

Recombination and Linkage

All genetic mapping methods aim to identify disease-associated variants based on their chromosomal position and the principle of genetic linkage. All cells contain two copies of each chromosome (called homologs): one inherited from the mother and one inherited from the father. During meiosis, the parental homologs cross over or recombine, creating unique new chromosomes that are then passed on to the progeny. Genes that are physically close to one another on a contiguous strand of DNA within a single chromosome are genetically linked (tend to be inherited together), and those that are farther apart or are on different chromosomes are genetically unlinked. Genes that are unlinked will recombine at random (i.e., there is a 50% chance of recombination with each meiosis). Genetic loci that are linked will recombine less frequently than expected by random segregation, with the degree of recombination proportional to the physical distance between them (i.e., the closer the physical distance, the more frequently loci will be transmitted together). The principle of linkage underlies the use of genetic markers, segments of DNA of known chromosomal location that contain variations or polymorphisms (described in more detail below). Strategies to map disease genes are based on identifying genetic marker alleles that are shared—to a greater extent than expected by chance—by affected individuals. It is presumed that such sharing reflects linkage between a disease locus and a marker locus, that is, the alleles at both loci are inherited “identical by descent” (IBD) from a common ancestor, and, furthermore, that this linkage pinpoints the chromosomal site of the disease locus.

The evidence for linkage between two loci depends on the recombination frequency between them. Recombination frequency is measured by the recombination fraction (Θ), which can be empirically determined by observing how often two traits or genetic loci are transmitted together and can be used to estimate the genetic distance between the two loci (1% recombination equals 1 centimorgan [cM] in genetic distance and, on average, covers a physical distance of about 1 megabase [mB] of DNA). A recombination fraction of 0.5% or 50% indicates that two loci are not linked but rather that they are segregating independently, whereas lower recombination fractions indicate that loci are sited near enough to each other that there is a tendency to be transmitted together: the lower the recombination fraction, the smaller the distance between the loci. In practice, a logarithm of the odds ratio (LOD) score is estimated from empirically derived observations to determine the likelihood that two loci are linked at any particular genetic distance. The central statistic for a LOD score is an odds ratio which is calculated by dividing the likelihood of acquiring the observed data if the loci are linked at a given recombination fraction by the likelihood of acquiring the data if the loci are unlinked ($\Theta = 0.5$). The log (base 10) of this odds ratio is the LOD score. A LOD score of 3.3 translates to an approximately 1,000-to-1 odds that two loci are linked rather than segregating independently. A LOD score can be obtained for various values of the recombination fraction, from $\Theta = 0$ (completely linked) to $\Theta = 0.5$ (unlinked). The value of Θ that gives the largest LOD score is considered to be the best estimate of the recombination fraction between the disease locus and the marker locus. This recombination fraction can then be converted into a genetic map distance between the two loci. In practice, large families and/or samples including a large number of smaller families are needed to estimate accurate LOD scores.

Linkage Disequilibrium

Linkage disequilibrium (LD) is a phenomenon that is analogous to family-based measures of linkage but is used to evaluate the genetic distance between loci in populations rather than in families. When alleles at two loci occur together in the population more often than would be expected, given the allele frequencies at the two loci, those alleles are said to be in LD. When strong LD is observed between two loci, it usually indicates that the two loci are sited in very close physical proximity to one another on a given chromosome and is useful in mapping disease susceptibility loci because one locus can be used to predict the presence of another locus. This predictability is important because current gene-mapping strategies are able to sample only a subset of the estimated 10 million common human polymorphisms. Because of the existence of LD, one can use data from a subset of genotyped polymorphisms to infer genotypes at nearby loci. Clusters of alleles that are in LD and inherited as a single unit are termed haplotypes. Thus, LD mapping "consolidates" genomic information by identifying haplotypes in populations that can then be used to infer IBD sharing among unrelated individuals (a central tenet of gene mapping using the association methods described below).

There are several methods to measure the extent of LD. One of the most commonly used measures of LD is r^2, a measure of the difference between observed and expected haplotype probabilities. A large r^2 value indicates that the observed frequency of association between two alleles is greater than that expected by chance; that is, the alleles are in LD. LD studies have traditionally been used to complement traditional pedigree analyses, for example, to hone in on a locus that has been mapped by linkage analysis. However, LD-based association analysis has become the method of choice for whole-genome screens, particularly for diseases where traditional linkage studies have been unsuccessful. These studies have one great advantage over a traditional family analysis; because affected individuals are chosen from an entire population rather than from one or a few pedigrees, the number of potential subjects is limited only by the size of the population and the frequency of the disease. Maximizing the potential number of affected individuals that can be included in the analysis is extremely important for disorders where genetic heterogeneity or incomplete penetrance is likely to be factors.

Genetic Markers

Mapping studies, regardless of their type, depend on the availability of genetic markers. The most widely used markers are single nucleotide polymorphisms (SNPs) and microsatellite markers (also called simple tandem repeats [STRs], or simple sequence length polymorphisms [SSLPs]). SSLPs are stretches of variable numbers of repeated nucleotides two to four base pairs in length. These markers are highly polymorphic, as the number of repeat units at any given STR locus varies substantially between individuals. SNPs, as the name implies, are single base pair changes at a specific nucleotide; they are the most common form of sequence variation in the genome. SNPs are widely used for genetic mapping studies because they are distributed so widely across the genome and because they can be assessed in a high-throughput, automated fashion. Other forms of genetic variation that have been investigated for use as genetic markers include small insertion or deletion polymorphisms, termed indels, that generally range between 1 and 30 base pairs, and copy number variations (CNVs), which can refer to either deletions or duplications. Recent genome-wide surveys have revealed that CNVs are common and can range in length from several base pairs to several million base pairs. CNVs may contribute to chromosomal recombination and rearrangements, thereby playing an important role in generating genetic diversity, and also, as many of these variants are sizable, it is hypothesized that they may significantly influence the expression of genes that encompass or are adjacent to the variant.

MAPPING STRATEGIES

The genetic variants that contribute to disease susceptibility can be roughly categorized into those that are highly penetrant and those that are of low penetrance. High-penetrance variants, by definition, have a large effect on phenotype and therefore identifying these variants usually provides fundamental insights into the biologic pathways contributing to the disease. Because individuals carrying high-penetrance variants have a high probability of expressing a disease phenotype, such variants tend to be rare and segregate in families and are generally most powerfully mapped using pedigree-based linkage mapping approaches (Figs. 1.19–1 and 1.19–2). In contrast, low-penetrance variants have a relatively weak effect on phenotype, and therefore, identifying individual low-penetrance variants may, at least initially, provide relatively little new biologic knowledge. However, because of their small effects, such variants are typically common in the population, and therefore identifying them may add to the understanding of disease risk in the population as a whole. It is not expected that these variants will segregate strongly with the disease phenotype in pedigrees; efforts to identify them focus on population samples and require large sample sizes because of their relatively small effect on the phenotype. In the following sections, two common family-based linkage strategies (pedigree and sib pair analyses) are described, followed by an overview of population and family-based association analyses.

Pedigree Analysis

The primary goal of pedigree analysis is to determine if two or more genetic loci (i.e., a genetic marker of known location and the unknown disease loci) are cosegregating within a pedigree. A typical pedigree analysis, which is conducted in multigenerational families, consists of scanning the genome or a portion of the genome with a series of markers in one or more affected pedigrees, calculating a LOD score between the marker and the disease phenotype at each marker position, and thereby identifying the chromosomal regions linked to the disease trait.

Following the successful application of pedigree analysis to map Mendelian disorders such as Huntington disease, many investigators adopted this strategy for mapping psychiatric disease genes with, at best, mixed success. In the late 1980s and mid-1990s, several pedigree-based studies reported the mapping of susceptibility loci for Alzheimer disease, bipolar disorder, and schizophrenia. Although the linkage findings for three Alzheimer disease loci were relatively quickly replicated, the findings reported for bipolar disorder and schizophrenia were ultimately determined to have been false positives. While a number of different explanations have been proposed for the failure of pedigree-based approaches to map psychiatric loci, most investigators now recognize that these studies were generally drastically underpowered considering the apparent etiologic complexity of psychiatric disorders.

Pedigree analysis in psychiatry has increasingly turned toward an application for which it is more appropriately powered, namely, the mapping of quantitative trait loci (QTLs). QTLs are defined as genetic loci that contribute to the variation in continuously varying traits as opposed to categorical traits such as disease diagnoses. QTLs are typically loci of small effects that only contribute to a portion of the observed variance of a trait in the population. It is now generally accepted that using analytical methods developed in the late 1990s, it may be possible to use pedigree studies to map a wide range of quantitative traits that are relevant for understanding psychiatric disorders, including brain and behavioral phenotypes. Several such studies are now being undertaken, typically with multiple phenotypes being assessed in each individual in the pedigree. A more detailed discussion of quantitative phenotypes is provided after the overview of population-based mapping strategies.

Sib Pair Analysis

Affected sib pair (ASP) analysis, first proposed in 1935, became widely used during the 1990s for the genetic mapping of complex traits, including many psychiatric disorders. Sib pair analysis examines the frequency with which sibling pairs concordant for a trait share a particular region of the genome compared with the frequency that is expected under random segregation. Sib pair analysis is based on the fact that siblings share approximately 50% of their genomes IBD. Therefore, if a set of unrelated sib pairs affected with a given trait shares a particular area of the genome at a frequency significantly greater than 50% (the proportion of sharing expected under conditions of random segregation), then that area of the genome is likely to be linked to the trait in question. In this method, siblings are genotyped and population frequencies and parental genotypes are used to estimate the proportion of genes shared IBD at each site for each sib pair. The linkage analysis then compares those pairs concordant and discordant for each locus.

Like pedigree studies, ASP studies have more power to locate genes of large effect than genes of small effect. This limitation can be partially addressed by a two-tiered design that incorporates additional markers or family members after an initial linkage study in affected siblings or by increased sample size. It generally requires less effort to identify and assess even large sets of affected sibs than to identify and assess all members of extended pedigrees, particularly when investigators can take advantage of data repositories that include samples and phenotype data from sib pairs ascertained from multiple sites. For example, the U.S. National Institutes of Mental Health (NIMH) maintains such repositories for sizable collections of sib pairs affected with schizophrenia, bipolar disorder, autism, and Alzheimer disease. An additional benefit of the ASP design is that it allows for the incorporation of epidemiologic information, permitting the simultaneous examination of environmental and gene–environment interactions.

Association Studies

In the past few decades, there has been increasing acceptance of the notion that association studies are more powerful than linkage approaches for mapping the loci of relatively small effect that are thought to underlie much of the risk for complex disorders. While linkage studies attempt to find cosegregation of a genetic marker and a disease locus within families, association studies examine whether a particular allele occurs more frequently than expected in affected individuals within a population. As noted previously in this chapter, mapping genes using association studies is based on the idea that certain alleles at markers closely surrounding a disease gene will be in LD with the gene; that is, these alleles will be carried in affected individuals more often than expected by random segregation, because they are inherited IBD.

There are two common approaches to association studies (Fig. 1.19–2), case-control designs and family-based designs, which typically investigate trios (mother, father, and an affected offspring). In a case-control study, allele frequencies are compared between a group of unrelated affected individuals and a matched control sample. This design is generally more powerful than a family-based design, as large samples of cases and controls are easier to collect than trios and are less expensive as they require the genotyping of fewer individuals. Case-control samples may be the only practical design for traits with a late age of onset (such as Alzheimer disease) for which parents of affected individuals are typically unavailable. The main drawback of the case-control approach is the potential problem of population stratification; if the cases and controls are not carefully matched, then they may display substantial differences in allele frequency that reflect population differences rather than associations to the disease.

Family-based association studies are designed to ameliorate the problem of population stratification. In this design, the nontransmitted chromosomes (the copy of each chromosome that is not passed from parent to child) are used as control chromosomes, and differences between allele frequencies in the transmitted and nontransmitted chromosomes are examined, eliminating the problem of stratification as the comparison group is by definition genetically similar to the case group. Although more robust to population stratification than a case-control study, family-based studies are only about two-thirds as powerful using the same number of affected individuals.

In the past, it was not practical to conduct association studies on a genome-wide basis, as relatively few SNPs were available. Therefore, association studies focused on testing one or a few markers in candidate genes chosen on the basis of their hypothesized function in relation to a given disease. However, as a result of international efforts that have identified millions of SNPs distributed relatively evenly across the genome and the development of technology for genotyping them relatively inexpensively, genome-wide association (GWA) studies are now a common reality, and over the past decade, such studies are starting to generate an extensive catalog of common variants contributing to common diseases. Early GWA studies in psychiatric disorders failed to identify any risk variants; however, recent studies have made use of very large samples, providing further support for the hypothesis that underpowered study designs bear much of the responsibility for the disappointing results of previous psychiatric genetic investigations.

Statistical Considerations

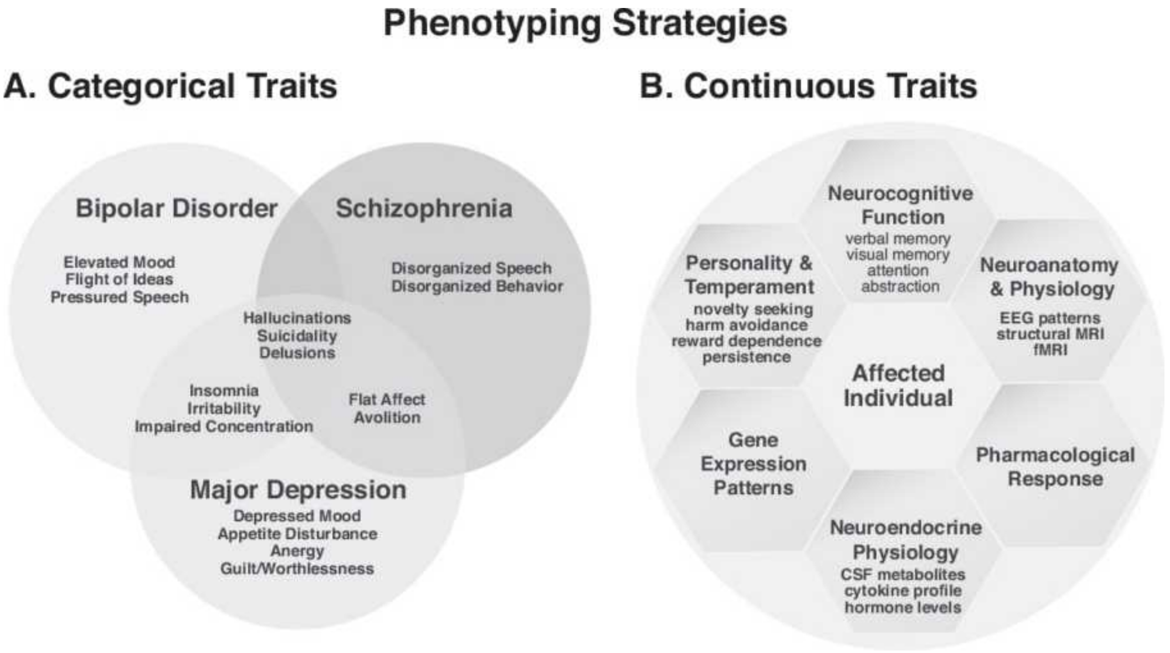
Scientists in other biomedical research fields are often surprised by the apparently high level of statistical evidence that geneticists require to consider a linkage or association result to be significant. Most simply, this requirement can be thought of in terms of the very low expectation that any two loci selected from the genome are either linked or associated with one another. The likelihood that any two given loci are linked (i.e., the prior probability of linkage) is expected to be approximately 1:50, based on the genetic length of the genome. To compensate for this low prior probability of linkage and bring the posterior (or overall) probability of linkage to about 1:20, which corresponds to the commonly accepted significance level of $P = .05$, a conditional probability of 1,000:1 odds in favor of linkage is required, corresponding to the traditionally accepted LOD score threshold of 3. This generally provides an acceptable false-positive rate (Fig. 1.19–3), but some false-positive findings have exceeded even this threshold.

It is important to note that the accepted significance threshold for linkage studies is relatively low compared to the much more stringent thresholds required for current GWA studies. The reason for more stringent thresholds is that the expectation that any two loci in the genome are associated with one another is even lower than that of their being in linkage, and typically a P value of less than about 10^{-7} is considered to indicate “genome-wide significance.” Another very important consequence of the expectation that any two loci are unlikely to be associated with each other is that candidate gene studies should be held to the same stringent standards used in genome-wide studies. A rigorous candidate gene study would use the agnostic assumption that all loci have the same low prior probability of association and would discount the high prior probability that some investigators assign to variants in candidate genes chosen on the basis of their hypothesized functional relevance to a given disorder or trait. GWA studies are now replicating associations with very low *P* values for a wide range of complex traits, while the vast majority of candidate gene associations (which usually report significantly much higher *P* values) remain unreplicated. It is therefore increasingly apparent that genome-wide levels of significance are appropriately applied to all initial association studies for a given trait, even when tests are limited to a small number of genetic variants within a defined set of candidate genes. As more rigorously confirmed biologic data is obtained for associations between genetic loci and diseases or behavioral traits, future association studies will be able to relax the stringent agnostic standards. For example, if a genome-wide mapping study identifies an association between a locus and a trait like neuroticism using a stringent threshold, future studies of the same locus and similar traits like a diagnosis of an anxiety disorder would be considered meaningful with a less stringent threshold.

Genetic dissection of complex traits: guidelines for interpreting linkage results. *Nat Genet*. 1995;11(3):241–247, with permission from Springer Nature.)

THE PHENOTYPE

The generally disappointing results of psychiatric genetic mapping studies have focused increasing attention on the problem of defining and assessing phenotypes for such studies. Most psychiatric mapping studies to date have relied on categorical disease diagnoses, as exemplified by the *Diagnostic and Statistical Manual* (DSM) classification scheme. Criticisms of this approach rest on two arguments. First, diagnosis of psychiatric disease depends on subjective clinical evaluation, a fact that underscores the difficulty in ascertaining individuals who can be considered definitely affected by a given disease. Second, even when a psychiatric diagnosis can be established unambiguously, the menu-based system used for psychiatric classification provides the possibility that any two individuals affected with a given disorder may display largely nonoverlapping sets of symptoms, likely reflecting distinct etiologies. Concern that the diagnosis-based approach to phenotyping may represent one of the chief obstacles to the genetic mapping of psychiatric phenotypes has generated considerable interest in mapping heritable traits known to demonstrate continuous variation in the population. Continuous measures that are hypothesized to be related to psychiatric disorders include biochemical measures (e.g., serum or CSF levels of neurotransmitter metabolites or hormones), cognitive measures, personality assessments, structural or functional brain images, biophysical markers such as responses to evoked potentials, or molecular assays such as gene expression profiles. Key features of categorical and continuous phenotyping strategies are shown in Figures 1.19–4 and 1.19–5, and each is discussed in more detail below.



Phenotyping Strategies

hormone levels

FIGURE 1.19–4. Two alternate schemes for conceptualizing psychiatric phenotypes. **A:** Categorical traits as conceptualized by the *Diagnostic and Statistical Manual* (DSM) represent a “menu-based” approach to psychiatric disorders. Individuals are assessed for a checklist of signs and symptoms that are then used to categorize the individual as “affected” according to a specific diagnosis. Not all symptoms are present in samples of individuals who carry a particular DSM diagnosis, and many of these symptoms occur across diagnostic boundaries, as illustrated in this Venn diagram. DSM phenotypes therefore probably represent etiologically heterogeneous categories. **B:** Alternatively, in the continuous traits model, “affectedness” can be conceptualized in terms of an expectation that an individual will demonstrate extreme values on a set of continuous measures that correlate with psychopathology and thus are hypothesized to underlie the disorder (as illustrated by examples of six different types of measures shown in the hexagon). Such measures may also be associated with particular components of categorical phenotypes, such as those depicted in the Venn diagram. The justification for using continuous measures as the phenotypes for genetic mapping studies is that they are considered etiologically simpler and more reliably assessed compared to categorical phenotypes. In addition, mapping such traits combines information from all members of the study population (affected and unaffected individuals alike), which adds considerably to power.

Categorical Phenotypes

The most commonly used categorical phenotypes in psychiatry are DSM diagnoses. Some studies focus on a single DSM diagnosis, while other studies include individuals with a range of different diagnoses. The latter approach is typically used for disorders that are hypothesized to represent a single disease spectrum, such as mood disorders. Using the categorical approach, it is important to be able to classify subjects as unambiguously as possible. Several strategies are used to accomplish this goal. The first strategy involves deciding on the appropriate diagnostic criteria for the study in question and deciding how these criteria will be applied to individuals in the study. One way of standardizing the procedures used to identify and assess potential study subjects is to use only experienced clinicians in the diagnostic process and to train them in the administration of the instruments and the diagnostic criteria to be employed. In addition, a “best estimate” procedure and/or a consensus diagnosis are frequently used. The best estimate process involves making use of every piece of available information, including medical records, interviews, and videotapes, to arrive at a diagnosis. For a consensus diagnosis, two or more diagnosticians independently review the material and make a diagnosis for each individual. The diagnoses are then compared and individuals for whom an agreement in diagnosis cannot be reached are not entered as “affected” into the study.

FIGURE 1.19–5. The endophenotype (also known as intermediate phenotype) strategy aims to map genes associated with quantitative measures acquired from multiple levels of physiology in order to characterize the biologic pathways that cause psychiatric disorders. In contrast to conventional studies that map genes associated with dichotomous disease categories, the endophenotype method can be implemented across diagnostic categories to identify the differences/commonalities in biologic systems that contribute to psychiatric disorders. Because intermediate phenotypes are "closer to genes" compared to diagnostic categories, they are expected to have more power in gene-mapping studies.

A well-designed study makes use of all available information about the genetic epidemiology of the disorder to choose a sample of affected individuals to study. It is often the case that a subset of families carries the disorder in what appears to be a simple Mendelian pattern, while the inheritance pattern is less clear for other families or groups. In a disorder where there are likely to be multiple genes contributing to the phenotype, it makes sense to begin with a study sample where there may be major loci. Redefining the disease phenotype can often simplify the mapping process by identifying such groups or families. For example, in the search for a genetic defect for Alzheimer disease, the process was advanced enormously by limiting the study population to those individuals who had an early age of onset (before age 65); the early onset trait segregated in an autosomal dominant fashion. Other ways of redefining the phenotype include focusing on factors such as ethnic background, treatment response, symptom severity, or the presence of comorbid disorders.

Narrowing the phenotype using the approaches discussed above may increase the chances of finding a genetic defect in complex diseases, but it can also greatly reduce the power of the study by limiting the number of available affected individuals. For this reason, it has been argued that for some disorders, broadening the phenotype is an appropriate strategy. The suggestion is that for some complex diseases, the phenotype of interest may represent the extreme end of a spectrum and that to have enough power to map genes; other phenotypes within the spectrum must also be included. For example, mapping studies of bipolar disorder might include affected individuals with MDD as well as those individuals diagnosed with bipolar disorder.

Although the two approaches of narrowing the disease phenotype and broadening the disease phenotype may seem to be mutually exclusive, many groups studying complex disorders have incorporated both approaches into their study designs. One way to do this is to create stratified diagnostic categories ranging from a narrow diagnostic category to a broad diagnostic category, and test for genetic linkage under each of these schemas. Some investigators argue that for complex diseases that are part of a spectrum, this strategy decreases the rate of false negatives, that is, of missing an existing linkage because of misspecification. Others argue that using several models and picking the one that gives the highest scores greatly increase the rates of false positives, that is, of identifying an area of linkage where none exists. One problem that clearly exists with the use of multiple diagnostic categories is that as more models are used (and therefore, more statistical tests are performed), increasingly stringent levels of evidence are required to consider a result significant.

While categorical phenotypes remain the mainstay of psychiatric genetic studies, the limitations of DSM nosology as the basis of phenotyping for genetic studies are becoming clear. Genetic investigations are focusing increasingly on traits that may be components of one or more DSM diagnostic categories. For example, there is growing evidence that genetic susceptibility to psychosis, broadly defined, contributes to both severe bipolar disorder and schizophrenia, and a number of investigative approaches are being employed to attempt to identify genes that underlie such susceptibility and even to explore possible etiologic relationships between psychiatric and nonpsychiatric disorders. For example, bioinformatics models have been employed to investigate medical records databases and have uncovered extensive pairwise correlations among a diverse list of psychiatric disorders, neurologic disorders, autoimmune disorders, and infectious diseases. Eventually, the results of such model-fitting experiments may provide a framework to design more powerful linkage and association studies that can search for alleles that contribute to susceptibility to multiple disorders.

Continuous Phenotypes

Because of the difficulties experienced in genetic mapping of categorical diagnoses, neurobehavioral geneticists are increasingly focused on investigating quantitative traits that are hypothesized to underlie a particular psychiatric diagnosis and that may be simpler to genetically map. The rationale for efforts to map such alternative phenotypes, termed endophenotypes or intermediate phenotypes, is that the genes identified through such efforts may provide clues regarding the biologic pathways that are relevant to understanding a particular disorder or multiple disorders that may have overlapping etiologic pathways (Fig. 1.19–5). Several features characterize useful endophenotypes. First, they should be state independent; that is, they should not fluctuate as a function of the disease course or medication treatment and should show adequate test–retest stability. Second, they should be heritable; that is, there should be evidence that genetic factors are responsible for a substantial proportion of the variability of the trait within the population. Third, the endophenotype should be correlated with the disease under investigation;

that is, different values of the trait measure are observed in patients compared to unrelated control subjects. Measures of brain structure and function are now under investigation as endophenotypes for psychiatric disorders. For example, several features of brain morphometry (as assessed by magnetic resonance imaging [MRI]) are highly heritable (in the range of 60% to 95%), including total brain volume, cerebellar volume, gray and white matter density, amygdala and hippocampal volume, and regional cortical volume. Several studies show that brain structural features that are correlated in clinical samples with disorders such as schizophrenia or bipolar disorder are also abnormal in relatives of affected individuals. Physiologic measures of brain activity that have been employed as candidate endophenotypes for psychiatric disorders include electroencephalography (EEG) patterns. In addition to brain measures, behavioral traits relevant to psychiatric disorders are an active field of gene-mapping studies, including neurocognition, impulsivity, emotional regulation, and temperament (i.e., neuroticism).

Animal Models

In contrast to categorical phenotypes, endophenotypes can be more straightforwardly related to phenotypes that can be assessed in animal models. Studies of genetic variations that affect circadian rhythms provide a good example. Variations in circadian rhythms have long been recognized as important features of mood disorders, and quantitative assessments of activity patterns have been proposed as endophenotypes for such disorders. Numerous studies in animal models have demonstrated that genetically controlled biologic clocks determine circadian activity and that variations in clock genes are associated with variations in such activity from bacteria to humans. Genetic mapping efforts in fruit flies starting in the early 1970s resulted in the identification of at least seven “clock genes,” beginning with *period.* Subsequent studies showed that the homologs of several of these genes play essential roles in regulating mammalian circadian rhythms. Genetic mapping studies in mice also have identified previously unknown circadian rhythm genes, beginning with the discovery and characterization in the early 1990s of *clock.* These genetic discoveries have not only explicated the cellular networks and neurophysiologic circuits responsible for the control of mammalian circadian rhythms but have also generated animal models that may shed light on the pathobiology of psychiatric syndromes such as bipolar disorder. For example, mice carrying a targeted mutation in *clock* demonstrate abnormal activity patterns, such as hyperactivity and decreased sleep, which are apparently modified by the administration of lithium.

PROGRESS IN THE GENETIC DISSECTION OF SPECIFIC DISORDERS

Taken as a whole, the progress in identifying susceptibility genes for psychiatric disorders has been slower compared to that observed for nonpsychiatric disorders. The final sections of this chapter will review the progress that has been made in identifying the genetic underpinnings of several specific psychiatric disorders. Alzheimer disease represents the most successful application of gene-mapping strategies to complex neurobehavioral disorders, and the section on this disease provides an example of how genetic linkage studies add to understanding the pathogenesis of a complex trait. Gene-mapping studies of autism provide examples of genetic investigations of syndromes that have relatively simple inheritance patterns and demonstrate how these studies have provided starting points for investigations of more complex autism spectrum disorders (ASDs). Finally, recent progress identifying risk variants for schizophrenia, bipolar disorder, and major depression are used to illustrate the exciting directions that are beginning to revolutionize the current understanding of the etiology of these complex disorders.

ALZHEIMER DISEASE

Alzheimer disease provides an excellent example of the power of genetics to elucidate the complex biology of a neuropsychiatric disorder. Alzheimer disease is a well-defined form of dementia characterized by progressive impairment of memory and intellectual functioning. The clinical signs and symptoms, although characteristic, are not limited to Alzheimer disease but are also found in several other types of dementia. Alzheimer disease has several distinguishing histopathologic features; the presence of senile plaques (made up of a core of β-amyloid fibrils surrounded by dystrophic neurites), tau-rich neurofibrillary tangles, and congophilic angiopathy in the brain parenchyma and associated blood vessels are pathognomonic for Alzheimer disease.

A variable age of onset has been noted for Alzheimer disease, ranging from as early as age 35 to as late as age 95. Family history is the second greatest risk factor after age for the disease. The concordance rate for Alzheimer disease in MZ twin pairs is about 50%, indicating a moderately strong genetic contribution to disease risk. It is now evident from a wide range of genetic studies that Alzheimer disease can be divided into two broad categories: familial forms, which account for about 5% of Alzheimer disease cases and are characterized by early onset and autosomal dominant inheritance with high penetrance; and sporadic forms, in which the genetic contribution is hypothesized to be similar to that characterizing other common neuropsychiatric diseases.

The search for the genetic basis of familial Alzheimer disease began with traditional linkage studies. First, an investigation of a candidate locus on chromosome 21 in humans identified mutations in the *APP* gene in a small number of families in which significant linkage had previously been observed to markers from this region. The *APP* encodes the amyloid precursor protein, a cell surface and transmembrane precursor protein that is cleaved to form multiple peptides of various function. Some of the peptides are secreted and function to promote transcriptional activation, whereas other peptide products form the basis of the β-amyloid fibrils. Transgenic mice with different *APP* mutations were created and have been shown to produce β-amyloid deposits and senile plaques as well as to show synapse loss, astrocytosis, and microgliosis, all part of the pathology of Alzheimer disease. Mutations in the genes that encode β-APP all lead to an increase in the extracellular concentration of longer fragments of β-amyloid (Aβ42). Most of the strains of transgenic mice with mutations in APP exhibit increased rates of behavioral changes and impairment in several memory tasks, indicating dysfunction in object-recognition memory and working memory among others. These findings represent striking evidence that mutations in the β-amyloid gene are indeed responsible for at least some of the histopathologic elements of Alzheimer disease.

Even as the above findings were being reported, it was clear that mutations in the β-amyloid gene could not completely explain the etiology and pathology of Alzheimer disease, not least because it was shown that linkage to chromosome 21 was excluded in most early-onset Alzheimer disease families. In addition, no neurofibrillary tangles are observed in most of the different β-amyloid transgenic mice. The subsequent search for the genetic underpinnings of Alzheimer disease using genome-wide linkage analysis of early-onset Alzheimer disease families resulted in the identification of two additional Alzheimer disease susceptibility genes: *presenilin-1* (*PS-1*) on chromosome 14q24.3 and *presenilin-2* (*PS-2*) on chromosome 1q. PS-1 and PS-2 are integral transmembrane proteins with at least seven transmembrane domains. The *presenilins* are aspartyl proteases that carry out γ-secretase cleavage of *APP* to generate β-amyloid. Similar to mutations in *APP,* genetic variation in *presenilins* causes an increase in the expression of longer fragments of β-amyloid.

These findings emphasize one of the strengths of using family-based linkage analysis. Pedigree-based studies are especially suited to identify highly penetrant disease genes that serve critical roles in important biologic processes. Mutations in *APP* and *presenilin* are rare, but different mutations in these genes have occurred in different founders; to date, 185 mutations have been identified in *PS-1,* 13 mutations for *PS-2,* and 24 mutations for *APP.* Virtually all of these mutations are transmitted in an autosomal dominant and fully penetrant manner. The convergence of different mutations within the same genes clearly confirms the involvement of these genes in the disorder. Although the mutations in *APP* and *presenilin* are rare, research into the biology of the expressed proteins has provided key insights into the pathophysiology of dementia. Because these highly penetrant mutations elucidate important biologic functions, they also provide a firm ground to design therapeutic interventions. For example, β-amyloid "vaccines" designed to induce an immunogenic response to pathogenic amyloid are now in advanced clinical trials. In addition, γ-secretase modulators have been developed to target the dysfunction of the *presenilin* gene products. Unlike the current psychopharmacologic treatments for Alzheimer disease that nonspecifically target cholinergic and glutamatergic systems, the β-amyloid vaccines and γ-secretase modulators specifically treat the causes of Alzheimer disease by generating an immune response or altering the processing of *APP* and may actually prevent or reverse the deposition of senile plaques.

Sporadic and Late-Onset Alzheimer Disease

Mutations in *APP, PS-1,* or *PS-2* are present in a majority of familial cases of early-onset Alzheimer disease but do not account for sporadic or familial late-onset Alzheimer disease. For this reason, investigators turned to other approaches to search for the evidence of linkage in a large number of small families with late-onset Alzheimer disease. In 1991, the results of a linkage study using 36 markers in late-onset Alzheimer disease families provided evidence for a susceptibility gene on the long arm of chromosome 19. In 1993, association studies revealed that the e4 allele of the *apolipoprotein E* gene was strongly associated with late-onset Alzheimer disease and that this association almost certainly was responsible for the previously observed linkage signal on chromosome 19. There are three known alleles of this gene—e2, e3, and e4. These three alleles are distinguished by combinations of amino acids at residues 112 and 158; e2: Cys_{112}/Cys_{158}, e3: Cys_{112}/Arg_{158}, and e4: Arg_{112}/Arg_{158}. In most populations, the e3 allele is the most common. However, in familial late-onset Alzheimer disease, the incidence of e4 is approximately 50%, and in sporadic late-onset Alzheimer disease, it is 40%, compared with about 16% in normal controls. Inheritance of a single copy of e4 increases the risk for the disease by 4-fold, and inheritance of two copies of the allele increases the risk by 10-fold. Epidemiologic studies suggest that between 30% and 60% of late-onset Alzheimer disease cases have at least one *apoE-e4* allele. The e4 genotype appears to be a more important risk factor for Alzheimer disease in populations of European and Asian origin when compared with populations of African origin. The *apoE* gene has a well-characterized role in the metabolism and transport of lipids and is believed to play a role in the clearance of β-amyloid from the brain. Overall, the association of *apoE-e4* with Alzheimer disease remains probably the strongest association yet identified for a common human disease.

The establishment of *apoE-e4* as a susceptibility allele for late-onset Alzheimer disease has led to the search for additional alleles that might interact with *apoE-e4* to modify disease risk. In 2007, investigators used GWA strategies in histologically confirmed cases and controls to identify *GAB2* (GRB-associated binding protein 2) as an additional risk allele in *apoE-e4* carriers (but not in Alzheimer disease patients who were not e4 carriers). Initial studies suggest that carriers of both *apoE-e4* and *GAB2* risk alleles have an almost 25-fold greater risk for Alzheimer disease than individuals who do not carry either risk allele. *GAB2* appears to modulate β-amyloid production through its interaction with GRB2 (growth factor receptor-bound protein 2), which physically interacts with APP and the presenilins.

Since the initial GWA studies that identified *GAB2,* there have been more than a dozen additional GWA studies and, together, have identified more than 40 confirmed Alzheimer risk genes. Unlike *APP* and the *presenilins,* these genes have small effect sizes (odds ratio <1.2) and are relatively common in the general population. Their role in the pathophysiology is less clear compared to the current understanding of *APP* and the *presenilins* biology, though analysis of the known function of genes identified in GWA studies point to the involvement of immunity, lipid metabolism, tau binding proteins, and amyloid precursor protein metabolism. Notably, the population-based GWA studies have identified genes associated with β-amyloid processing other than *APP* and *presenilins*, showing a convergence on a common pathway in both familial and sporadic forms of the disease. For example, the *ATXN1* gene product modulates γ-secretase levels and impacts the cleavage of APP and the murine knockout model of *ATXN1* shows cognitive impairment by age 6 months. Other genes identified by GWA studies appear to influence the risk of Alzheimer disease by impacting immune and inflammation pathways, including factors that regulate cellular interactions required for immune reactions (e.g., CD33) and inflammatory processes (e.g., *CR1,* the receptor for the complement molecule C3b). These immune/inflammatory processes have been postulated to mediate the neurotoxic response to β-amyloid.

As the results of GWA studies of Alzheimer disease continue, genes associated with protection and resilience have emerged alongside genes associated with risk. Resilience to Alzheimer disease, also known as asymptomatic Alzheimer disease, is of great interest because of the possibility of identifying biologic pathways that confer protection from the disease. As many as 70% of cognitively normal older adults show clear evidence of Alzheimer histopathologic changes, and up to 30% of cognitively normal older adults meet full autopsy-confirmed neuropathologic criteria for the disease. Characterization of the genetic and environmental factors that confer protection despite clear evidence of brain pathology holds promise for prevention or treatment strategies to mitigate the impact of the disease processes. For example, a recently identified missense mutation within the APP gene near the β-secretase cleavage site was shown to be protective against the disease and slow the cognitive decline. In vitro studies showed that the mutation resulted in suboptimal β-secretase cleavage with subsequent reduced aggregation of pathologic Aβ by 50% compared to wild-type cells. Such studies provide potential pathways to intervene with the goal of preventing or slowing the processes that eventually result in the full manifestation of the disease.

Summary

Progress in the field of Alzheimer research has achieved significant momentum, and there are now more than 40 genes implicated in the pathogenesis of this disorder. Linkage studies of rare familial forms of Alzheimer disease led to the discovery of high-penetrance variants that have had a profound impact on the understanding of Alzheimer disease pathogenesis and on the basic understanding of a wide range of cellular processes within the CNS. Association studies have unequivocally identified lower-penetrance variants that together explain much of the genetic contribution to disease risk at the population level. Taken together, the risk genes converge on a few basic biologic pathways: processing of β-amyloid, lipid metabolism, immunity, and inflammation. In addition to the identification of risk alleles, gene-mapping studies have also identified genetic variants that confer protection from the disease. The identification of risk and protective variants has provided the promise of two types of medical breakthroughs. New therapies are in development that target the molecular pathways identified through these studies. In addition, the emerging picture of genetic risk for common forms of Alzheimer disease suggests that it may soon be possible to focus prevention and early intervention strategies on individuals who are at high risk.

AUTISM

Autism is a severe neurodevelopmental disorder that was originally described as “enclosure in one’s self” by Leo Kanner in 1943 and is characterized by three primary features: impaired language and communication, abnormal or impaired social interaction, and restricted, repetitive, and stereotyped patterns of behavior. Understanding of the etiology of autism has proceeded slowly, but there is now convincing evidence that alterations in specific cellular and molecular neurodevelopmental pathways are important in its etiology. There is particularly strong evidence for a genetic contribution to the risk of autism and ASDs. The sibling recurrence risk for autism and/or ASD is between 2% and 6%. Given a population prevalence of about 1 in 2,000 (0.04%), this means that the siblings of autistic individuals are approximately 50 to 100 times more likely to develop autism than a person in the general population. Twin studies of autism not only show extraordinarily high heritability (as demonstrated by MZ twin concordance of 80% to 92%) but also demonstrate the genetic complexity of these disorders, with the DZ twin concordance rate of 1% to 10% suggesting a highly multigenic mode of inheritance.

Increasing interest is focused on the possibility that large-scale chromosomal aberrations (CNVs) contribute an important role in autism. Early studies found an increased frequency of CNVs in autistic individuals at a rate of 5% to 10% compared to 1% to 3% in controls. Subsequent studies failed to replicate the initially identified high rate of CNVs compared to controls; however, recent work has suggested that the specific location and functional consequence of CNVs are more critical than the relative number of abnormalities. Two large studies identified a heterogeneous collection of CNVs that were not randomly distributed within the genome but rather concentrated within a subset of loci. Functional analysis of these loci showed that they are involved in synapse development, neuronal migration, and axon targeting. These functional findings converge nicely with investigations of well-characterized non–CNV-related abnormalities (discussed in detail below) and provide confidence that sporadic or inherited CNVs represent an important etiologic factor for some cases of the disorder. Collectively, the large population studies estimated that CNVs account for 5% to 8% of syndromic cases of autism.

Even prior to the demonstration of high rates of de novo mutations in autism, epidemiologic studies had strongly suggested that the genetic basis of this disorder is likely complex. For example, although the risk of autism in first-degree relatives of autistic probands is high, there is a substantial falloff for second- and third-degree relatives of such probands, suggesting that multiple genetic variants must interact to increase susceptibility to this syndrome. Segregation analyses of autism also support the hypothesis that it is a heterogeneous disorder that reflects the actions of multiple genetic variants of small effect. Genetic studies of autism have included whole-genome screens, candidate gene studies, chromosome rearrangement studies, mutation analyses, and comparative genomic hybridization studies. Taken together, these studies have contributed to an emerging picture of autism susceptibility that includes genes involved in three major systems: those involving synapse formation and maintenance, morphogenesis, and calcium regulation and signaling.

Synapse Formation and Maintenance

Perhaps the biggest breakthroughs in identifying susceptibility genes for autism have come from studies of disorders that display clinical features associated with autism or ASDs but with simpler inheritance patterns, including fragile X syndrome, tuberous sclerosis, and Rett syndrome. In general, the genetic defects associated with these disorders affect synapse formation and maintenance. Fragile X, which accounts for 3% to 4% of autism cases, is caused by an unstable trinucleotide repeat in the 5′ region of the *FMR1* gene at Xq27.3. This repeat expands as it is transmitted to succeeding generations, resulting in abnormal methylation and inhibition of expression of *FMR1. FMR1* produces an RNA-binding protein that acts as a chaperone for the transport of RNA from the nucleus to the cytoplasm and is involved in mRNA translation at the synapse. Abnormalities in dendritic spine density (increased over normal) and morphology (longer and thinner than normal) have been reported in individuals with fragile X as well as in mouse models of this disorder. Tuberous sclerosis, which accounts for perhaps 2% to 10% of autism cases (the rate of tuberous sclerosis is higher among autistic individuals with seizure disorders), results from mutations in one of two tumor suppressor genes, *TSC1* on 9q34, and *TSC2* on 16p13, both of which are involved in guanosine triphosphatase (GTPase) inactivation. Loss of a single copy of *TSC1* in mice has been shown to disrupt cytoskeletal dynamics and dendritic spine structure.

The *neuroligin* (*NLGN*), *SHANK,* and *neurexin* gene families are additional risk loci that appear to play a role in synapse formation and may be affected by mutations observed in some individuals affected with autism. The *NLGN* genes, situated on the X chromosome, produce cell adhesion molecules that are located on postsynaptic glutamatergic neurons. When mutated in rodents, these genes show defective trafficking and synapse induction. In nonmutated form, their expression induces the formation of normal, presynaptic terminals in axons. In mutants, there is defective transport of vesicles to the synaptic membrane and reduced synaptic induction. Mice carrying a human mutation of *NLGN3* show an interesting phenotype characterized by impaired social novelty preference and reduced vocalizations, two of the central features of the disorder in humans. The *SHANK* gene family encodes scaffolding proteins that are located in the postsynaptic membrane and serve as master organizers of the PSD. *SHANK3* is one of three members of the *SHANK* gene family and is located in the minimal region of the 22q13 deletion syndrome, known as Phelan-McDermid syndrome, which includes prominent autistic features. Larger studies have found that *SHANK3* mutations are present in about 0.85% of all autistic subjects. A third family of synapse-related genes associated with autism are the neurexins. Neurexins interact with neuroligins and are critical to the formation of presynaptic boutons. Neuroexins also link calcium channels to synaptic vessels and mediate neurotransmitter release through exocytosis. Like neuroligins and SHANK3, mutations in neurexins (*NRXN1*) occur rarely but have emerged multiple times in independent familial lines of individuals with autism.

Morphogenesis

Many individuals with syndromic forms of autism display facial dysmorphisms and/or abnormal body growth rates. About 20% of autistic children show macrocephaly with increased trajectories of head growth during the first few years of life, although a smaller proportion of patients show microsomia. Although the etiology of the abnormal growth patterns is not yet clear for most cases, several syndromic forms of autism have been associated with rare mutations of genes involved in embryogenesis and organogenesis. Mutations in *HOXA1,* a gene necessary for normal development of the brain stem, cerebellum, cranial nerves, and portions of the calvarium, have been identified in several families with heterogeneous phenotypes that include autistic features. Missense mutations have been identified in the tumor suppressor gene *PTEN* on chromosome 10q23. *PTEN* mutations have been associated with a broad cluster of syndromes, including Cowden syndrome, Bannayan–Riley–Ruvalcaba syndrome, Proteus syndrome, and Lhermitte–Duclos disease. *PTEN* has been shown to interact in the ERK/P13K/mTOR pathway, which is critical for incorporating information regarding nutrient availability and growth factor signals to regulate cell proliferation and body growth. *PTEN* mice knockout models show macrocephaly, CNS overgrowth, and excessive dendritic and axonal growth. Syndromes involving *PTEN* mutations have heterogeneous features, including nonpsychiatric phenotypes like cancer, highlighting that the final expression of specific genetic mutations depends on a complex interplay of genetic background (other mutations) and environmental factors.

Another syndromic form of autism is Rett syndrome, an X-linked pervasive developmental disorder (the first with a known genetic etiology) that occurs only in girls and is associated with normal early development followed by loss of skills, particularly social engagement and purposeful hand skills by age 4. The syndrome also points to abnormalities in synapse formation and maintenance in ASD and ASD-like disorders. Rett syndrome is caused by mutations in *MeCP2,* which makes a methylated-DNA–binding protein that regulates gene expression and chromatin structure and is required for normal brain development. Loss of *MeCP2* is associated with delayed neuronal maturation and abnormal synaptogenesis. Loss-of-function mutations in *MeCP2* are lethal in males and cause severe symptoms in about 70% of females; however, some mutations result in relatively mild phenotypes with some intellectual disability and/or verbal deficits. The heterogeneous expression of these mutations on the syndromic phenotype again highlights the key role that genetic background plays in determining the final manifestation of symptoms.

Calcium Regulation and Signaling

Another class of genes that has been linked to at least some cases of autism includes ion channels, receptors, and Ca^{2+}-regulated signaling molecules. Gain-of-function mutations in several L-type voltage-gated Ca^{2+} channels that express constitutively active channels and lead to excessive Ca^{2+} influx have been associated with autism. Timothy syndrome is caused by gain-of-function mutations in *CACNA1C,* an L-type voltage-gated Ca^{2+} channel and is characterized by intellectual impairment and autism. Interestingly, *CACNA1C* has been associated with schizophrenia and bipolar disorder, providing an example of a genetic risk factor that can cross diagnostic categories. Gain-of-function mutations in *CACNA1F,* another L-type voltage-gated Ca^{2+} channel, are the cause of congenital night blindness that can be accompanied by autistic features. Several other genetic mutations have been identified in other genes that are linked to calcium regulation. In one autism case, a mutation was identified in *SCN2A,* which expresses a sodium channel that is regulated by calmodulin. The mutation disrupts the binding affinity between calmodulin and the channel, leading to sustained channel activity during depolarization. In another case, a chromosomal translocation was identified that disrupted *KCNMA1* that codes for a potassium channel that is activated by depolarization or intracellular Ca^{2+} and leads to constitutively depolarized resting membrane potential and anomalous neuronal excitability.

The Role of Common Variants in Autism

The genetic mutations described in the preceding sections are rare and collectively explain less than 10% of autism cases. In large samples of genotyped individuals, it has been estimated that common variants explain between 40% and 60% of the liability for the disorder, and in 2019, after many underpowered gene-mapping investigations failed to identify any significant findings, an international consortium assembled a sample of almost 20,000 ASD cases and 30,000 controls to identify the first robust GWA study findings: five replicated risk alleles for the disorder. Analysis of transcriptome data from fetal and adult brains showed that the ASD risk loci were associated with molecular pathways impacted by rare and/or de novo variants found in nonfamilial cases of Autism, including *PTBP2*, *CADPS*, and *KMT2E*, demonstrating the shared cellular biology between familial and nonfamilial cases of the disorder.

The same ASD GWA study described above integrated the ASD sample with a large independent sample that included phenotypes on educational attainment and found that the ASD sample shared genetic factors associated with *higher* educational achievement and intelligence. The finding of shared genetic influence between intelligence and ASD diagnosis was only found among higher functioning individuals with ASD (e.g., individuals classified with Asperger syndrome), showing that the spectrum of higher functioning autism disorders can be distinguished from other pervasive developmental disorders based on their genetic architecture. In fact, combined with results from other genetic studies, the emerging picture of autism and other developmental disorders demonstrates that many highly heritable psychiatric disorders are positively correlated with intelligence and have extensive polymorphic contributions from small effect common genetic factors. These are etiologically distinct from the heterogenous cluster of sporadic pervasive developmental disorders that have lower heritability (i.e., less influenced by inherited alleles) and a higher prevalence of de novo mutations that have a larger impact on cognitive functioning.

Summary

Genetic investigation of autism has progressed considerably in the last several years. Successes in autism genetics may be attributed largely to three factors: (1) the high heritability of many of the forms of this disorder, (2) international collaborations that have made large samples of autism families readily available to the scientific community for a wide range of investigations, and (3) the relatively consistent findings obtained using complementary approaches, including linkage studies, investigation of known chromosomal abnormalities, comparative genomic hybridization, mutation analyses, and investigation of animal models that display phenotypes relevant to autism. Compared to other psychiatric disorders like schizophrenia, bipolar disorder, and major depression, there are now relatively elaborated models of the molecular biology and cellular pathways that are involved in the etiology of ASDs, which appear to have significant overlap between familial and nonfamilial versions of the disorder. The progress is largely attributable to the investigation of syndromic cases of autism which are caused by rare mutations of large effect, but emerging evidence is beginning to uncover the genetic architecture of familial cases. Interestingly, well-powered GWA studies of familial autism show that there is a common set of cellular pathways between syndrome and familial cases but also show that the genetic basis of familial cases diverges from syndromic cases for genetic factors associated with cognitive functioning and intelligence. Familial cases of ASD are associated with genes that contribute to higher intellectual functioning, whereas nonfamilial cases are associated with higher rates of de novo mutations that predispose to lower intellectual functioning. Recent progress has been enlightening and has much more to discover; the current genetic loci associated with ASD explain only a small proportion of the total heritability, indicating that there are many loci remaining to be discovered.

BIPOLAR DISORDER, SCHIZOPHRENIA, MAJOR DEPRESSION, AND ANXIETY

Bipolar Disorder

The search for the genetic basis of bipolar affective disorder has been fraught with missteps and partial answers. The history of genetic mapping attempts for bipolar disorder illustrates not only the extreme complexity of psychiatric disorders but also the evolution of genetic approaches to such diseases. Numerous genetic epidemiologic investigations conducted over several decades have strongly supported a genetic contribution to the risk for bipolar disorder. Current estimates of concordance for bipolar disorder range between 65% and 100% in MZ twins and between 10% and 30% in DZ twins, indicating that the disorder is highly heritable (between about 60% and 80%). Several studies have shown that bipolar disorder is substantially more heritable than unipolar major depression, which has an estimated heritability between 30% and 40%. Early family studies suggested that bipolar disorder segregation patterns were compatible with single-gene inheritance of a locus of major effect. Although it is possible that some bipolar disorder pedigrees segregate such a locus, mounting evidence indicates that if such pedigrees exist, they must be quite rare. Furthermore, the fact that genetic linkage studies have failed to uncover such a locus with unequivocal evidence in any pedigrees argues against this possibility. The observed rapid decrease in recurrence risk for bipolar disorder from MZ cotwins to first-degree relatives is also not consistent with single gene inheritance models but rather suggests models of multiple interacting genes.

Tremendous excitement followed the first reports of linkage to bipolar disorder on chromosomes X and 11 in 1987. Investigators noted that in several families, bipolar disorder and other affective disorders appeared to be inherited in an X-linked fashion. Likewise, these disorders appeared to cosegregate in several Israeli families with color blindness and G6PD deficiency, which map to the X chromosome. Linkage studies in these pedigrees using color blindness or G6PD deficiency as marker loci, gave LOD scores between 4 and 9. Early studies of chromosome 11 were similar to those for chromosome X in that they reported significant linkage after testing only a few markers in a single region, in this case, in an extended Old Order Amish pedigree heavily loaded for bipolar disorder.

Not surprisingly, these findings generated a great deal of interest. Both studies showed high LOD scores and seemed to provide clear evidence for linkage. However, replication studies in other populations failed to produce positive results for either the X chromosome or chromosome 11, and evidence for linkage essentially disappeared in both chromosomal regions in the samples in which linkage was originally reported when the pedigrees were extended to include additional affected individuals and when additional markers were typed in the putative linkage regions. The most likely explanation in each case is that the original linkage results were false-positive findings and may have reflected an overoptimistic interpretation of evidence that, in retrospect, was relatively scant.

The early linkage studies of bipolar disorder evaluated only a few markers because they were all that were available. With the construction of genetic linkage maps of the genome in the 1990s, linkage studies of most complex traits, including bipolar disorder, began to search genome wide. The advantage of genome-wide mapping studies is that they do not require a priori knowledge of the biologic underpinnings of a particular phenotype. Complete genome screens provide an opportunity to evaluate the evidence of linkage at all points in the genome without bias. While genome-wide studies clearly had greater power to detect true linkage than studies focused on only a few markers in arbitrary locations or around a few candidate genes, these investigations have also generally had disappointing results. The challenge of achieving replicated significant linkage results for bipolar disorder and other complex traits is apparent when one reviews the many gene-mapping studies that have suggested—but not demonstrated unequivocally—bipolar disorder susceptibility loci on chromosome 18.

The first report of linkage came from a partial genome screen that examined 11 markers on chromosome 18 and identified suggestive linkage near the centromere. Because the inheritance patterns for bipolar disorder are unknown, the results were analyzed using both recessive and dominant models. Some of the markers were positive under a recessive model in some families, some were positive under a dominant model in other families, and some markers gave positive LOD scores in a subset of families under both models. Attempts to replicate this finding in other populations have been mixed. So far, at least two groups have found no evidence for linkage to the pericentromeric region of chromosome 18 in their samples, although one other group has found evidence to support linkage to this region. Other studies have found suggestive evidence for linkage on chromosome 18, including a complete genome screen in two large Costa Rican pedigrees that gave evidence for linkage on chromosome 18q22–23 as well as in an area on 18p. The combined evidence of these several studies, although somewhat contradictory and confusing, points to at least two different susceptibility loci on chromosome 18: one on 18p and another on 18q.

The complexities outlined above for chromosome 18 highlight the potential difficulties encountered in gene-mapping studies. Replications of significant findings in small studies often fail in samples of different families. One approach to overcome the low power of small linkage studies is to use meta-analyses to combine numerical results of several individual studies to estimate the average effect of interest. The largest meta-analysis to date included almost 1,000 families, but even for this large sample, it is still debatable whether any unequivocal linkage signals were identified. Various explanations have been put forward to interpret the lack of findings for these meta-analyses; at the top of the list is the possibility that they have been statistically underpowered. Another consideration is that multiple genes of small effect are interacting to cause the disorder, in which case these genes will be difficult to detect with linkage approaches. Another possibility is that each family is segregating a unique set of genetic variants, and linkage analysis has little power to identify risk loci in these situations. Ultimately, it may turn out that the genetic architecture of bipolar disorder includes a mix of common variants segregating in the general population and rare alleles that are specific to recent ancestors and only segregating within a relatively small set of families. Much of the recent gene-mapping effort in psychiatric genetics has focused on identifying common risk loci of small effect using GWA methods. Compared to several decades of frustrating linkage studies, recent GWA investigations are appreciating considerable success (described below). However, individual common variants identified in GWA studies account for only a small proportion of disease risk (~1% to 2%). Therefore, family-based linkage methods have a potentially important role in the full elaboration of the genetic architecture of psychiatric disorders by identifying rare risk variants that occur in the background of common risk variants and determining which individuals develop the disorder.

In contrast to the disappointing results from linkage analysis described above, GWA studies of bipolar have begun to yield statistically rigorous significant findings. In 2007, the Wellcome Trust Case Control Consortium (WTCCC) conducted the first GWA study of bipolar disorder in 2,000 cases and 3,000 controls genotyped at ~500,000 SNPs but did not identify any genome-wide significant risk variants. The negative finding was notable given that six other common disorders were included in the WTCCC, all of which generated some significant findings. In 2008, a similarly sized investigation was implemented in samples from the Systematic Treatment Enhancement Program for Bipolar Disorder and University College of London (STEP and UCL) and also failed to identify any genome-wide significant risk loci. The WTCCC, STEP, and UCL then combined their data to obtain a sample size of 4,387 cases and 6,209 controls and finally reported the first genome-wide significant association for the disorder for an SNP residing in the *ANK3* (ankyrin G) gene on chromosome 10q21.2. The *ANK3* finding has subsequently been replicated multiple times in additional studies, which have also extended the list of risk loci such that by the end of 2020, about 30 loci had been established as confirmed risk factors for bipolar disorder. As expected for population-based GWA findings, the effect sizes of the risk alleles are low (odds ratios between 1.1 and 1.3), indicating that individually these common variants only contribute to a small increase in disease risk.

Although a definitive list of genes and biologic pathways impacted by risk loci requires more work, there is emerging confidence in several findings. The *ANK3* gene has been identified in multiple GWA studies and encodes ankyrin B, which is highly expressed in brain tissue and is involved in the organization of the neuronal axon. Several of the SNPs associated with bipolar disorder are also associated with expression levels of the ankyrin B. A conditional knockout of the gene in pyramidal neurons of the mouse forebrain results in disruption to the voltage-gated sodium and potassium channel architecture of the axon. Interestingly, the knockout mice showed disrupted behavior resembling mania, which was modified with lithium. A second gene with strong evidence linked to bipolar disorder is the *CACNA1C* gene, which is also associated with autism (see above), depression, and schizophrenia (see below). *CACNA1C* encodes an L-type voltage-gated channel involved in neuronal development and synaptic functions. A third gene strongly associated with bipolar disorder is *TRANK1*, which is also associated with schizophrenia and may be involved in blood–brain barrier physiology. Most of the risk loci associated with bipolar disorder have not been firmly linked to biologic functions. Pathway analysis leverages the growing body of evidence in gene ontology databases to group genes into specific biologic pathways and has provided evidence for the involvement of a range of cellular processes in bipolar disorder, including ion channelopathies, endocrine regulation, and posttranscriptional modification. The current understanding of the genetic architecture of bipolar disorder, which was murky just 5 years ago, has started to come into focus and in combination with family-based studies and intermediate phenotype approaches, promises to translate into clear mechanistic disease models.

Schizophrenia

Similar to bipolar disorder, the mapping of genetic variants associated with schizophrenia began with strong epidemiologic evidence of heritability followed by pedigree-based linkage studies that produced equivocal results, then followed by a period of rapid discovery of common, small effect variants through GWA studies. As of 2021, there are over 200 replicated risk variants with plans to continue increasing sample sizes through international consortia. Prior to successful gene mapping, family studies had clearly established that schizophrenia was strongly influenced by genetic factors, with heritability estimates between 60% and 80%. In the early 1990s, family-based linkage studies began to identify chromosomal regions linked to the disorder. Chromosome 6p24–22 was among the first regions to be implicated by a complete genome screen for schizophrenia, in this case, from a study of Irish families heavily loaded for schizophrenia. Six additional linkage studies have shown positive results over approximately the same region, but at least three studies have found no linkage to the region. Fine-scale mapping of this region using association analysis in the original Irish kindreds led to the proposal of *Dysbindin* (*DTNB1*) as a candidate gene for schizophrenia. Additional association studies of *Dysbindin* have been equivocal. Separate linkage studies subsequently pointed to a region on chromosome 1 containing the candidate genes *DISC1* and *DISC2* (*disrupted in schizophrenia 1* and *2*) located on chromosomes 1q21–22 and 1q32–42. These genes were initially identified in a large Scottish pedigree in the early 1990s. A balanced translocation between chromosomes 1 and 11 was segregated in this pedigree and was possibly associated with serious mental illness. *DISC1* and *2* were identified in the original Scottish family because of their location near the chromosomal translocation breakpoint. As with *Dysbindin,* follow-up studies of *DISC1* and *2* have been equivocal.

Around the same time as the linkage studies mentioned above, a genome-wide screen focused on extended Icelandic kindreds identified a schizophrenia candidate region on chromosome 8p21–22. Fine mapping of the region narrowed the search and eventually led to the proposal of *Neuregulin 1* (*NRG1*) as a schizophrenia candidate gene. Association studies again provided equivocal and difficult-to-interpret results. Meta-analysis of 14 separate studies using the SNP marker that demonstrated an association in the original study showed significant heterogeneity between the follow-up studies. It also showed that there is no consistent association between the specific risk allele “tagged” by the marker SNP and schizophrenia in different populations. However, after taking into account the statistical power of each association study, the meta-analysis showed a positive association between *NRG1* at the level of the gene (as opposed to the SNP or haplotype level).

Despite the equivocal genetic studies, significant resources have been channeled into molecular and neurophysiologic investigations of the functional products of *Dysbindin, DISC1*, and *Neuregulin.* Mutant mice for each of the three genes are now available and have been used to demonstrate interesting biologic findings. For example, *Dysbindin* is expressed in the hippocampus and dorsolateral prefrontal cortex. The dysbindin protein binds to β-dystrobrevin and has been implicated in synaptic structure and signaling. *DISC1* has been shown to influence neurite formation in cellular studies, and mutant mice for *DISC1* show impairments in a wide variety of tests, including learning, memory, and sociability. Neuregulin belongs to a family of growth factors that mediate numerous functions, including synapse formation, neuronal migration, and neurotransmission. Targeted disruption of *erbB4,* the postsynaptic target of neuregulin, leads to synaptic glutamatergic hypofunction. Despite the interesting biology uncovered, it remains unclear whether and to what extent any of these genes contribute to the etiology of schizophrenia in humans and many geneticists have been cautious in their endorsement of the legitimacy of the mutant mice generated from the current list of candidate genes as models of psychiatric disorders.

Like other psychiatric disorders, GWA studies of schizophrenia produced disappointing results until 2009, when the International Schizophrenia Consortium, Molecular Genetics of Schizophrenia, and the Schizophrenia Working Group of the Psychiatric Genomics Consortium combined samples and identified an SNP in the major histocompatibility complex (MHC) on chromosome 6p22 as a risk locus for the disorder. The mapping of a schizophrenia risk locus to the MHC region was an exciting discovery, although the full significance of the finding is difficult to interpret. It has long been known that exposure to maternal infection is a risk factor for schizophrenia. Therefore, specific MHC configurations may lead to anomalous immune responses that impact brain development and/or processes that predispose to the disorder. In addition, neurons express MHC molecules where they are involved in several aspects of brain development, including synaptogenesis, neurite outgrowth, and long-term plasticity. Therefore, genetic variations in the MHC may directly impact brain development outside immunomodulatory mechanisms.

Shortly after the discovery of the MHC as a risk locus, GWA studies identified more than a dozen additional risk loci, and as sample sizes increased, the number of novel and replicated risk loci accumulated. In 2014, the Schizophrenia Working Group of the Psychiatric Genomics Consortium, which by then had reached a sample size of 37,000 cases and 113,000 controls, identified 108 distinct loci contributing to risk for schizophrenia.

It is important to note that the identification of a genetic association at a specific SNP does not imply that the genotyped SNP is the causal allele. In fact, it is unlikely that the genotyped SNP on most current genotyping platforms has functional significance. The genotyped SNPs are more likely in LD in the immediate vicinity (∼100 kb) of the causal variant. In addition, given the extensive sequence variation even within relatively small regions, establishing a specific variant or set of variants as causal factors in the development of a complex disorder is not trivial. Complicating the definitive identification of variants is the expectation that many of the risk loci identified by GWA studies will harbor causal variants that impact more subtle aspects of gene functioning compared to Mendelian genes of large effect. While Mendelian mutations often lead to major disruptions in the coding sequencing of genes, common risk variants of small effect have been hypothesized to impact gene functioning at the level of expression or regulation. In contrast to mutations that impact protein-coding regions, it is more difficult to identify mutations that lie outside the intron/exon structure of genes that may be affecting regulatory regions that control expression or chromatin structure. Ongoing initiatives like the ENCODE project aim to characterize biochemically active regions of the genome, including regulatory protein binding sites and open chromatin regions, thereby providing a valuable resource for guiding the interpretation of mutations in noncoding regions.

Although the elaboration of the specific biologic pathways involved in the pathogenesis of schizophrenia will require definitive identification of causal mutations and their impact on specific genes, the recent accumulation of risk loci provides suggestive directions. The risk loci do not appear to be randomly distributed among genes involved in all cellular processes, but rather appear to be enriched near genes involved in a smaller subset of processes important for brain functioning, including neurodevelopment (FXR1 on 3q26.33, SATB2 on 2q33.1, PODXL on 7q32-q33, BCL11B on 14q32.2, TLE1 on 9q21.32, TLE3 on 15q22, and BRINP2 on 1q24), glutamatergic neurotransmission (GRIN2 A on 16p13.2, GRIA1 on 5q33.2, SRR on 17p13.3, CLCN3 on 4q33, and GRM3 on 7q21.12), neuronal calcium signaling (CACNA1C on 12p13.3, CACNB2 on 10p12, CAMKK2 on 12q24.2, NRGN on 11q24, ATP2A2 on 12q24.11, CACNA1I on 22q13.1, and RIMS1 on 6q12–13), and synaptic function and plasticity (KCTD13 on 16p11.2, NLGN4X on Xp21.33–32, IGSF9B on 11q25, CNTN4 on 3p26.3, MEF2C on 5q14.3, PTN on 7q33, CNKSR2 on Xp22.12, PAK6 on 15q14, and SNAP91 on 6q14.2).

Although GWA studies have appreciated substantial success over the past several years, it has become clear that common variants segregating in the general population are not able to account for all of the estimated genetic contribution to psychiatric disorders; this fact has been labeled as the “missing heritability” problem. For example, based on twin and family studies, the heritability for schizophrenia is around 70%, but the total amount of variance explained by common genetic polymorphisms is estimated to be about 30%, such that there is a “gap” of unexplained heritability. Various explanations have been put forward to account for the missing heritability problem. One factor that is likely to explain at least some of the missing heritability is the possibility that rare genes of medium-to-large effect that are not detectable with GWA methods are present in affected individuals. As with all other psychiatric disorders, the future directions of genetic mapping for schizophrenia will include continued efforts to (1) a mass ever-larger sample sets to increase power for population GWA studies, (2) identify rare variants of medium/large effect that are present in single individuals (i.e., de novo mutations) or segregating in extended families, and (3) using intermediate phenotype approaches to characterize the genetic architecture of the biologic pathways involved in the pathogenesis of the disorder.

Major Depression

Major depression is the most common psychiatric disorder and is one of the leading causes of morbidity worldwide. Lifetime prevalence varies across countries but generally ranges between 8% and 12%. Evidence for a genetic contribution to major depression comes from family studies that show an increased risk of the disorder in first-degree relatives of probands that is two to three times greater than the general population. The heritability of major depression is generally lower than other mood and psychotic disorders and is estimated to be between 30% and 40%. Large population studies have consistently shown that there is a higher prevalence of the disorder in women, and twin studies have shown that the disorder is, in fact, more genetically influenced in women, with an estimated heritability of ~40% compared to ~30% for men. These same studies have estimated that although a substantial proportion of genetic causes of major depression are shared between men and women (genetic correlation between the sexes is estimated between 0.6 and 0.9), a significant proportion of genetic factors are sex specific. In addition to genetic differences between the sexes, there also appear to be genetic differences between subtypes of depression; for example, recurrent depression appears to have a higher genetic influence compared to single-episode (heritability of 40% vs. 30%), and postpartum depression has higher heritability compared to nonpostpartum depression (50% vs. 30%). The differing estimates of genetic influence across sexes and disorder subtypes highlight the heterogeneity of the disorder and the fact that many complex interacting biologic and environmental factors influence the emergence or resilience of the disorder in each individual.

Prior to implementing GWA studies, genetic research was largely focused on testing candidate genes for influence on depression. Starting four decades ago, researchers began testing specific genes or small clusters of genes related to neurotransmitters and associated metabolic pathways that were hypothesized to be relevant to the biology underlying depression. More than 1,500 investigations of over 200 purported candidate genes have been published over the past decades with conflicting and confusing results. Recent GWA studies have adequate power to identify significant associations reported in candidate gene studies but have consistently failed to do so. A focused analysis in very well–powered datasets of 18 of the most commonly studied candidate genes found evidence for the *DRD2* (dopamine receptor D2) gene but failed to find any evidence for any of the other genes indicating that the vast majority of “significant” candidate gene findings reported to date are false positives.

Like other neuropsychiatric disorders, the genetic architecture of major depression is expected to include a mix of rare or novel variants of medium-to-large effect and many common loci of small effect. To date, family-based linkage studies have failed to identify any strong findings for rare variants contributing to the disorder. Recent whole-exome and whole-genome sequencing studies have provided suggestive evidence that individuals with major depression have higher burdens of deleterious single exonic variants, but larger sample sizes will be needed to confirm these findings. There is also suggestive evidence that short deletion CNVs mapped to enhancer regions are enriched in individuals with major depression. Despite the suggestive evidence for CNVs and exonic variants, the characterization of novel and rare variants will require larger datasets and more refined analysis methods (e.g., analyses of disorder subtypes and intermediate phenotypes).

Unlike the unsuccessful searches for rare variants, GWA studies of major depression have started to bear fruit. However, compared to other psychiatric disorders like schizophrenia, the lower heritability and higher heterogeneity of major depression have led to the need for much larger discovery samples. For example, GWA studies of schizophrenia began appreciating rigorous success with sample sizes of around 15,000 and are identifying new loci, on average, with each new addition of around 250 cases. In contrast, the first rigorous genetic findings for major depression required 75,000 cases and need, on average, about 1,500 new cases for the discovery of new risk loci. The first successful GWA was achieved in 2016 by the direct-to-consumer company 23andMe using self-reported depression diagnoses. In subsequent years, GWA studies by the Psychiatric Genomics Consortium and the Million Veterans Program added to the list of confirmed risk loci, and currently, over 100 risk loci have been identified. Collectively, the overall variance explained by recent GWA studies explains only about 3% of all the estimated genetic contribution to the disorder, again highlighting the highly polygenic nature of major depression and the need for increasing sample sizes and more refined analyses of disorder subtypes and intermediate phenotypes.

Gene-level and pathway analyses have been used to aggregate associations across the genome and explore the biologic pathways that contribute to the disorder. These analyses have implicated synaptic machinery, voltage-gated calcium channels, glutamate receptors, genes involved in neuronal growth and differentiation, and genes involved in immunity and inflammation. The most robustly supported individual genes are *NEGR1* (neuronal growth regulator 1) and *OLFM4* (olfactomedin 4). Each of these loci has a small effect size with an estimated odds ratio of 1.04. *NEGR1* is a cell adhesion molecule involved in neuronal outgrowth and synapse formation. *OLFM4* is secreted glycoprotein involved in inflammation and immunity. Other genes within the set of confirmed loci also participate in these biologic processes confirming the emerging picture that common variants of small effect accumulate within a subset of biologic pathways, including synapse function, neuroreceptors, and immunity/inflammation to collectively bend an individual toward major depression contingent on the individual's exposure to environmental risk factors.

Anxiety

Pathologic forms of the otherwise normal emotions of fear and anxiety are among the most common mental health conditions, with a lifetime prevalence of over 20%. Prior to DSM-V, OCD and post-traumatic stress disorder were included in the category of anxiety disorders but have been removed from the category due to their distinct characteristics and biologic mechanisms. The anxiety disorders now include the diagnoses of generalized anxiety disorder, panic disorder, and phobias. Genetic mapping studies of anxiety disorders have followed the same pattern as other psychiatric disorders; first, epidemiologic investigations showed evidence for familial aggregation, followed by pedigree-based linkage studies that identified largely nonreplicated loci and numerous candidate gene studies that produced inconsistent findings, and finally, GWA studies that have started to produce rigorous findings of common variants in large population samples.

Epidemiology investigations of anxiety disorders in families have provided consistent evidence for familial aggregation, with first-degree relatives of patients having a four- to six-fold increased risk for anxiety disorders. Twin studies estimate the heritability of the various anxiety disorders to be between 30% and 50%. Risk within families includes the development of a range of anxiety disorders, suggesting that there is substantial shared genetic overlap among the different diagnoses. Statistically, modeling methods confirm that a relatively uniform set of common genetic factors contribute to the core set of anxiety disorders, with environmental factors influencing the final form of the disorder.

Pedigree-based linkage studies of anxiety disorders have largely focused on families with panic disorder, but the strongest mapping signals have been obtained for broad phenotypes that include panic, phobia, generalized anxiety symptoms, and even medical conditions like headaches. During the late 1990s and early 2000s, a series of investigations identified linkage signals on chromosomes 1q, 2q, 7p, 9q, 13q, 15q, and 22q. Compared to similar studies on Alzheimer disease and bipolar disorder, there have been significantly fewer efforts to map anxiety disorder genes in families and none of the findings have been replicated to date. Around the same time that linkage studies were being conducted, many groups were focused on candidate gene association studies based on hypothesized biologic mechanisms. Like candidate gene studies for other psychiatric disorders, candidate gene studies of anxiety phenotypes produced inconsistent results, and the field now recognizes that the sample sizes were very underpowered to identify statistically significant findings until recent GWA studies were able to accumulate large population samples.

Like GWA studies of other psychiatric disorders, the initial foray into anxiety disorders had underpowered sample sizes and did not generate any replicable findings. In 2016, a meta-analysis of seven previous studies assembled a sample size of over 18,000 cases and identified two genome-wide significant loci, including an SNP in the *CAMKMT* gene on chromosome 3. Shortly after, several groups assembled sample sizes exceeding 20,000 and identified another half-dozen risk loci that included a region on chromosome 9 that had been previously associated with neuroticism. One of the risk genes with the strongest biologic support is *PDE4B*, a phosphodiesterase family gene involved in signal transduction. Altered activity of the protein has been characterized in bipolar disorder, and schizophrenia and mice models deficient in the protein exhibit anxiety-like behaviors. The largest GWA study to date was implemented in the Million Veterans Program with a sample size of almost 200,000 individuals. The investigators used screener questions from the generalized anxiety disorder 2-item instrument (GAD-2) as the phenotype for gene mapping. The GAD-2 does not provide a specific diagnosis but uses self-report on a Likert scale to assign a continuous measure of anxiety based on two questions that query the frequency of anxious feelings and the inability to stop worrying. Using this phenotype, the study identified five significant genome-wide loci, including one on chromosome near the *SATB1* gene, a global regulator of gene expression, and one on chromosome 6 near the estrogen receptor gene *ESR1* which encodes an estrogen receptor. A third loci on chromosome near the *MAD1L1* gene was previously identified in GWA studies of schizophrenia and bipolar disorder. The overlapping findings between anxiety risk loci and other psychiatric disorders highlight the genetic overlap among the disorders and are the focus of the next section.

GENETIC OVERLAP AMONG PSYCHIATRIC DISORDERS

The preceding sections have emphasized that categorically defined psychiatric disorders display substantial genetic heterogeneity, indicating that the symptom clusters that specify diagnostic categories can emerge from mutations in different sets of genes. The converse is also true; mutations in specific genes can cross diagnostic boundaries. Early family studies showed that relatives of an individual diagnosed with a specific disorder (i.e., schizophrenia) are at higher risk of developing not only schizophrenia but also major depression or bipolar disorder. Gene-mapping studies have confirmed that genetic risk loci are shared by different disorders. For example, mutations in the calcium channel gene, *CACNA1C,* have been linked to autism, bipolar disorder, and schizophrenia.

The availability of genotypes for large samples of individuals allows for the estimation of genetic correlations between psychiatric disorders and nondiagnostic traits. The genetic correlation (r_g) between two traits can be determined from family data or from population-based genotypes and provides an estimate of the shared genetic factors that are influencing both traits, also known as pleiotropy. The Psychiatric Genomics Consortium investigated the overlap of genome-wide common variants in a large sample (~30,000 cases and ~30,000 controls) that included patients from five categorically defined psychiatric disorders: autism, attention deficit hyperactivity disorder (ADHD), bipolar disorder, major depression, and schizophrenia. The investigation found a remarkable degree of overlap between schizophrenia and bipolar disorder; about 68% of the polygenic risk attributable to common variants was shared between these two disorders. Major depression also showed a substantial overlap with other disorders, where about 45% of the genetic risk attributable to common variants was shared with both schizophrenia and bipolar disorder, and about 30% was shared with ADHD. Schizophrenia showed a low (~15%) but significant overlap with ASDs. Autism did not show significant genetic overlap with bipolar disorder, major depression, or ADHD. Similarly, aside from the genetic overlap with major depression, ADHD did not show significant overlap with any of the other disorders. These findings seem to parallel clinical scenarios, where, for example, schizophrenia and bipolar disorder can sometimes be difficult to disentangle, but bipolar disorder and autism are usually easy to distinguish. The findings also provide hints into the emerging pattern of cellular pathways underlying psychiatric disorders, alterations in some molecular pathways (e.g., calcium signaling) can perturb neural systems nonspecifically such that the final psychiatric presentation is determined by other genetic and/or environmental factors. This scenario may be particularly true for schizophrenia, major depression, and bipolar disorder, which share a substantial proportion of common genetic risk factors. In contrast, disorders like ADHD do not share as many common genetic risk factors with other disorders and may emerge through alterations of cellular pathways distinct from those leading to psychotic and mood spectrum disorders.

Genetic correlations can also be used to help understand the genetic relationship between psychiatric disorders and nonpsychiatric traits. For example, the GWA study of GAD-2 scores described in the section on anxiety is highly correlated with depression ($r_g = 0.81$) and the personality trait neuroticism ($r_g = 0.75$). Similarly, major depression shares significant genetic factors with neuroticism ($r_g = 0.70$) and subjective well-being ($r_g = -0.75$). The negative estimate for the correlation with subjective well-being indicates that genetic factors that confer increased risk for depression influence well-being in the opposite direction, that is, genetic loci that increase the risk for depression tend to reduce measures of subjective well-being. Major depression also has a negative genetic correlation with educational attainment and cognitive performance, albeit much lower than with the personality traits at about $r_g = -0.15$. The genetic correlations with nonpsychiatric traits can help to start dissecting subtypes of the disorder. For example, there appears to be shared genetic factors between atypical depression and body mass index (BMI) in patients that experience weight gain but not in patients who do not experience changes in appetite or weight. As genetic correlations between psychiatric disorders and a wide range of medical and nonmedical traits become available, we will develop a clearer understanding of the complex heterogeneity that exists in mental health. This may be especially important for disorders like depression, which reflects a common endpoint for many diverse and independent processes that manifest in a relatively common cluster of symptoms.

FUTURE DIRECTIONS

The field of psychiatric genetics is in a state of transition. New technologies have made the genetic exploration of complex behaviors a real possibility. While 35 years ago, human gene-mapping studies involved the use of a few markers in a small number of individuals, it is now routine to genotype millions of markers in samples of tens of thousands of individuals. The development of exciting new technologies for phenotyping the human nervous system—such as high-resolution neuroimaging—and the implementation of many such assays in genetic mapping studies have created extraordinary opportunities for the large-scale association of phenotypes and genotypes in psychiatric research. While the analysis of such vast and complex datasets remains a substantial challenge, the development of methodologies for this purpose is now a central focus of research in statistical genetics and bioinformatics.

As the field of psychiatric genetics progresses, several major questions that have emerged may soon be answered, at least partially, through the analysis of large-scale datasets. One major question is whether genetic risk for psychiatric disorders derives mainly from a few rare variants of large effect or many common variants of small effect (or some combination of rare and common variants). While well-powered GWA studies should identify common variants, they have very little power to identify rare variants. The failure thus far of linkage studies to identify rare causative variants for psychiatric disorders does not preclude the possibility that rare variants of somewhat lesser effect could play an important role in susceptibility to these diseases. Whole-genome sequencing of large samples is now feasible and is being implemented with the goal of identifying rare variants segregating in families with heavy genetic loading for psychiatric disorders.

The second question concerns the degree to which psychopathology will be dividable into discrete disorders, as in the current DSM nosology, or if the heterogeneity and overlap among syndromes are so great as to require a thorough overhaul of the current classification systems. Estimates from population-based investigations of common genetic variations show that the mood and psychotic disorders share a substantial overlap of genetic risk factors, whereas disorders like autism and ADHD may be more genetically distinct from other psychiatric disorders. To elaborate on this issue more completely, it will be necessary to begin examining how genetic risk factors interact with other risk genes and the environment to predict the symptomatology in specific individuals. In addition, the increasing focus of the field on the genetic investigation of brain, behavioral, and other endophenotypes for major psychiatric disorders may be a step in the direction of such a revolution.

A third major question is characterizing the role of interactions between genes and environment in the etiology of disorders. Gene-environment interactions occur when specific phenotypes emerge or are influenced due to the interplay of an individual genetic background with specific features of the environment. Identifying gene-environment interactions requires even more statistical power than identifying first-order correlations between genes and phenotypes, and although many such studies have been published to date, they have been underpowered to make firm conclusions. However, as sample sizes with adequate assessments of demographic and historical data continue to grow, the rigorous identification of gene-environment interactions will become possible. For example, a recent investigation of over 500,000 individuals from the U.K. Biobank with genetic and socioeconomic data as measured by the Townsend Deprivation Index showed: (1) socioeconomic scores are associated with anxiety, bipolar disorder, depression, self-harm, and overall health, and (2) suggestive associations from a genome-wide scan of gene-by-environment analysis between specific genetic loci that contributed to disease phenotypes depending on the socioeconomic scores. The interpretation is that certain genetic loci will contribute to disease risk only in the presence of the environmental factor. As big data accumulates with methodically acquired data related to socioeconomics, trauma, exposure to substances, and other known or suspected influences on mental health, gene-environment analyses will provide powerful tools to characterize the complex pathways that contribute to risk and resilience and will provide a guide to understanding both the etiology and the treatment of such disorders.

The final question concerns the impact of anticipated psychiatric genetic discoveries on health outcomes—in terms of either prevention or improved treatments. For Alzheimer disease, concrete advances have been made, and answers to this question may be obtained soon. For the other disorders discussed in this chapter, rapid advances have been made in the last several years, but the emerging picture is still fluid, and it may still be several years before enough is understood to frame this question in answerable terms.

1.20 Epigenetics in Psychiatry: The Promise for New Biomarkers and Treatments

ARIE KAFFMAN, M.D., PH.D.

In 1942 Conrad Waddington coined the term “*epigenetics*” by fusing the terms “*genetics*” and “*epigenesis*”—an old term used to describe the developmental program by which the zygote gives rise to different cell types in a multicellular organism. Epigenetics, as defined by Waddington, represented the cooperation between genetic traits and environmental conditions that together established a stable cellular phenotype. The notion that nongenetic factors play an important role in development was further formalized by defining epigenetics as “a stably heritable phenotype resulting from changes in a chromosome without alterations in the DNA sequence.” More recently, the term epigenetics has been further broadened to emphasize the contribution that environmental factors make to the formation of a stable cellular phenotype that may or may not be heritable. In this review, the latter definition was adopted, and the term epigenetics is used to describe “*changes in gene expression that lead to predictable, stable, and possibly heritable alterations in cell function that are not due to changes in DNA sequence*.” This definition is particularly relevant in psychiatry, where environmental factors, such as stress or substance abuse, alter the expression of genes in postmitotic neurons that are not heritable but contribute to psychiatric pathologies such as major depression, anxiety, and addiction.

Table 1.20–1.
Differences and Similarities between the Genetic and the Epigenetic Codes

Variable	Genetic Code	Epigenetic Code
Components	Long strand of DNA composed of four nucleotides (A, G, C, T)	Histones, histone-modifying enzymes, structural proteins, DNA modifying enzymes, ATP-dependent chromatin-remodeling machinery
Structure	One-dimensional linear strand	Dynamic three-dimensional structure
Cellular content	Identical in all cells	Unique for each cell type Dynamic, may change in response to environmental cues and cell cycle progression
Environmental impact	No change in response to environmental changes	Rapid changes in response to environmental changes, could also be long lasting
Can modify gene expression	Yes	Yes
Heritable	Yes	Sometimes

Table 1.20–1 summarizes some of the key similarities and differences between the “*genetic*” and the “*epigenetic*” codes. Structurally, the genetic code is made of a one-dimensional sequence of nucleotides that are joined together to form a long DNA strand. The epigenetic code, on the other hand, is composed of a host of proteins and noncoding RNAs that coat the DNA and transform it into a three-dimensional structure that can be compressed, decompressed, and twisted into loops. The genetic code is identical in all the cells in the body, while the epigenetic code is highly variable between different cell types and may also change during different phases of the cell cycle within the same cell. Epigenetics thus comprises the mechanisms by which the same genetic blueprint is used to generate different cell types. This concept is illustrated in Figure 1.20–1, where the same genetic code, represented as a linear sequence of letters, is selectively masked by two different epigenetic programs to read STAND (top) or SIT (bottom), depending on what letters within the underlying code are made visible. The genetic code is static, whereas the epigenetic code is highly dynamic and can change rapidly in response to environmental cues. This dynamic property allows postmitotic neurons to modify the expression of genes that drive changes in synaptic plasticity, learning, and behavior. Finally, the genetic

and the epigenetic codes share some similarities. These include the ability to modify gene expression in a manner that can be transmitted across generations.

Epigenetics research is one of the most exciting and rapidly growing frontiers in psychiatric research. This is due to its potential to advance the field in six specific areas (summarized in Table 1.20–2). First, epigenetics provides a molecular mechanism to explain how environmental factors shape vulnerability to psychiatric conditions. In some cases, such as substance abuse or post-traumatic stress disorder (PTSD), the contribution of the environment is quite obvious. In other examples, such as schizophrenia or bipolar disorder, a strong environmental influence can be surmised from the observation that the concordance between monozygotic twins is slightly less than 50%. One of the goals of this chapter is to provide specific preclinical and clinical examples in which epigenetic changes explain how specific environmental conditions modify the risk for psychopathology. It is important to recognize that environmental manipulations can also induce epigenetic changes that alleviate psychiatric symptoms. In fact, many of the known interventions in psychiatry, such as antidepressant medications, electric convulsive shock (ECS), diet, and exercise, have been shown to cause epigenetic changes that modify vulnerability to stress, anhedonia, and drug-seeking behaviors in animals. A better understanding of how epigenetics mediate environmental risk and protective factors is likely to generate new and perhaps more effective strategies to treat mental illness.

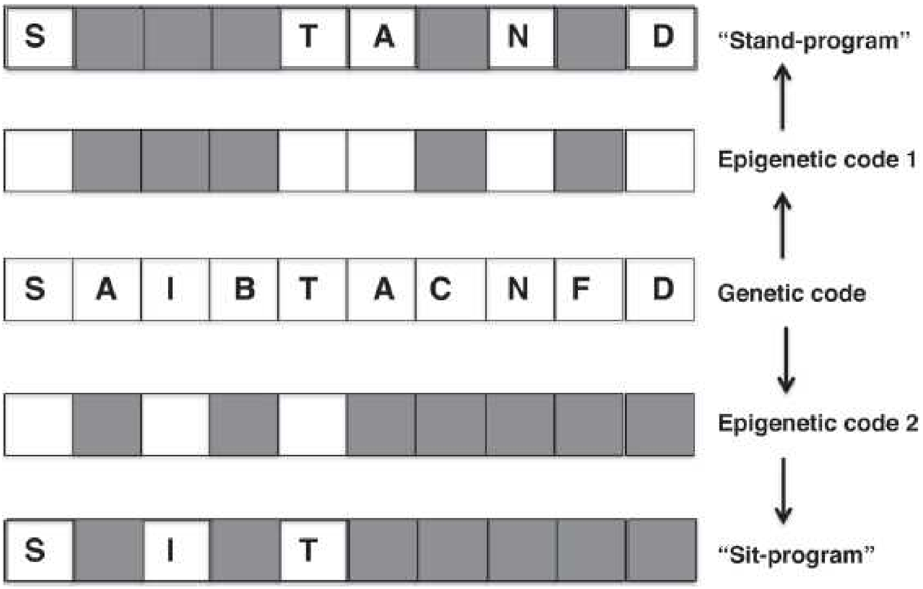

FIGURE 1.20–1. The epigenetic code modifies the genetic instructions in response to environmental demands to generate either a "STAND" (**top**) or "SIT" program (**bottom**).

Second, epigenetics play a central role in guiding neurodevelopment and therefore provides a possible mechanism to explain how abnormal brain development contributes to the vulnerability to many psychiatric conditions. This observation is evidenced by the large number of neurodevelopmental disorders that are caused by epigenetic dysregulation (Table 1.20–3). A better understanding of this process is likely to lead to the development of new treatments (see The Epigenetic Etiology of Fragile X Syndrome section below). Moreover, a growing body of work, some of which is summarized in this chapter, demonstrates that epigenetics play a critical role in modifying brain development and the vulnerability to several psychopathologies in children exposed to abuse or neglect (discussed in detail below).

Third, epigenetics research is responsible for recent advances in generating inducible pluripotent stem cells (iPSCs). This technology allows researchers to harvest somatic cells (e.g., skin cells) from individuals with specific psychiatric illnesses (e.g., schizophrenia) and reprogram their epigenetic code in a way that transforms them into neurons, glial cells, and even entire organoids. These cells can then be grown and studied in culture. This remarkable process solves one of the key hurdles in psychiatric research, which is how to gain access to and manipulate functional brain tissue from humans.

Fourth, despite significant progress over the past decade to map genetic causes of highly heritable psychiatric conditions such as schizophrenia (81%) and bipolar disorder (85%), genetic mutations account for only a small fraction of the cases. There is a growing consensus that epigenetics may also contribute to the heritability of these disorders because heritability is calculated as the relative rates of concordance between monozygotic and dizygotic twins, and monozygotic twins share many more epigenetic similarities than dizygotic twins. In addition, the ability of some epigenetic markers to be inherited may explain how exposure to a specific stressor in the parental generation may modify the risk for psychopathology in the offspring. For example, prolonged parental stress in rodents modifies noncoding small RNA content in the sperm that is responsible for alterations in neurodevelopment, physiology, and behavior in the offspring. These preclinical findings provide a novel conceptual framework for evaluating similar changes in noncoding small RNA sperm content seen in stressed men.

Fifth, the dynamic interactions between the underlying DNA sequence and its packaging chromatin provide a molecular mechanism to explain how genes modify the ability of certain environmental conditions to induce psychopathology. Such gene-by-environment interactions have been elegantly demonstrated between different alleles of the serotonin transporter and the ability of childhood maltreatment to modify the risk for adult depression and are illustrated in this chapter by examining how genetic and epigenetic changes coordinate the expression of FKBP5 and thus influence the risk for developing PTSD.

Table 1.20–2.
Epigenetics Promise in Psychiatry

Contribution	Practical Implications
1. Provides molecular mechanisms to explain how environmental change modifies behavior and psychopathology	Novel therapies
2. Clarifies how abnormal neurodevelopment leads to psychopathology	More effective early interventions
3. Allows for the generation of inducible pluripotent stem cells	Gaining access to “brain tissue” from live patients with mental illness
4. Provides additional ways to explain how psychopathology is inherited	Novel diagnosis and interventions
5. Elucidates the mechanisms by which gene and environmental factors interact to modify vulnerability to mental illness	More specific biomarkers and interventions
6. Provides reliable biomarkers to diagnose psychiatric vulnerabilities	The availability of objective and quantifiable markers to diagnose and assess treatment response

Sixth, many epigenetic markers, such as DNA methylation, are stable biomarkers that can be accurately quantified using a very small number of cells. These properties make epigenetic changes a potentially valuable biomarker for diagnosing and assessing treatment response. Biomarkers are desperately needed in psychiatry, where no objective disease markers are currently available to diagnose or assess treatment response. Recent findings suggesting that the methylation rate of a stress-related gene, SKA2, can be used to predict suicidal behavior are presented in the last section of this chapter. This kind of work exemplifies the utility of epigenetics in identifying useful biomarkers of psychiatric conditions.

This chapter is divided into three sections. The first section provides a comprehensive review of the cellular machinery involved in epigenetic regulation. The second section describes several preclinical examples in which epigenetic changes have been shown to modify psychiatrically relevant phenotypes in animals and how targeting these changes can potentially generate novel psychiatric treatments. The third and final section provides several clinical examples to illustrate how epigenetics may modify clinical understanding and practice in psychiatry.

THE EPIGENETICS MACHINERY

Evolutionary studies in archaebacteria suggest that chromatin originally evolved as a mechanism to rapidly regulate gene expression in response to environmental demands. This more complex multilayered form of transcriptional regulation was later adapted to support cellular differentiation, in which the same genetic code is used to generate different cell types. With the expansion of the genome, chromatin was essential to compact the lengthy DNA so it could fit into a small nucleus. Finally, chromatin serves many other functions that are essential for maintaining the integrity of the genetic code. These include DNA repair and the formation of telomeres and centromeres.

Table 1.20–3.
Chromatin-Mediated Neurodevelopmental Disorders

Disease	Protein/Gene	Chromatin Modifications	Clinical Features
Alpha-thalassemia/mental retardation syndrome, X-linked (ATR-X)	ATRX/XH2, member of SWI/SNF family of proteins (chromatin-remodeling enzyme)	Defective chromatin remodeling that is implicated in down-regulating the α-globin locus	X-linked inheritance; mental retardation, hemolytic anemia, splenomegaly, facial, skeletal, and genital anomalies
Prader–Willi syndrome	The parental 15q11–13 chromosome is maintained in an open chromatin state, allowing for the expression of genes necessary for normal development	Deletion of parental 15q11–13 locus	Initial neonatal hypotonia with a failure followed by hyperphagia, childhood obesity, hypogonadism and mild intellectual disability
Angelman syndrome	The maternal chromatin at the 15q11–13 locus is highly compacted, preventing the expression of UBE-3A antisense RNA and allowing the expression of the UBE3A gene	Deletion of maternal 15q11–13 locus or mutations in the maternal UBE3A gene.	Cortical atrophy, cerebellar abnormal myelination, seizures, mental retardation
Coffin–Lowry syndrome	RSK2 (Kinase)	Abnormal histone acetylation and phosphorylation	X-linked inheritance; psychomotor retardation, skeletal and craniofacial deformities
Fragile X syndrome	FMR1 and FMR2	DNA hypermethylation of expanded trinucleotide repeats at the FMR1 and FMR2 promoters	Most common inherited form of intellectual disability, signs of autistic behavior, long and narrow face with large

			ears and macroorchidism
Immunodeficiency–centromeric instability–facial anomalies syndrome (ICF)	Dnmt3B (De novo DNA methyltransferase)	Hypomethylation at centromeric regions of chromosomes 1, 9, and 16	Mild mental retardation, immunodeficiency, facial anomalies
Rubinstein–Taybi syndrome	CBP (HAT)	Reduced histone acetylation, Autosomal dominant inheritance	Mental retardation, abnormal facial features, blunted growth
Rett syndrome	MeCP2 (MBP)	Abnormal recruitment of MeCP2 to methylated DNA	X-linked, pervasive developmental disorder, predominantly affecting girls with arrested brain development, cognitive decline, and autistic-like behavior
The 9q34 subtelomeric deletion syndrome	GLP (HMT)	Abnormal H3K9 methylation	Severe mental retardation, hypotonia, facial anomalies

The basic folding unit of chromatin is the *nucleosome*. The nucleosome consists of a histone octamer core wrapped by a DNA loop (Fig. 1.20–2A). The octamer core is assembled from four highly conserved, positively charged histone proteins (H2A, H2B, H3, and H4). H3 and H4 form a tetramer that is sandwiched between two H2A/H2B dimers forming the octamer core. The octamer core is wrapped by a 146bp DNA loop, a structure that is stabilized by large numbers of ionic contacts made between the negatively charged DNA and positively charged amino acids found in histones. Each histone protein has a long unstructured N-terminal tail that protrudes and probes the surrounding space. This tail plays a critical role in the ability of the chromatin to condense or open up.

In the open chromatin conformation, also known as "*beads on a string*," neighboring nucleosomes are separated by a short (10 to 80 bp) linker DNA (Fig. 1.20–2B). The "beads on a string" chromatin structure alters the properties of the underlying DNA in two important ways. First, it compacts the DNA by about 5- to 10-fold. Second, significant portions of the wrapped DNA are not accessible for the binding of transcriptional activators. As a result, even in its most accessible form, chromatin represents a barrier to basal transcription. Moreover, the long N-terminal tails on histones make contacts between neighboring nucleosomes that tend to compact the chromatin. These higher-order filaments can be stabilized by the binding of a fifth histone, histone H1, forming higher-order 30-nm filaments that further compact the DNA, making it even less accessible. This natural tendency of chromatin to coil into less accessible, more compact structures is regulated by several mechanisms that include posttranslational modifications of the histone N-terminal tails, recruitment of chromatin-remodeling machinery, and the use of invariant histones, described in some detail below. In summary, the nucleosome unit regulates accessibility to the DNA sequence, which is critical for gene expression without altering the DNA chemistry or genetic code.

Histones Modifications

The N-terminal tails of histones are decorated by a large number of posttranslational modifications such as acetylation, methylation, phosphorylation, ubiquitylation, and sumoylation as some of the main examples. These modifications are reversible and are carried out by large multisubunit protein complexes that coordinate their activities in a way that can either condense or open the chromatin in response to environmental cues. Histone modifications affect chromatin structure via three distinct mechanisms. First, some modifications disrupt ionic contacts between positively charged residues on histone tails and the negatively charged DNA backbone, loosening DNA-histone contacts. Second, nucleosomes contact one another via their N-terminal tails. These inter-nucleosomal contacts can be strengthened or disrupted by posttranslational modifications. Third, alterations of the histone tails provide binding sites that recruit chromatin-remodeling machinery. These proteins can use ATP hydrolysis to slide or remove nucleosomes from chromatin (Fig. 1.20–3).

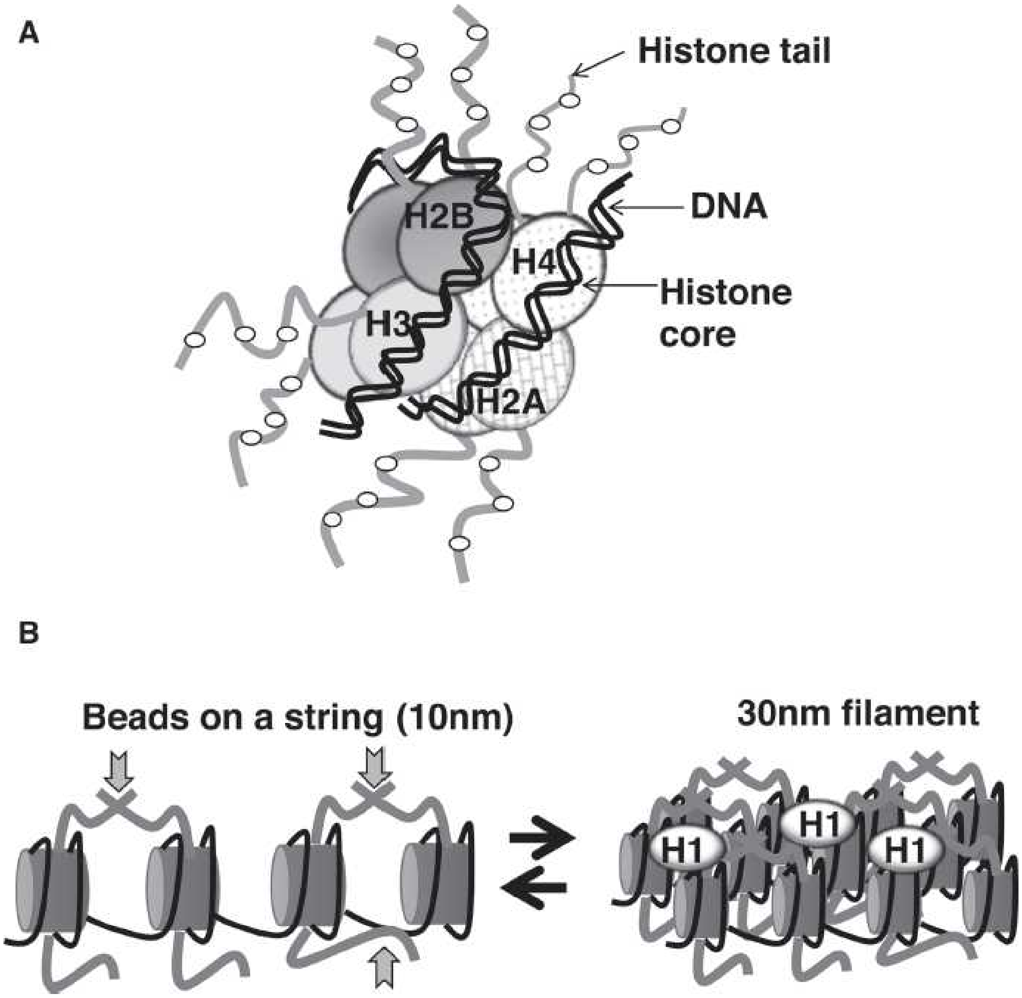

FIGURE 1.20–2. **A:** The nucleosome as a basic folding unit of chromatin. **B:** Chromatin can transition from a "beads on a string" 10-nm filament to a more compact 30-nm filament structure that is stabilized by the presence of histone H1 (*light ovals*). Histone tails (in *gray*) make contacts between neighboring nucleosomes known as internucleosomal contacts (*top arrows*) and with the underlying DNA (*bottom arrow*).

Histone Acetylation. Acetylation neutralizes lysine residues, rendering the N-terminal tails on histones less positively charged. This decrease in positive charge is thought to disrupt contacts with the negatively charged DNA and with neighboring nucleosomes. Histone acetylation is associated with transcriptional activation and other cellular processes that require access to the underlying DNA, such as DNA replication and repair (Table 1.20–4). Histone acetyltransferases (HATs) acetylate lysine residues on the tails of histones H3 and H4, while histone deacetylases (HDACs) remove these acetylations (Fig. 1.20–4). Acetylation modifies lysines (K) that are systematically spaced on Histone 3 (e.g., 9, 14,18, and 23) and Histone 4 (e.g., 5, 8, 12, and 16). Different HATs and HDACs are responsible for acetylating and deacetylating specific residues. On histone H3, for example, K14 and K18 are acetylated by cAMP response element-binding protein (CREB)-binding protein (CBP/P300), while K9, K14, and K18 are acetylated by a different HAT, PCAF/GCN5.

This enzyme specificity provides an opportunity to develop more selective and targeted pharmacotherapies to act on this system. Recent work using reconstituted purified histones found that a single acetylation at lysine 14 in histone 4 (H4K14-Ac) was sufficient to maintain chromatin in the “beads on a string” state by preventing interactions between neighboring nucleosomes. Interestingly, the H4K14-Ac modification inhibited the ability of the chromatin-remodeling enzyme ACF to slide nucleosomes, suggesting that this modification “locks” chromatin into an open state.

Consistent with histone acetylation opening chromatin, deacetylation of histones leads to chromatin compaction and transcriptional repression (Fig. 1.20–4). HDACs fall into three classes, Class I, Class II, and the NAD-dependent Class III of the SIR family. These classes are based on structural similarities and are therefore inhibited by different pharmacologic agents. In general, HDACs seem to have less specificity than HATs with regard to the lysine resides they deacetylate. Different HDACs are targeted and bind to different compartments within the nucleus, allowing them to conduct somewhat distinct functions. For example, HDAC1 seems to play a general role in chromatin condensation and repression, while HDAC3 is tethered to the nuclear periphery, where it forms highly repressive null chromatin (see Chromatin Domains section below).

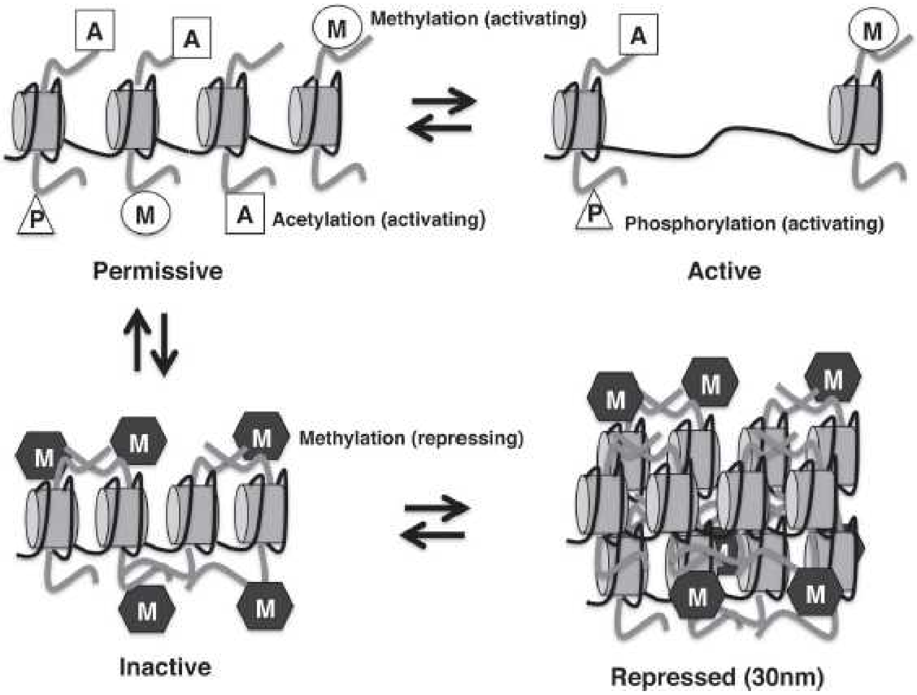

FIGURE 1.20–3. "Permissive chromatin" (**top left**) is acetylated (*gray squares*), methylated (*open ovals*) and phosphorylated (*gray triangle*). These histone modifications open up the chromatin by disrupting internucleosomal contacts and DNA–nucleosome contacts and recruit ATP-dependent chromatin-remodeling enzymes (not shown) that further open up the chromatin to form "active chromatin" (**top right**). Permissive chromatin can be modified to form "inactive chromatin" (**bottom left**) by removing activating histone modifications and the addition of inhibitory histone methylations (windowpane-patterned hexagon). These repressive modifications compact chromatin by promoting internucleosome and DNA–nucleosome contacts. Inactive chromatin can be further condensed to form "repressed chromatin" (**bottom right**) by recruiting ATP-dependent chromatin-remodeling enzymes and other structural proteins (not shown).

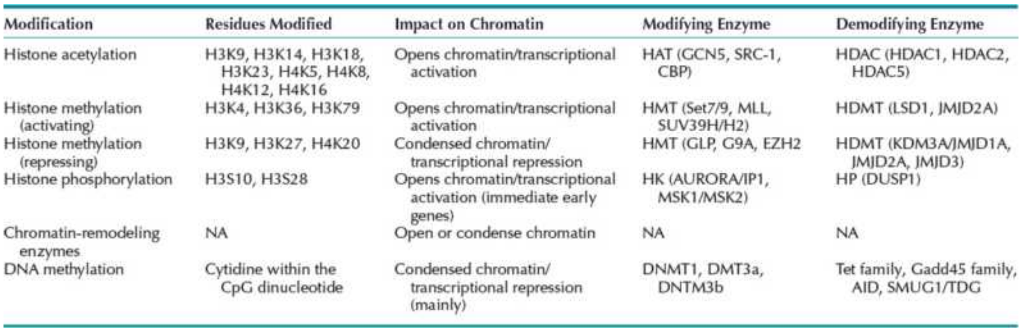
Table 1.20–4.
Enzymatic Activities That Modify Chromatin



Modification	Residues Modified	Impact on Chromatin	Modifying Enzyme	Demodifying Enzyme
Histone acetylation	H3K9, H3K14, H3K18, H3K23, H4K5, H4K8, H4K12, H4K16	Opens chromatin/transcriptional activation	HAT (GCN5, SRC-1, CBP)	HDAC (HDAC1, HDAC2, HDAC5)
Histone methylation (activating)	H3K4, H3K36, H3K79	Opens chromatin/transcriptional activation	HMT (Set7/9, MLL, SUV39H/H2)	HDMT (LSD1, JMJD2A)
Histone methylation (repressing)	H3K9, H3K27, H4K20	Condensed chromatin/ transcriptional repression	HMT (GLP, G9A, EZH2	HDMT (KDM3A/JMJD1A, JMJD2A, JMJD3)
Histone phosphorylation	H3S10, H3S28	Opens chromatin/transcriptional activation (immediate early genes)	HK (AURORA/IP1, MSK1/MSK2)	HP (DUSP1)
Chromatin-remodeling enzymes	NA	Open or condense chromatin	NA	NA
DNA methylation	Cytidine within the CpG dinucleotide	Condensed chromatin/ transcriptional repression (mainly)	DNMT1, DMT3a, DNTM3b	Tet family, Gadd45 family, AID, SMUG1/TDG

Proteins that have a bromodomain-folding motif are able to bind acetylated histones in order to maintain open chromatin. Mutations in the HAT domain of CBP cause Rubinstein–Taybi syndrome, which is associated with mental retardation and cardiac abnormalities (Table 1.20–3). Interestingly, a mouse model of this condition showed that the cognitive deficits associated with low levels of CBP could be reversed by administrating HDAC2 inhibitors to adult mice. These findings suggest that the relative activities of HATs and HDACs in postmitotic neurons play an important role in neuroplasticity with broad implications for neurodevelopmental disorders, aging, and drug addiction (see Epigenetics in Preclinical Work). Indeed, increased HDAC2 has been shown to silence genes that are necessary for learning and memory, and HDAC2 activity was found to be elevated in Alzheimer's disease. Clinical work is currently underway to test whether specific HDAC inhibitors can be used to improve cognition in conditions such as early Alzheimer's disease, schizophrenia, and traumatic brain injury.

FIGURE 1.20–4. Histone tails are reversibly modified at specific residues. HAT-Histone acetyltransferases, HDAC-histone deacetylase, HMT-histone methyltransferase, HDMT-histone demethyltransferase, HK-histone kinase, HP-histone phosphatase.

Histone Methylation. Histone methylation is more complex than acetylation because both lysines (K) and arginines (R) can be methylated. Moreover, each lysine can be methylated once, twice, or three times, providing another layer of complexity. Lysine methyltransferases are more selective compared to acetylating enzymes, targeting specific lysine residues within the histone tail. Methylation on three sites is associated with transcriptional activation (H3K4, H3K36, H3K79), whereas methylation on 3 other lysine resides is associated with repression (H3K9, H3K27, H4K20), see Table 1.20–3 for a summary. In addition to transcriptional regulation, histone methylation also plays a role in DNA repair.

As with other chromatin modifications, methylated lysines can be demethylated by histone demethylases, allowing for dynamic and reversible chromatin changes (Fig. 1.20–4). Proteins that contain chromo-like domains (e.g., chromo, tudor, MBT) or the structurally unrelated PHD motif are able to bind methylated histones. Such proteins form large complexes that contain chromatin-remodeling enzymes and other histone modifiers. These complexes are recruited to methylated histones and, depending on the exact composition of the complex, are able to efficiently open or close the chromatin. For example, appropriate activation of the HOXC8 gene is essential for normal axis development in all vertebrates. Activation of the HOXC8 gene requires histone methylation during a specific period in development. This methylation step is required to recruit the nucleosome-remodeling factor (NURF) via the bromodomain PHD finger transcription factor (BPTF). The NURF complex contains a chromatin-remodeling enzyme (SNF2L) that removes nucleosomes from the HOXC8 promoter allowing for transcriptional activation. Mutations that interfere with the ability of BPTF to bind the methylated promoter cause abnormal expression of HOXC8 and abnormal axis formation in tadpoles. This sequence of events illustrates the multilayered coordination of chromatin regulation in which histone modification recruits additional machinery making the chromatin more accessible and allowing for the expression of genes necessary for normal axis development (Fig. 1.20–5).

Methylation at lysine 9 in histone 3 (H3K9-me2/ H3K9-me3) plays a critical role in maintaining a specialized form of chromatin known as *pericentric/constitutive heterochromatin*. One of the main functions of the pericentric chromatin is to support the formation of centromeres that are used to align and segregate chromosomes during cell division (see also Table 1.20–4). H3K9 is methylated by a specific histone methyltransferase (Suv39h1/h2), which in turn triggers the binding of the repressor protein HP1 via its chromodomain. HP1 then associates with several other proteins to form a complex that extends this specialized repressed chromatin structure through large sections of the underlying DNA. This is accomplished by the ability of HP1 to recruit additional Suv39h1/h2, allowing further histone methylation and HP1 recruitment to propagate down the DNA (Fig. 1.20–6). HP1 is also associated with DNA methyltransferases, DNMT1 and DNMT3a, allowing for DNA methylation and further chromatin compaction. Finally, during replication, HP1 is associated with chromatin factor 1 (CAF1) protein, which deposits histones at the replication fork. The presence of a complex containing HP1, Suv39h1/h2, DNMT1, and CAF1 at the replication fork provides a possible mechanism by which pericentric chromatin is inherited in daughter cells and a good example of how DNA methylation and histone modification activities are coordinated (see DNA Methylation section below).

HOXC8 expression
Normal axis development

FIGURE 1.20–5. Histone methylation recruits BPTF via its PHD domain bringing with it the chromatin-remodeling enzyme SNFL2 as part of the NuRF complex. Binding of SNFL2 allows for ATP-dependent removal of nucleosomes from the promoter, HOXC8 expression, and normal axis development in vertebrates.

Histone methylation is also critical for the creation of repressive polycomb chromatin structures, which are instrumental in maintaining the pluripotency of embryonic stem cells, regulating cell cycle progression, cell differentiation, and chromosome-X inactivation. In this process, histone methylation at H3K27 is catalyzed by the Polycomb Repressive Complex (PRC2), a highly evolutionarily conserved protein complex. PRC2 is recruited to specific regions of DNA via interactions with other DNA-binding proteins and noncoding RNA. Once recruited, PRC2 methylates H3K27 to form the di, and the tri methylated states (H3K27-me3), which then serve as tethering sites for the entire complex. H3K27-me3 also recruits the chromatin-remodeling machinery (PRC1) that further condenses chromatin into the highly repressive polycomb conformation (see Fig. 1.20–7 and Table 1.20–4). Interestingly, the PRC2 complex maintains its binding to DNA during DNA synthesis, providing a mechanism by which H3K27-me3 and polycomb chromatin repression are maintained in daughter cells. Mutations in the histone methylase activity of PRC2 prevent the stable propagation of polycomb repression into daughter cells, suggesting an essential role for methylation in this epigenetic form of inheritance, with critical implications for many developmental programs, including X-inactivation and the transition from cellular pluripotency to differentiation.

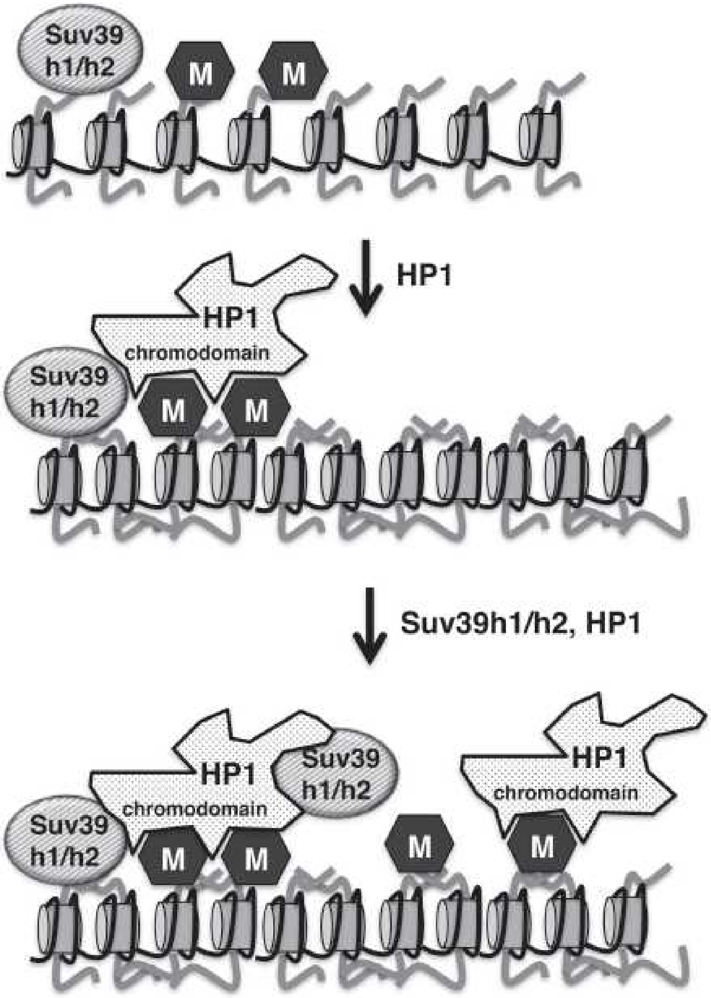

FIGURE 1.20–6. The HMT Suv39h1/h2 methylates H3K9 (**top**), recruiting HP1 via its chromodomain (**middle**). HP1 binds Suv39h1/h2 allowing for the propagation of this repressive pericentric/constitutive heterochromatin (**bottom**).

Histone Phosphorylation. Phosphorylation of histones plays a role in chromosome segregation during mitosis, induction of early response genes, and DNA repair. Histone kinases such as Aurora/Ip1 and the mitogen and stress-activated protein kinases 1 and 2 (MSK1/MSK2) phosphorylate serines (S) 10 and 28 on histone 3. The proximity of these serine residues to lysines 9 and 27 influences the decision as to whether these lysines will be acetylated or methylated. This influence is critical because acetylation at lysines 9 and 27 tends to activate transcription, whereas methylation at these same sites represses transcription (Fig. 1.20–4). Several environmental stimuli, such as stress, cocaine, changes in neurotransmission, and UV light, induce H3S10 phosphorylation by activating MSK1 and MSK2. Activated MSK1 is recruited to the promoters of immediate early genes, such as c-fos and Jun, in a complex containing 14-3-3 proteins, chromatin-remodeling machinery, and a HAT. This complex efficiently activates the expression of immediate early genes that provide appropriate cellular responses depending on the type of cells and the environmental context. In the dentate gyrus, this response facilitates helplessness behavior, while in the striatum, this response modifies drug-seeking behavior (see Epigenetics in Preclinical Work section below).

FIGURE 1.20–7. The PRC2 complex has an HMT activity that generates H3K27-me3, which further stabilizes PRC2 binding to chromatin (**top**). PRC2 recruits the PRC1 complex that further compacts chromatin by increasing nucleosome density (**middle**). These newly recruited nucleosomes are methylated by PRC2, allowing for the propagation of this polycomb repressive chromatin (**bottom**).

ATP-Dependent Chromatin Remodeling

Nucleosomes are distributed in a stereotypical pattern along actively transcribed housekeeping genes. This pattern is highly conserved from yeasts to mammals and is characterized by a 250 bp nucleosome-free region (NFR) that is flanked by two positioned nucleosomes in the promoter of housekeeping genes (Fig. 1.20–8). Similar NFRs are also found at the 3' end of the gene and in enhancer regions. This pattern allows the transcriptional machinery to bind and constitutively express housekeeping genes. Nucleosome positioning is accomplished in vivo by two mechanisms. First, specific DNA sequences within the promoter region can guide the nucleosome's position, providing an important example of how the genetic code influences the epigenetic code. However, this arrangement is static and does not allow for the rapid reorganization of chromatin in response to environmental demands. The second and perhaps more important mechanism is mediated by chromatin-remodeling enzymes. These enzymes are equipped with chromatin binding motifs and use ATP to remove, add, or slide nucleosomes along the DNA strand. In some cases, chromatin-remodeling enzymes maintain NFR by removing nucleosomes from specific promoter sequences. This, in turn, allows transcription factors to bind DNA and activate transcription (Fig. 1.20–8). Alternatively, nucleosomes can be pushed by chromatin-remodeling enzymes into NFRs, where they block transcription and form higher-order chromatin structures (Fig. 1.20–8). Recruitment of chromatin-remodeling enzymes has been implicated in the development of addictive-like behaviors after chronic cocaine exposure in mice via modification of the promoters of late-onset addiction-related genes, such as cyclin-dependent kinase 5 (CDK5) (see Epigenetic Mechanisms of Cocaine Addiction section).

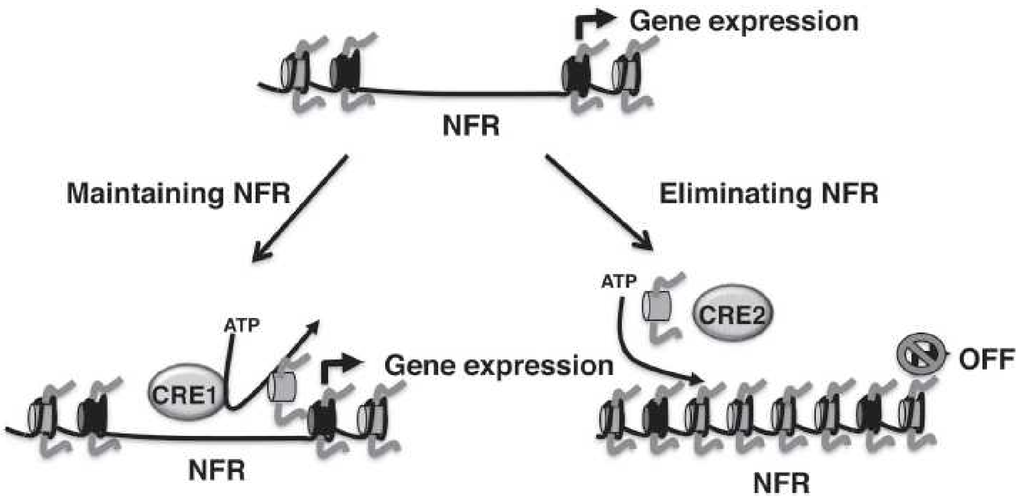

FIGURE 1.20–8. Top: Nucleosome-free region (NFR) can be passively maintained by DNA sequences that position nucleosomes on both sides of the NFR (shown in *dark gray*). This, in turn, allows transcription factors to bind and activate gene expression. In many cases, NFR is actively maintained by ATP-dependent removal of nucleosomes (depicted as CRE1 on the **lower-left panel**). ATP-remodeling activities (CRE2, on the **right lower panel**) use ATP to deposit nucleosomes making the NFR inaccessible and therefore turning transcription off.

DNA Methylation

Unlike histone modifications that do not alter the chemical structure of the genetic code, DNA methylation directly changes the molecular structure of cytosines. This is accomplished by transferring a methyl group from a donor molecule to the 5′ position on the cytosine ring to generate 5-methylcytidine (5mc). In vertebrates, DNA methyltransferase (DNMT) enzymes methylate cytosines in a dinucleotide (CpG) palindromic sequence. Cytosine methylation does not affect its ability to form correct Watson-Crick pairing with a guanosine on the antiparallel DNA strand and thus does not affect the underlying genetic information. Instead, DNA methylation marks the DNA at specific locations in a manner that can be inherited and allows the recruitment of histone and nucleosome-remodeling machinery to do the heavy lifting of opening or compressing chromatin.

Within the mammalian genome, CpG dinucleotides are either clustered in a high-density region known as CpG islands (CGIs) or found sporadically across the genome. CGIs usually mark promoters of active housekeeping genes and are thus generally unmethylated. In rare cases, when CGIs are methylated, they form a highly repressive chromatin structure that inhibits gene expression and, in many cases, is inherited. Some well-known examples include X-inactivation and imprinted genes. The observation that abnormal regulation of imprinted genes leads to several forms of intellectual disability demonstrates the importance of correct methylation of these CGIs for normal neurodevelopment (see Table 1.20–3 and Rescuing Prader–Willi Syndrome section below).

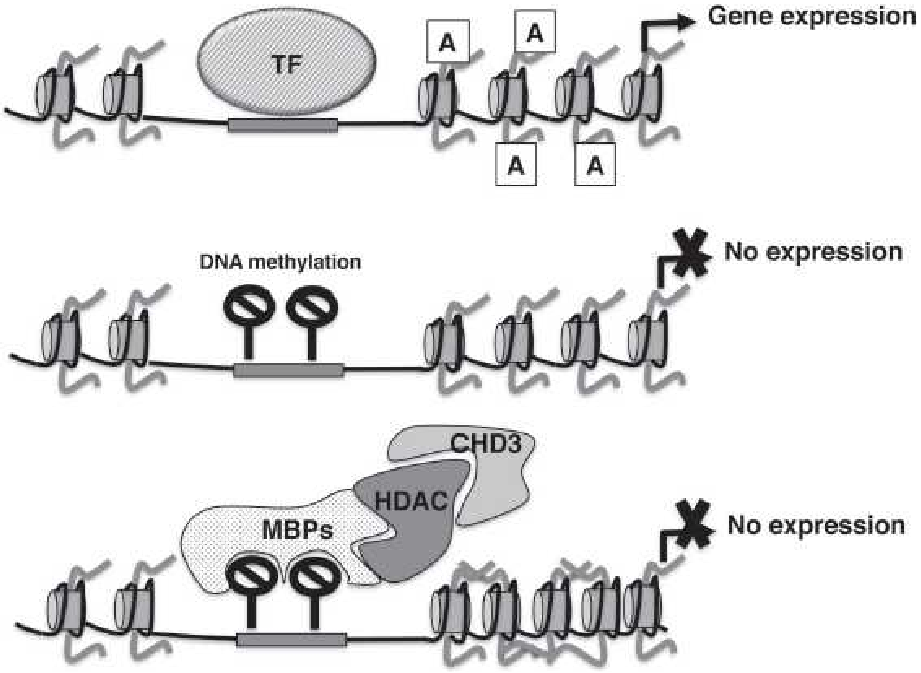

FIGURE 1.20–9. **Top:** In the absence of DNA methylation, a generic transcription factor (TF) binds a specific DNA sequence within the promoter and activates gene expression. **Middle:** DNA methylation (*black* no entry signs) prevents the TF from binding its binding site and therefore prevents gene expression. **Bottom:** The NuRD complex is recruited to methylated DNA via methyl-binding proteins (MBPs). These MBPs are complexed with enzymatic activities such as HDACs and the chromatin-remodeling protein CHD3 to compact DNA and terminate gene expression.

Methylation of CpG in sporadic regions usually down-regulates gene expression. This downregulation is achieved in one of two ways. First, DNA methylation can prevent the binding of a transcription factor to its binding site (Fig. 1.20–9). A second mechanism involves the direct binding of a methyl-binding protein (MBP) to methylated cytosines. Docking of MBP to methylated DNA recruits enzymes that further compress chromatin and inhibit gene expression. A good example of this repressive cascade is the nucleosome-remodeling deacetylases (NuRD) repressive complex. NuRD is a highly conserved multisubunit complex that synergistically represses chromatin. The NuRD complex includes two HDACs (HDAC1 and HDAC2), a chromatin-remodeling subunit (CHD3 or CHD4), and several MBPs (MBD2 and MBD3). The MBPs recruit the NuRD complex to methylated cytosines where CHD3/CHD4-mediated ATP hydrolysis compacts nucleosomes and stimulates deacetylation by HDACs. This synergism between ATP hydrolysis and histone deacetylation is thought to be due to the ability of chromatin-remodeling enzymes to make histone tails more accessible for deacetylation. The result is a highly repressive chromatin structure around methylated sites (Fig. 1.20–9). DNA methylation can therefore be thought of as a "molecular bridge" between the genetic code (i.e., CpG within specific binding sites) and the other chromatin-modifying machinery (e.g., Figs. 1.20–9, 1.20–13, and 1.20–14). The clinical section of this chapter provides an example of this concept, showing how the genetic code and changes in DNA methylation induced by early life stress interact to modify the expression of the FKBP5 gene and subsequent vulnerability to PTSD.

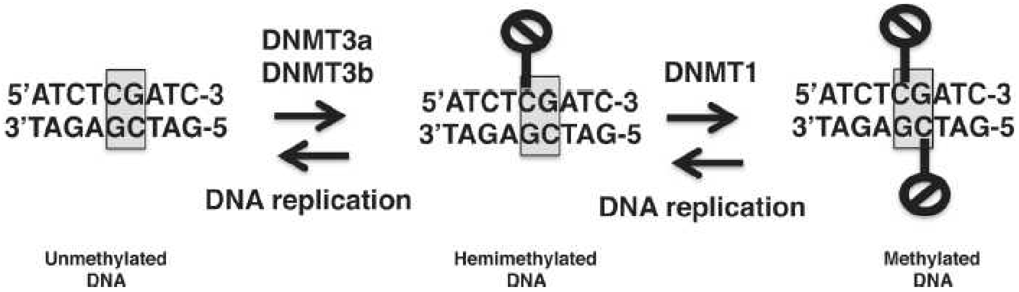

FIGURE 1.20–10. Unmethylated DNA is methylated by the de novo DNMTs, DNMT3a and DNMT3b, to form hemimethylated DNA. Hemimethylated DNA is methylated further by the maintenance DNMT, DNMT1. DNA methylation is lost after each round of DNA replication. The CpG dinucleotide is shown in gray, and the DNA methylation is shown as *black* “no entry” signs.
